(Cembra)—or Mountain Siberian Pine.] Rises with an upright straight stem, forty or fifty feet high; having long, slender, very smooth, light-green leaves, five in a sheath; and large close cones.

7. *PINUS palustris.*

Swamp Prickly-coned Carolina Pine.] Rises with an upright, straight stem, twenty to thirty feet high; very long, slender leaves, growing by threes in a sheath, at the ends of the branches, and subcylindrical prickly cones.

It grows naturally in low swampy grounds in Carolina and Georgia.

The above seven sorts are the principal species of the Pine kind; but there are several varieties that belong to one or other of them, and are distinguished in the nurseries by the following names and descriptions.

Frankincense three-leaved American Pine—Virginia cluster-coned Pine—Mugho two and three-leaved Mountain Pine—Jersey two-leaved prickly-coned Pine—Aleppo spreading-branched, two-leaved Pine—dwarf two-leaved American Pine.

Fir Kinds (Abies) having Solitary or Singly-placed Leaves.

There are about six species of these sorts, with some varieties; all hardy ever-green trees.

8. *PINUS Abies.*

(Abies)—or Common Fir-tree, commonly called Norway Spruce Fir.] Rises with an upright stem, to a great height, branchy to the bottom; solitary, narrow, awl-shaped, sharp-pointed, smooth, dark-green leaves, standing two ways; and large cones, six or eight inches long, hanging downward.

Varieties.] Red Norway spruce Fir—White Norway spruce Fir—Long-coned Cornish Fir, having longer leaves, and cones eight or ten inches long.

They grow naturally in Norway, and other northern parts of Europe, where they are commonly denominated Pitch-firs, because in those countries great quantities of pitch, &c. is extracted from them; their timber is the white deal, so greatly esteemed by the joiners.

9. *PINUS canadensis.*

Canada Spruce Fir.] Rises with an upright, straight stem, to a great height, branching from bottom to top; solitary, very narrow, shortish, obtuse-pointed, dark-green leaves; and small close cones an inch long.

Varieties.] Canada white spruce—red spruce—and black spruce Fir; differing from each other principally in the colour of the cones. These are all natives of North America.

10. *PINUS picea.*

Pitch-tree, commonly called Silver Fir.] Rises with an upright very straight stem, sixty or seventy feet high, or more, branching thinly, having a smooth bark; solitary flat leaves, emarginated at top, marked with two silvery white lines underneath; and has very long erect cones.

It grows naturally in the Alps, Germany, and in the Highlands of Scotland, and is remarkable for affording plenty of turpentine, &c.

11. *PINUS Balsamea.*

Balm of Gilead Fir.] Rises with an upright, straight stem, very branchy almost to the bottom; closely garnished with solitary, flat, obtuse leaves, slightly emarginated at the top, of a dark-green above, and marked with whitish lines underneath; and small roundish cones.

Variety.] With variegated leaves.

This tree and variety are natives of North America; they are remarkable for their balsamic aromatic nature; the buds and leaves being remarkably fragrant; and any part of the tree being cut or broken, it will emit abundance of fine balsamic juice, or turpentine. Both the varieties assume a beautiful growth, and have great merit for all ornamental plantations.

12. *PINUS americana.*

American Hemlock Spruce Fir.] Rises with an upright stem of moderate height, branching thinly; narrow obtuse leaves, ranged two ways; and roundish cones.

Cedar of Lebanon, and Larch Kinds, having Leaves in Bunches.

There are only three species of those kinds, one a celebrated ever-green tree, of noted antiquity;

riquiry; the others are beautiful deciduous trees; all of them valuable for ornament, and for timber plantations.

13. *PINUS Cedrus.*

Cedar of Lebanon.] Rises with an upright trunk, obtaining considerable height and magnitude, branching horizontally around to a great width: closely garnished with narrow, acute, stiff leaves, in bunches from the same point; and largish, thick, close cones.

It is a native of Mount Libanus in Syria; is very hardy, and prospers here in almost any soil and situation.

This famous and curious tree is the lofty and spreading Cedar so greatly celebrated in scripture; to which many beautiful allusions and comparisons are made; and is most certainly a tree of singular grandeur, after having arrived to some considerable growth, as it spreads its horizontal branches in the most agreeable form, very widely around; which agrees with the allusion of the Psalmist when saying—*She spreadeth her branches like the cedar-tree.* Mount Libanus seems to be the chief place of its natural or original residence; where, by accounts of travellers, there are still a few old trees of prodigious magnitude remaining; but the cones having been dispersed into many different countries, they have raised large plantations of the trees, which in some places are arrived to a considerable size; though in England there are only at present here and there some trees that are of any considerable growth: they, however, are now raised abundantly in all the public nurseries, and of late years numbers of the trees have been planted on many estates, for they will prosper in almost any soil and exposure, and have great merit for all ornamental plantations; likewise as timber-trees: the wood of which being of superior value.

It is said the timber of this fine tree is proof against all putrefaction, and that it will continue sound two thousand years: it was greatly used in the buildings of Solomon's temple, and other sacred structures of antiquity.

14. *PINUS Larix—(Deciduous.)*

(Larix) — the Larch-tree, or Deciduous Pine.] Rises with an upright, straight, whitish stem, to a great height; sending out many slender branches all around, garnished with long, finely-narrow, obtuse-pointed, light-green leaves, in bunches from the same point, spreading open above; and with flowers of different colours in the varieties; succeeded by small, close, acute cones, an inch long.

It is a native of the Alps, Switzerland, and Italy, &c. which, though deciduous, is a tree of beautiful growth.

Varieties.] Common red Larch-tree, having reddish flowers and cones—white Larch-tree—black American Larch-tree—horizontal Larch-tree—dwarf Larch-tree.

15. *PINUS pendula—(Deciduous.)*

Pendulous Siberian Larch.] Rises with a straight, upright stem, to a considerable height, branching out around into many long, slender, pendulous branches; garnished with very narrow-linear, obtuse-pointed, dark-green leaves, in bunches from the same point, spreading open above; and flowers succeeded by small close acute cones.

All these fifteen species of *Pinus* and their respective varieties, have very finely-narrow linear, chaffy, and bristle-shaped leaves, and small flowers of but little appearance, generally produced in April and May; all monocious, apetalous, amentaceous, and conic; the males collected into conic spikes at the ends of the branches; the females into close oval cones, of many rigid scaly calyxes, which together gradually grow to a hard scaly cone, involving the seeds, one under each scale, ripening in winter and spring; when the cones, as many as wanted for the seed, should be gathered.

Most or all the foregoing species and varieties are trees of lofty growth, of the first magnitude and beauty, straight, swift, and stupendous growers; of which the first-thirteen species are ever-greens; the others, consisting of the Larches, are deciduous; and are all of a hardy nature, so as to prosper in almost any soil and situation; having all great merit both to enrich our ornamental plantations, and most of them also as timber-trees; and for either purpose they may be employed in any exposure in gardens, parks, or fields, or either in plains, or the sides or tops of hills, and in woods and clumps of all sorts; the Scotch Pine in particular is the hardiest of all the sorts; scarcely any country, soil, or situation comes amiss to it, even on the tops of mountains and rocks where there is hardly any earth, and only crevices for their roots to strike into; in short, all the other species of *Pinus* in general possess nearly the same degree of hardiness; for though they may make the greatest progress in deep and somewhat moist soils, yet they will also thrive tolerably both in clayey and sandy soils, as well as in a gravelly, stony, and stony ground; so that all the sorts may be employed almost any where both for ornamental or profitable plantations; remarking, however, that the better the soil is, the greater progress they will probably make in their growth.

Therefore these fine trees are highly proper

for plantations of all kinds, both for pleasure and profit; and will greatly beautify and enliven the scene, as well as cause great variety among themselves, by the difference of their leaves and cones; and as all the sorts produce cones abundantly, furnished with plenty of seed, they may be easily raised in any quantity in the common ground. See their *Propagation*.

It is affirmed that plantations of these trees, besides their being beautiful to behold when growing, and profitable as timber-trees, render the air exceedingly wholesome by their balsamic and aromatic exhalations, which they emit, and diffuse widely around.

They are all very swift growers, as after being a few years old, they often shoot two or three feet in height in the course of one season, mostly performing the whole shoot by Midsummer; and always aspire with one erect firm shoot in the middle, forming the stem, which, at the termination of every year's shoot, sends out a tier of branches circularly.

Considered as forest or timber-trees, they are of great value, as their timber is the principal wood used in our buildings, &c. but the principal sorts for timber-trees are, the Scotch Pine—Pinaster—Weymouth Pine—Swamp Pine—Stone Pine—Spruce Fir, and varieties—and Silver Fir. The timber of these sorts is what we commonly call deal, and is of universal utility, particularly for all kinds of buildings, and innumerable other uses: they are also of great value in ship-building, and are most excellent for masts, in which they exceed all other trees yet known, particularly the Scotch Pine, Pinaster, and Weymouth Pine; but the latter most of all, as it often grows to above a hundred feet high, with proportionable substance.

The Cedar of Lebanon and Larch-tree may also be employed in our plantations of timber-trees, for they will arrive to a great size in this country, as is evident by some old trees now in some gardens, &c.

Most of these trees are resinous or gummy, of an agreeable aromatic smell, but bitter taste.

It is from the Pine and Fir kinds that pitch, turpentine, and rosin are procured; being extracted from the growing trees, in the countries where they abound, and of which is made a very considerable merchandise.

Most of these trees possess also very salutary medical properties. A decoction in milk of the seeds of Pinaster, or the extremity of the young branches pulled in spring, is said, with a proper regimen, to cure the most confirmed inveterate scurvy: the branches of the

common Spruce Fir are used by the Americans for making their spruce-beer.

All the species of these trees are propagated in great abundance in the public nurseries, where they may be purchased in any quantity at moderate rates, or may be easily raised from seed, as directed under the article of their *Propagation*.

It is advisable to plant out all these trees when they are young, three or four to five or six feet high; or if younger, the better; as they will root more freely, and make much greater progress.

The best season for planting all these kinds of trees is autumn or spring, i.e. September, October, and November, for the autumnal planting; and February and March for the spring; though they may also all be removed with tolerable success any time in open weather in winter, from September till March; but those transplanted early in autumn will generally have taken root before winter comes on, and begin to establish themselves more firmly before the drought of the ensuing summer.

When intended to have ornamental plantations of these trees, they may be planted both in clumps and in continued plantations, sometimes by themselves, and some in assemblage with other trees of similar growth, stationing the ever-greens principally with those of that tribe; though, for the general part, they appear to the best advantage when disposed by themselves in various elegant clumps, and running plantations: observing to have a proper intermixture of the different sorts, and allow a proper distance between the trees, that they may have room to spread their heads around distinctly, and be branchy quite to the bottom. Some trees of different sorts may also be disposed as single objects, in lawns, parks, and other spacious openings.

But when designed to have any planted for timber-trees, it is advisable to have quite young plants not exceeding three or four feet growth; and they should always be planted in continued plantations, and set pretty close, so as to draw each other up more effectually in height; for it is the length as well as the substance of this timber that greatly enhances its value; therefore they may be planted only four or five feet asunder, and in seven, eight, or ten years, according to their advanced growth, some may be thinned out, and in two or three years after, the thinning may be repeated; and so continue gradually thinning out the underlings, which will do for poles, spars, &c. and thus should these plantations be thinned occasionally till the principal trees designed for standing are arrived at maturity, whereby they will

will aspire to a great height, with stems as straight as an arrow.

After making any plantation of these trees either for pleasure or profit, no farther trouble or expense is necessary, than keeping down large weeds, &c. whilst the plantation is young, and fencing against cattle; for they do not require any trimming, as the branches of these trees should not commonly be lopped, which would not only spoil the beauty of their natural growth, but would retard their general growth in proportion.

Propagation and General Culture of all the Sorts.

All the species of *Pinus* and varieties in general are propagated only by seed, which will grow freely in the common ground, either in beds or borders of light earth, or in pots or boxes of the like soil, in order for moving occasionally to different situations at different seasons; and the season for sowing all the sorts is in March and April.

Most of the sorts produce cones abundantly in our gardens and plantations, ripening in autumn and winter, containing plenty of seeds; observing to gather the cones in the proper time. All those in particular that are of a loose nature ought to be gathered early in winter; otherwise they are apt to open and disseminate their seeds; but those that are compact and firm may hang longer, and be gathered any time about the middle or end of winter, or towards spring. The cones of most of the sorts are also sent us from the different countries where the trees abound; particularly the Italian Stone Pine, Cembra Pine, Cedar of Lebanon, and of several other curious sorts; and are sold at most of the public nurseries and seed-dealers at moderate rates; either the cones entire, or the seeds cleared from the cones: the method of taking out the seeds is as directed below.

It must be observed of getting the seed out of the cones, that as the cones are composed of numerous hard bony scales, very closely placed, having the seeds lodged between them; and that sometimes the scales being almost united, especially in some of the Pine kinds, Cedar of Lebanon, &c. and often so closely involve the seeds as they cannot be dislodged without violence of breaking or splitting the cones open with an instrument; though those of many of the sorts will open readily by exposing them before a fire, or to the Midsummer sun, when the heat will cause the scales to open gradually, so as the seeds will easily shake out; but by waiting till summer for the heat of the sun to open the cones, we lose a year in the time of sowing, therefore hav-

ing procured a quantity of the cones in autumn or winter, they may be laid before a moderate fire, at some reasonable distance, so as not to scorch the seeds: thus the scales will open, and the seeds may easily be beaten out of their cells; though some sorts, particularly the Stone Pine, Cembra, and Cedar of Lebanon cones, are so close and hard that the seeds cannot be dislodged without violence, as above observed, and is generally effected either by breaking them with a vice, or by boring a hole with an instrument up the middle of each cone, then having a wooden or iron wedge-form peg of a proper size, drive it through the hole, which will split and divide the cone so as the scales may be easily removed and the seeds taken out ready for sowing.

With regard to the proper soil and situation in which to sow these seeds, almost any common light ground in the nursery will do, but give preference, where practicable, to a light sandy loamy soil; and as to situation or exposure, it may either be any of the open quarters of the seminary, or in a somewhat shady border, in which they generally rise stronger than in a full exposure, unless the beds, &c. are shaded occasionally in hot dry weather in sunny days when the plants begin to come up.

The best season for sowing all the sorts is March, but not later than the beginning of April.

Having, therefore, a proper quantity of seed ready, and the ground prepared by proper digging, and formed into one or more beds, three or four feet wide, take advantage of a dry day, and sow the seeds, scattering them moderately thick all over the surface of the beds, beating them gently into the ground with the back of a spade smoothly, and cover them half an inch deep with finely-broken light mould; or where there are only a small quantity to be raised, the seeds may be sown in large pots, or boxes of light sandy loam, covering them the above depth; though this practice is more particularly necessary for the Cedar of Lebanon, in order to move the plants to a shady situation in summer, and to a sunny warm exposure in winter; but for the sake of which convenience, some sow several of the principal Pine kinds in pots or boxes; and sometimes, in order to forward them as much as possible, sow them in pots, and plunge them in a moderate hot-bed just to bring up the plants. They, however, will all succeed tolerably in the full ground, especially all the Pine, Fir, and Larch kinds; and most of the sorts will come up in six or seven weeks after sowing.

Having, however, sown the seed, the following

lowing little attendances are necessary in respect to the care of the seed-bed and young seedling plants. In the first place observe, that as these seedlings generally rise out of the ground with the husk of the seed on their tops, which being once observed by the birds, they will attack them from all parts, and if not prevented, will pull them up as fast as they appear above ground; it is therefore advisable to defend them at this time, by spreading nets over the beds, &c. upon proper support, to remain until the plants are all fairly come up, and have thrust their husks off their heads. In the next place, it will be of advantage at this time to give occasional slight shade of mats, in hot sunny days, to those in a full exposure. Give also occasional very moderate waterings in dry weather; and keep them clear from weeds all summer. With the above care the seedlings will advance and form little slender plants by autumn following, though some probably will only be furnished with a few leaves at top, and just formed buds in the centre, ready to push next spring; others, more forward, will likely have made a short shoot by autumn: observing they are to remain in the seed-bed till a year old: they are hardy enough to stand the winter without any covering, except the Cedar of Lebanon, which, if the weather proves severe, it may be proper to shelter occasionally either with mats or a hot-bed frame: but all the others generally stand the severest frost unhurt; and by spring following, all the sorts should be pricked out into nursery-beds.

In spring following, therefore, the seedlings being one year old, they should in general be pricked out from the seed-bed into nursery-beds: March or beginning of April is the proper time, observing to form beds for their reception four feet wide; then taking up the seedlings out of the seed-bed with all their roots as entire as possible, prick them in the new-prepared beds, in rows six inches asunder; here let them have two years' growth, when by the end of the second summer they will have shot six inches, or more; then, in spring after, it is advisable to transplant them in wider rows, also in the nursery; observing, in this second removal, to set them in rows two feet asunder, and one at least in the lines, as they are to remain here till of a proper growth for final transplantation; they will here shoot six or eight inches more in height the ensuing summer; and in another year they will push with much greater vigour, probably make a shoot of half a yard or two feet long; so that when about four or five years old, they will be advanced a yard or more high; and if they

stand a year or two longer, they will be proportionably taller, and of full size for final transplantation.

Though, for a general plantation, it is most advisable to transplant these sorts of trees finally when not above two or three feet high, as they generally take root sooner, and set to growing more freely than trees of larger growth; for although most of the sorts may be transplanted when six or eight feet high, yet trees of two or three feet most commonly make the greatest progress.

However, when there is a necessity of retaining these trees longer in the nursery, it will be of advantage to transplant them every two years, whereby the principal roots will be kept shorter, and throw out many smaller lateral ones and fibres horizontally, so as to admit of being removed with safety; for, without the precaution of removal, trees of some years' standing would extend their main roots to a great distance, and be unfurnished with fibres, in which case large trees would be very liable to fail, but in the other method, trees of six or eight feet stature are sometimes removed with tolerable success; though the transplantation of such large trees of these kinds should only be practised where an immediate show is required in ornamental plantations.

But I should advise, for the general part, that most of the sorts, the Pine and Fir kinds in particular, have their final transplantation when not more than two or three to four or five feet high, as before hinted, especially where any considerable plantation is intended, more particularly if designed as forest-trees. I have, indeed, assisted in planting many thousands of the Scotch Pine, and others, when little more than a foot high, on the sides of hills and waste grounds, without any previous preparation of the soil, than just making an aperture or hole for each plant, and frequently only making a slit with the spade for the reception of each, leaving them to shift for themselves, and securing the boundaries of the ground against cattle: most of them have succeeded; though, in general, plants about two feet or a yard high are an eligible size for any considerable plantation.

The season for making plantations of these sorts is autumn or spring, or even in winter during mild weather, as already noticed.

In taking up all these kind of trees for any plantation, observe with particular care to raise them with all the roots as entire as possible: preserve also their tops perfectly entire, likewise all their branches, and in that state let them be planted; only previously with your
knife

knife trim any broken or very straggling part of the root.

With regard to the distribution or arrangement in the different plantations, and mode of planting, they are as follow:—Those designed for embellishing the shrubby compartments, and for ornamental plantations in general, may be disposed both in assemblage with other trees, and to form clumps, and continued plantations occasionally of themselves. But those intended as forest-trees should generally be disposed alone in considerable plantations: and, as to the method of planting them, it is the same as for other hardy trees (see PLANTING): observing, however, where large plantations in out-grounds are intended either for pleasure or profit, there will not be any great necessity for a previous preparation of the soil, with respect to digging or ploughing, only just to dig a hole for each tree: the same rule may also be observed in planting clumps of them in lawns, parks, and other grass-ground. Observing, that those designed principally for ornament should be disposed at such distances as their branches may extend freely every way; for the beautiful display of the head is a great merit in these trees in pleasurable plantations; but those intended for timber plantations may be planted only four or five feet distance, in order that they may draw one another up straight and tall more expeditiously, and to admit of a gradual thinning after a few years' growth, for poles, &c. as already observed.

After having their final transplantation, they require but very little more trouble, only observing to clear them, while young, from overbearing weeds; and if any large trees, five or six feet high, or upwards, are planted, it is proper to support each tree with a stake, to secure them against the power of tempestuous winds, till firmly rooted.

Let all the sorts take their own natural growth; being careful to preserve their tops perfectly entire, to shoot up as fast as possible; suffering them also to branch out in their own way; for no pruning is wanted, unless the lowermost tier of branches in any particular trees should be thought too low and straggling, when these may be occasionally trimmed, cutting close to the stem; but prune no further, for it should be very sparingly practised to these resinous trees, as lopping the branches contributes to retard their growth, as well as impair their beauty. Indeed, in large forest plantations, where the trees are arrived to a large growth, it is customary to lop their lower branches gradually for faggots, according as they begin to decay, for where these

trees stand close, the upper branches generally kill those below, so that the lower tiers decay gradually and successively one tier after another; and in which case, these decaying lower branches may be lopped by degrees in winter.

When the plantations designed for timber-trees have had from eight to ten or twelve years' growth, it may be proper to begin to thin them, observing the rules before laid down: those thinned out will serve for many smaller purposes, being careful in thinning to leave a sufficiency of the finest plants standing at proper distances, to grow up for timber.

PIPER, Pepper.

The plants of this genus are principally herbaceous and shrubby perennials of the West and East Indies, introduced here for variety in our hot-houses; obtaining in growth from one or two feet to five, ten, or twelve high, adorned with ovate, oblong, cordate, and lanceolate leaves; and terminal and lateral spikes of small apetalous flowers; no stamina, only two roundish antheræ; a large oval germen, crowned by a triple style or stigma, and succeeded by a roundish, unilocular berry with one seed.

Class and order, *Diandria Trigynia*.

There are many species: the most noted in our gardens are,

1. PIPER *obtusifolium*.

Obtuse Fleshy-leaved American Pepper.] Low herbaceous, succulent stalks; and ovate, thick, fleshy, nerveless leaves.

2. PIPER *reticulatum*.

Netted-leaved American Pepper.] With heart-shaped, seven-nerved, netted leaves.

3. PIPER *Amalago*.

(Amalago) — or Jamaica Pepper.] With leaves lanceolate, five-nerved, and wrinkled.

4. PIPER *nigrum*.

Black Indian Pepper.] With ovate, smooth, mostly seven-nerved leaves.

5. PIPER *aduncum*.

Hooked-spiked Jamaica Pepper.] With ovate, lanceolate leaves, nerves alternate, and recurved hooked spikes.

6. PIPER *longum*.

Long Indian Pepper.] With hearted leaves, some petiolated and some sessile.

7. PIPER *peltatum*.

Peltated, or Target-leaved Indian Pepper.] With target-shaped, orbicular, hearted leaves, obtusely scalloped, and umbellate spikes.

Several of these exotics are retained in our stove collections, to increase the variety; the first three or four sorts are the most noted, or generally known; of which the first is a dwarfish

dwarfish plant: all the others are of considerably superior growth; they being all tender plants originally from South America and the Indies, require the constant protection of our hot-houses in this country, planted in pots, and managed as other similar stove exotics: and may all be propagated by seeds obtained from the countries of their natural production, sowing them in pots plunged in a hot-bed under glasses, or in the bark-bed in the hot-house: some are also occasionally raised by layers and cuttings; and the first sort by its rooting stalks.

PISCIDIA, Jamaica Dogwood-tree.

A genus furnishing for our stove collections two exotic trees, of the West Indies and South America, of moderate growth; garnished with pinnate opposite leaves, composed of several pairs of ovate folioles, terminated by an odd one; and with papilionaceous whitish flowers, having quinque-dentate cups, an emarginated rising standard, two oblong wings, and moon-shaped keel: ten diadelphous stamina, a linear germen, and slender rising style, succeeded by an oblong, narrow, four-bordered, jointed, leguminous pod, of one cell, with cylindrical roundish seeds.

Class and order, *Diadelphia Decandria*.

The species are,

1. **PISCIDIA Erythrina**.

(*Erythrina pinnata*)—*Pinnated ash-leaved Erythrina, or Jamaica Dogwood Tree*.] Piscidia with pinnated leaves, having ovate folioles or lobes.

2. **PISCIDIA carthagenensis**.

Carthagen American Piscidia.] With pinnated leaves, composed of ob-ovate folioles.

Both these species are of the tree or shrub kind, very tender exotics, retained here in our stoves for variety; in which they may be propagated by seed, procured from the West Indies, &c. by the seedsmen, of whom it may be obtained in the Spring, sowing it in pots, and plunged in a hot-bed or bark bed in the stove; and the plants managed as in the general culture of the exotics of that department.

PISONIA, Fingrigo.

In this genus are two species of moderate tree growth, exotics from the West and East Indies, introduced in our hot-houses as plants of variety and curiosity; in which they grow with shrubby-like stems, branching by opposite pairs; garnished with smallish oblong obverse-ovate leaves, and small bunches of yellowish flowers, hermaphrodites and males on two separate plants, having acutely-five-parted calyxes; the corolla tubulous, funnel-shaped, quinquefid, including five stamina, an oval germen with one style, crowned by five spread-

ing stigmas, succeeded by a pentangular, unilocular capsule, containing one oval seed.

Class and order, *Polygamia Diœcia*.

The species, as above, are,

1. **PISONIA aculeata**.

Prickly American Pisonia, or West India Fingrigo.] Pisonia with spreading spinous prickles at the axillas of the branches.

2. **PISONIA mitis**.

Mild or smooth Indian Pisonia.] With the branches smooth or unarmed, not furnished with prickles.

These plants, natives of the hot parts of the Indies, in this country require a constant situation in the hot-house or stove, and treated as other shrubby exotics of that repository; and are propagated generally by seeds in the spring, sown in pots, and to have the assistance of a hot-bed or bark-bed of the stove, &c.

PISTACIA, Pistachia-nut, or Turpentine-tree.

This genus consists of the tree and shrub-kind, furnishing hardy deciduous trees for the shrubbery, and ever-green shrubs for the green-house, all of them of upright growth, rising twenty or thirty feet high, garnished with pinnated and trifoliate leaves, and dioecious, amentaceous, apetalous flowers, succeeded by drupaceous berries, furnished with oval nuts, which in some species are eatable.

Class and Order, *Diœcia Pentandria*.

Characters.] **CALYX**, male and female flowers on distinct trees, the males collected into loose, sparsed amentums, composed of small scales, each having one floret, furnished with a very small, five-parted perianthium; and the females in clusters, with small trifid cups. **COROLLA**, small florets without petals. **STAMINA**, five very small filaments, having large, oval, tetragonous, erect, petalous antheræ. **PISTILLUM**, an oval germen, three reflexed styles, with thick hispid stigmas. **PERICARPIUM**, an oval berry-like drupe, having an oval smooth nut.

There are five species, four of which are hardy shrubs, mostly deciduous; the other is a tender ever-green for the green-house.

Hardy Kinds.

These kinds, however, though denominated hardy, are rather tender whilst young, at least those raised from seed, requiring shelter of a green-house or garden-frame, in winter, till four or five years old, and are become a little woody.

1. **PISTACIA vera**.

True Pistachia-tree.] Rises with an upright stem, branching twenty or thirty feet high, covered with a russety cracked bark, but the younger branches smooth; large pinnated leaves,

leaves, of two or three pair of oval recurved lobes, terminated by an odd one; and from the sides of the branches small greenish flowers in amentums and bunches, succeeded in the female trees by clusters of oval fruit, containing large eatable nuts.

It is a native of Persia, Arabia, and Syria, from whence the nuts are brought annually, for they rarely ripen here in our gardens, and are sold in the shops by the name of Pistachia-nuts.

2. PISTACIA *Terebinthus*.

(*Terebinthus*) — or *True Turpentine-tree*.] Rises with an upright branchy stem, about thirty feet high, having a dark bark full of cracks; pinnated, dark-green, alternate leaves, of three or four pair of oval-spear-shaped lobes, terminated by an odd one; and small greenish flowers.

It grows naturally in Italy and Spain, and from its trunk flows the true Turpentine; but that of some of our Pine-trees is commonly substituted.

3. PISTACIA *trifolia*.

Trifoliate Pistachia-tree.] Rises with an upright branchy stem, between twenty and thirty feet high, having a rough brown bark; trifoliate or three-lobed, dark-green leaves; and small greenish flowers.

4. PISTACIA *narbonensis*.

Narbonne Turpentine-tree.] Rises with an upright branchy stem, about twenty feet high, having a whitish bark; pinnated leaves, mostly of three or five roundish lobes; and small greenish flowers.

The first sort is the hardiest of all the above four species, and the third and fourth are the tenderest, and are often kept here in the green-house collections, also sometimes the common Turpentine-tree; but they may all be gradually hardened to bear the full air the year round.

Green-house Kinds.

5. PISTACIA *Lentiscus*.

(*Lentiscus*) — or *Mastic-tree*.] Rises with an upright branchy stem, fifteen or twenty feet high, having a greyish bark; abruptly pinnated leaves, of three or four pair of spear-shaped lobes, not terminated by an odd one; and small greenish flowers.

From this species and variety is collected the Mastic of the shops.

Variety.] Narrow-leaved *Lentiscus*.

All the above five species of *Pistacia* flower generally in April; they are universally dioecious, or male and female upon two separate trees; are small and without petals, with the males collected into amentums, and the females in bunches, mostly of a greenish colour, so make

no show; and those of the females are succeeded by clusters of fruit, ripening to a blue or blackish colour, inclosing the nuts; but these never ripen in England.

With respect to the merit of those trees in our gardens, observe as follows:

The first four species are proper to increase the collection in curious shrubberies, observing, as they are of somewhat tender quality, some should be kept in pots for moving to occasional shelter from frost whilst young, till three or four years old, so as they have obtained a little strength, and become woody, when they may be turned out into the open ground, in a dry warm situation; and should also retain some in pots, to have occasional shelter among the green-house plants in severe winters, more particularly the *Trifoliate* and *Narbonne* kinds; which two sorts, if sheltered in winter, will often retain their leaves great part of the year; and being more tender than the first and second, they are in many gardens retained as green-house plants. All these four sorts, however, denominated hardy, may be gradually hardened to bear the full air the year round, as aforesaid.

The fifth sort, *Lentiscus* or *Mastic*, is a pretty ever-green, of a tenderer nature than the other four, so must have shelter, all winter, of a green-house; in which collection it highly merits culture, as it effects a distinguishable variety at all seasons of the year.

Their Propagation, &c.

The propagation of all the five species is principally by seed; and some sorts also by layers.

By seed.—The nuts are the seed, which of all the sorts are procured from abroad annually, and may be obtained at most of the seed-shops and nurseries, &c. observing they all require the aid of a hot-bed. Let them be sown early in spring, in pots of light earth, half an inch deep, and plunge the pots in a hot-bed, just to bring up the plants: when this is effected, be careful to admit a large portion of fresh air daily, and by degrees harden them to it fully in June, giving frequent refreshments of water all the summer; and in autumn remove the pots to the shelter of a hot-bed frame, or a green-house, to remain all winter; then in spring following, plant them out into separate small pots, which if directly plunged in a moderate hot-bed, it will greatly facilitate their rooting, and set them forward; but when they begin to shoot, harden them to the full air, still continuing a proper supply of watering, and in autumn remove them again to a frame or green-house, for the winter; which care must be repeated to all the sorts till they are three or four years old,

old, as aforesaid; shifting them occasionally into larger pots. After this, most of the four hardy kinds may be turned out into the shrubbery compartments to remain, retaining some in pots for removing under protection of a frame or green-house, occasionally in severe winters: but the *Lentiscus* must always be continued in pots to have shelter in winter with other green-house exotics.

By Layers.—Most of the sorts may be tried by this method: but the *Lentiscus*, in particular, is very commonly propagated by layers. Choose the most conveniently situated young shoots, which lay in spring or summer by common laying, and they will be mostly well rooted by the following autumn; when they should be taken up and potted separately, and managed as the seedlings.

PISTILLUM, the Pistil, or Pointal of the flower, or female organ of the generation of plants, rising in the centre of the flower like a column, consisting of the germen, style, and stigma.

1. The *Germen* forms the base of the *Pistillum*, and is the seed-bud, or rudiments of the seed-vessel, or fruit, and supports the style, elevated like a pillar in the middle of the flower. See GERMEN.

2. The Style (*Stylus*) stands upon the summit of the germen, elevated like a column, and corresponds to the *vagina* in animals, being generally somewhat hollow like a tube, though the tubular parts are often so fine as to be scarcely perceptible, serving to transmit the effluvia of the fecundating dust, or *Pollen*, through into the heart of the germen, or seed-bud, for the purpose of impregnating the seeds, and is terminated by the stigma. See STYLUS.

3. The Stigma is the summit or head of the style, appearing frequently like a knob or head, and when there is no style, it adheres to the summit of the germen; and its use is to receive the male dust from the antheræ; thence transmitting its vapour through the *vagina*, or style, aforesaid, into the heart of the seed-bud, for the purpose of impregnation. See STIGMA.

Each of the above parts of the *Pistillum* is more particularly explained under its respective head.

PISUM, the Pea.

This genus consists wholly of hardy herbaceous plants, one species of which, the *common Pea*, an annual, is the parent of all the numerous varieties of Peas cultivated in our gardens and fields for common use, the merits of which, as esculents, are universally known; all of which rise with long, slender, cirrhous

climbing stalks; garnished with cirrhous-pinnated leaves, and papilionaceous flowers, succeeded by that sort of seed-vessel called a legumen, or pod, filled with Peas, the eatable part of the plant.

Class and Order, *Diadelphia Decandria*.

Characters.] CALYX is monophyllous, acutely five-parted and permanent. COROLLA is papilionaceous, consisting of a broad heart-shaped, reflexed, indented standard, ending with a point; two short, roundish, connivent wings, and a shorter, compressed, semi-lunulated keel. STAMINA, ten diadelphous filaments, crowned by roundish antheræ. PISTILLUM, an oblong compressed germen, a triangular, rising, membranaceous style, and oblong hairy stigma. PERICARPIUM, a large, long, bivalvular pod, ending in a point, containing one row of roundish seeds or Peas.

The principal distinction between this genus and *Lathyrus*, (*Everlasting Pea*, &c.) is, the style of this is triangular, and that of the *Lathyrus* is plane. See LATHYRUS.

There are several species belonging to this genus, but, of which, not more than one merits particular observation for our purpose, considered as a plant of valuable utility, or a profitable domestic esculent for general culture, which is the *Common Cultivated Pea*, comprising, however, numerous varieties; for all the sorts of garden and field Peas are varieties only of one species; but whether the common white Pea of our gardens, or the grey field Pea be the original kind, is uncertain. The other species alluded to are considered principally as plants of botanical variety.

Cultivated Kinds.

1. *PISUM sativum*.

Cultivated common Pea.] Rises with long, slender, trailing stalks, by clasping upon support, from two to six or eight feet high; pinnated, cirrhous leaves of two or three pair of lobes, terminated by cirrhi, or tendrils, and have taper foot-stalks, with roundish, indented stipulæ below; and at the axillas long pedunculi supporting many flowers, &c.

Varieties.] Common white Pea—common grey field Pea: each of which comprising many varieties.

Each of these two principal varieties of this species, *Pisum sativum*, comprise numerous others, particularly the white sort; and new ones are obtained almost every year, in one place or other, differing from one another in some little particular, either in their growth, manner, and time of blossoming and bearing, size and form of the pods and peas, together with their quality for eating; and several other

other little properties or singularities, all of which are accidental varieties, rising from one another; for suppose we were to cultivate only any one of the varieties, we by observation will find plants varying from the original sort, sometimes probably for the better, and sometimes worse; but the first only is to be regarded; and it is by observing this, that curious persons have increased the valuable varieties, when by examining their crops, and finding one plant very different from all the rest, or any other known sort, either by its blossoming and bearing earlier, or some other valuable singularity, they carefully mark it, and preserve all its produce for seed; which being sown separately for two or three years, or till having multiplied them sufficiently to be distributed, they are sent into the world as a new sort, bearing the name probably of the place, or person who first obtained them, such as the Charlton Pea, &c. Thus the different varieties of Peas are obtained, and each respective variety multiplied for public supply; some of which varieties differ very materially from one another, either by their early bearing, or by their larger growth, or the like, though some reputed varieties differ so immaterially that the difference is hardly distinguishable. And it is to be remarked of all these acquired varieties, that although some are tolerably permanent, yet without proper care in saving the seed of each sort separate, they will all gradually degenerate to one another, or to the common white or grey kind; so that it would in a manner be impossible to pretend to enumerate all the varieties of Peas, or to give any particular description of all the different sorts; therefore we shall only exhibit a list of the principal varieties that are at present the most commonly known and esteemed; which, though pretty many, there are not above five or six that have merit for general culture; some of which are moderate growers, and early bearers, commonly called Hotspurs, others are large growers, and come late into bearing.

Most material general varieties are of the two following classes.

1. *Principal, middling, and smaller Kinds for early and main Crops, &c.*

Early Charlton Hotspur Pea—early golden Hotspur—Nichols's early golden Hotspur—Reading long Hotspur—Masters' Hotspur—Ormrod's Hotspur—early dwarf Hotspur—Leadman's dwarf Pea—dwarf fan Spanish Pea—early dwarf frame Pea, for hot-bed frames—pearl Pea—cluster Pea—royal green Pea—large grey Pea—crooked grey Pea—egg Pea—long bearing Pea—green seeded field Pea, for the dry Peas to boil—white field Pea for the same occa-

sion, &c.—with several other supposed varieties of less note, that hardly differ any thing from some or other of the above sorts.

Most of the above varieties in this class of Peas are moderate growers, rising upon support of sticks three or four to about five feet high, in the larger kinds; the dwarf sorts scarcely half so much, some not above a foot high; the greater part are plentiful bearers, but the most profitably so for general service in garden culture, in the first five or six sorts, proper both for early and main crops, producing largest well-filled pods, and continue longer in successional production and abundance: and of which, in the early Hotspur kinds, the first three differ not very materially, only in some arriving to bearing for gathering a few days or a week earlier than the others, more particularly in the golden Hotspurs, which, and the Charltons, are the most estimable for the first early and principal general forward crops; though any of the other three larger Hotspur kinds are very eligible for a general and principal succession crop; particularly the Readings, Masters, and Ormrods, which have preferable merit to make a principal share in the general crops, on being remarkably full bearers, and producing fine long pods regularly well-filled with larger-middling Peas, generally of equal full growth: or may also admit some of the other larger sorts in a secondary way for variety—and as to the dwarf Peas, they, according to their size of growth, are mostly very full bearers, the pods generally small and numerous, with the Peas small in proportion, but particularly sweet eating while young, and are eligible to sow in smaller portions, a few for early production, and a larger sowing for succession and late crops, especially of the Leadman's dwarf, for its very abundant bearing: likewise some of the forwardest dwarf sorts have peculiar merit for small early crops both in borders and frames.

However, for the general early and principal crops, the larger Hotspur kinds before noticed are the most valuable; and by different sowings of these from the latter end of October, or beginning or some time in November every month till May, or occasionally some of the other larger sorts and dwarf kinds, they will produce a daily supply of young green Peas from May or June until August or September, though will be succeeded in July and August plentifully by the following largest kinds of Peas.

2. *Larger-growing later Kinds with largest Pods, &c.*

Large marrowfat Peas, of tallest growth and largest pods—dwarf marrowfat Peas, of lower growth

growth and fine large pods—green marrowfat Pea, very fine—Spanish moratto Pea, moderately large pods—green nonpareil Pea, middling large pods—large egg Pea—green rouncival Pea, of strong growth, and fine large pods—white rouncival Pea of similar growth, and large pods—grey rouncival Pea, similar to the foregoing in growth and production—large crooked sugar Pea, of strong growth, and very large long bowed pods—dwarf sugar Pea, with similar pods—rose or crown Pea, rising with thick strong stalks, crowned by the blossoms and pods principally at top in a large umbellate cluster, esteemed more for curiosity for its singular mode of flowering and bearing, than to cultivate for any general crop; though the pods are large, and the Peas exceeding good eating while young—painted-lady rose or crown Pea, similar in growth to the last, the blossoms variegated red and white, and produced in a cluster at top as above—large grey field pea.

These large kinds mostly assume a strong growth, and will rise upon support five or six feet, or some seven or eight feet high, and produce fine large pods in tolerable plenty; the marrowfats and Spanish morattos in particular bear abundantly, and are profitable both for family use and market; but the marrowfats are most esteemed for the main crops; though the green nonpareils, and the rouncivals, being also fine large good Peas, are very eligible to cultivate as secondary latter crops, in variety with the other large kinds, especially in family gardens; likewise, where there is proper scope of kitchen ground, the sugar and crown peas are very deserving of culture in the order as above, in moderate portions; the former being curious in its large, long, crooked pods, and the young Peas thereof exceedingly sweet and good; and the crown Pea singularly curious in its peculiar strong growth and mode of production: so that, agreeable to these intimations, the different varieties of the above large kinds may be cultivated more or less as inclination or convenience may suit. Observing, all these large kinds are proper to sow chiefly in spring, from January and February until May, to supply the table in July and August; and by sowing late in May and in June, a succession may be continued from the beginning of July until near Michaelmas.

Great as the above number of the different varieties of the cultivated common Peas, both of the first and second class thereof, they are wholly the off-spring of one parent species, that have arisen from the seed at different periods of time by chance; and the respective

sorts, according as they occurred, have been abundantly increased by good culture sufficiently for general supply.

2. *Pisum Ochrus.*

(*Ochrus*)—or *Wild Winged Pea*.] Hath angular stalks growing about a yard long; diphyllous or two-lobed leaves, having membranaceous, decurrent-winged foot-stalks; and pedunculi sustaining one yellow flower, succeeded by oblong pods, containing roundish compressed Peas.

3. *Pisum-maritimum.*

Maritime Perennial Pea.] With angular stalks, petioles plane, above arrow-pointed stipulæ: and peduncles having many flowers.

4. *Pisum Americanum.*—*American, or Cape Horn Pea.*

Of the above four species of *Pisum*, the principal and only economically useful one is the *Pisum sativum*, including all its different varieties before explained under the said parent species; most valuably useful culinary vegetables of the annual tribe, produced from seed sown annually in spring, &c. arriving to perfection of growth the ensuing summer and autumn, yielding their abundant produce in those seasons, then wholly decay or perish the same year; the plants being of very short duration after attaining full growth, seldom continuing longer in the same crop than about two or three weeks in production, so that a fresh supply must be raised annually from seed; and that to have a regular supply of the varieties of the common Pea for use from the earliest part of summer until Michaelmas, several different sowings from October or November until May or June are necessary; for as a crop of Peas continues but about a fortnight in full bearing, a repetition of sowings once in three weeks or a month during the above period, furnishes a constant succession in continuation four or five months.

The other three species of *Pisum* are only proper for culture, principally for variety in general collections, or as may be required.

General Observations.

All the sorts are hardy, and thrive in the open ground in almost any common soil of a garden and field: observing the early sowings should generally be in a warm dry situation, and the general and later crops in any open exposure.

The plants of all the varieties are of trailing growth, though of the cirrhous-climbing kind; for being furnished with cirrhi or tendrils, terminating the ends of all the leaves that catch hold of any adjoining bushes, or branchy sticks, &c. they encounter in their progress, the stalks thereby climb, ascend aloft,

aloft, and fupport themfelves very erect, and mount feveral feet high, bloffoming and bearing as they afcend in their advanced growth: which indicates, that although they are procumbent or trailing plants, they being furnifhed with claspers for climbing, as above, nature feems to have designed that the generality of them fhould climb and erect themfelves from the earth, for the more effectually producing their refpective crops in the utmoft plenty and perfection; therefore, in their general culture in gardens, it will always be found of much advantage, in their production, to allow the whole or principal part, as far as poffibly convenient, the fupport of tall branchy fticks, three or four to five, fix or feven feet erect, according to the growth of the different varieties; which may be practicable enough for moderate quantities, in places where branchy loppings of trees or of any bufhy underwood, &c. can be obtained in fufficient plenty; and, as garden peas are always cultivated in rows, by placing a range of fuch branchy feathered fticks along each row, the plants moft readily attach themfelves thereto by means of their cirrhouf claspers, and afpire faft in height to their tops; bloffoming and bearing as they advance, in confiderably greater abundance and perfection, and the plants continue longer in fucceffional production than fuch as have no fupport, but permitted to trail on the ground.

In the garden culture of peas, they are always cultivated in rows, by fowing in drills two or three, to four or five feet afunder, according to the fmaller, middling and larger-growing kinds; which being not only the moft commodioufly effectual method of fowing Peas in general, but is alfo the moft eligibly adapted according to the nature of growth of the plants, as well as for admitting of proper room between the rows to perform the occafional neceffary cultural work of hoeing, ficking, &c. and of gathering the produce, &c.

Peas, comprehending the different varieties, rank among our moft ufeul and profitable fummer efculents of the kitchen garden, valuable both to fupply our tables with their produce, young and green in the pod all fummer, from May, or June, till September; and alfo when ripe, in fome of the middling-fmaller kinds dried and threshed out, for dry Peas to lay up till winter, &c. for feveral very ufeul culinary purpofes, as Peas-foup, Peas-pudding, &c. though the chief merit of the principal varieties for garden culture is for young green Peas to gather for immediate ufe during the fummer feafon; principally in

June, July and Auguft, for the main crops, fown at different times from December or January, until May, &c. but by fowing fo early as October or November, and continuing it in a monthly repetition till fpring, then in the advanced part of that feafon, from March till May, every three weeks, and then once a fortnight until the end of June or July, a daily fucceffion of green Peas is thereby obtained, from the beginning, middle, or fome time in May, according to the temperature of the feafon, till the latter-end of September; though the late crops, fown after the middle of May, and in June and July, for gathering in Auguft and September, are feldom fo effectually prosperous in production as the early and general fummer crops, being fometimes liable to be attacked by the autumnal mildew, or much retarded by the drought of the ground, and heat of the weather; however, as in fome families young green Peas are in request as early and long in the feafon as poffible, in which cafe it is eligible to fow both early and late, but always in larger fupplies for the principal general crops: fo that the moft general feafon for green Peas in full production for gathering, in the main crops, it may be obferved, from the above intimations, is principally June, July, and great part of Auguft, by fowing in December, January, February, &c. until May; but by fowing fo early as October or November, continuing a monthly repetition, as before fuggelted, till June or July, we often obtain a regular fucceffion from May to the end of September.

Of the foregoing two claffes and different varieties of the cultivated Peas, the principal forts moft eligibly eftimable for general culture, or fuperior bearers and preferable quality of the produce, are, chiefly the Goldens, Charltons, Reading and Mafter Hotfputs, for the firft early and general crops; and of the larger forts, the Marrowfats, Spanifh Morattos, Nonpareil, and Rouncivals, for the fecond or fucceffional general fupply: all of which are great bearers, and excellent fine eating Peas; the Marrowfats are fuperior of the large Peas for fweetnefs of eating, and richnefs of flavour, and merit culture in larger crops than the others of that clafs: but as there are many other different varieties of Peas than the above-mentioned, curious perfons, having eligible fcope of ground and other accommodation, may raife any of the forts, lefs or more, according as may be convenient, though generally in fmaller quantities than of the above-named principal varieties; efpecially as I have generally obferved, that

about five or six different principal sorts were always fully sufficient for the main general crops, with which the table has been plentifully supplied during the whole season of Peas; though any of the others in request are also eligible, as Secondaries, to increase the variety, and several of which are very deserving of culture, agreeable to the above intimations.

In the first class of varieties, consisting of the middling and smaller kinds of Peas, are comprised several valuable principal sorts most eligible for the early and first main crops; particularly the early Golden and Charltons, the Reading, Masters, and Ormrod hotspurs; the two former coming in the earliest, and the three latter are excellent for a full crop, with some preference to the Readings in producing larger long pods in singular abundance: though all these sorts have a great similarity, are most excellent and profitable Peas, and desirable kinds for principal culture, almost the whole Pea season, and are peculiarly adapted for the early and principal forward crops, as they come into bearing sooner than the large kinds of the second class, by a fortnight, if both sorts are sown in the same day, beginning first with the Golden and Charltons, for the principal early and first and second large crops, to sow before and after Christmas, or may be continued through the spring sowings, if thought eligible; proceeding in the first sowing towards the latter-end of October, or rather the beginning or middle of November for a more certain successful early crop, repeating the sowings in December and January, &c. in larger portions, at about three weeks' or a month's interval, or not above three weeks in the advanced spring months; observing also to sow some good crops of the Readings, &c. before mentioned; remarking, that these and the other hotspur kinds may be sown in full crops in December, or January and February, &c. at the above mentioned intervals; but in April and May once a fortnight, or eighteen or twenty days at most, would be eligible; and by which intervals of sowing you will have a plentiful daily supply for gathering in regular succession throughout the proper season, May or June, July and August, &c. each crop continuing only about a fortnight or three weeks in bearing; so that the different sowings succeed each other regularly.

All of which kinds should be sown in drills not less than two feet and a half to a yard asunder; but where designed to assist them with support of sticks, three feet and a half, or four feet, between the rows, is eligible;

or for sticking, some may be sown in double drills, i. e. two rows together a foot asunder, allowing a wide interval of four feet between the double rows; so, in either method, placing a range of sticks to each row of Peas, when arrived to a proper growth of six or eight inches.

I have, in some early crops of Hotspurs, advancing to bearing soon in May, permitted the gleanings to stand for seed, which ripening pretty forward in June, have threshed them out and sown them directly; and the plants coming up in a few days advanced freely to full growth, and produced a crop of Peas the same year for gathering in August and September.

Respecting the other varieties of Peas, ranged in this first list; some of the dwarf sorts are estimable for their early production, such as the dwarf Hotspur, proper to sow early on warm borders, and others for early crops in frames; and some are singular and curious in their dwarfish growth, requiring but little room, comparatively, in their culture, and bear very agreeably, according to their peculiar nature, and are eligible to cultivate occasionally in small secondary crops for variety, sown any time in the common season, January, February, or March, till May or June; but generally more abundantly in the Leadman's dwarf, for its great prolification, and which may be sown both in the early and middle season, or in any of the spring and summer months, till June or July, as it also succeeds peculiarly well for a late crop in autumn: all of which dwarf kinds are sown in drills two feet asunder, and generally have sticks to run upon, proportioned to their growth; and with respect to the other larger sorts of Peas comprised also in the said first class, they, although not possessed of any superior property for principal culture, are mostly tolerably full bearers, and very good common eating Peas; any of them are eligible to cultivate occasionally, as may be required, to furnish a greater variety of different sorts for the table; and may be sown in the common middle season, January or February, March and April, &c. in drills, the distance intimated for the principal Hotspur kinds.

And of those of the second class, comprehending all the principal largest varieties of Peas, the greater part are most excellent sorts to cultivate for the main successional and general latter crops; and for which occasions a considerable share should always be allotted in every garden, &c. where there is ample scope of ground to admit of their culture accordingly;

ordingly: preferring principally the Marrowfats for the large main crops, and as secondaries, the Spanish Moratto, Nonpareils, Rouncivals, and egg Pea; all of which may be sown in any of the spring months, or in repeated monthly sowings from December, January or February, in open weather, till May; though, in March and April, a sowing every three weeks or fortnight is proper, and once a fortnight in May and June, and which different sowings will furnish principal crops in full bearing in July and August, and smaller successional productions in September; but observing, in the principal general sowings, still to give preference to the Marrowfats for the chief crops, particularly the dwarf kind, for principal culture; secondary to these two sorts, the Spanish Morattos, then the Nonpareils and Rouncivals, &c. and of the latter it is proper to remark that they are not only proper to sow any time in common with the others as above, but are also peculiarly eligible for late crops, sown in April and May, or even till June, as these sorts generally endure the drought of summer better than most of the other large kinds; however, where variety is in request, any or all the above sorts, if approved of, may be sown at different times, less or more, as required; also the sugar and crown Peas, the former curious in its large bowed pods, and the Peas thereof most sweet eating; and the crown Pea is a singular curiosity in producing its large bunches of blossom and pods crowning the top of the stalks in a curious manner: generally, in the whole, beginning with the Marrowfats, not earlier than December or principally in January or February, March and April, &c. first the dwarf kind, which indeed, in some respects, is rather preferable, or more eligible for general continuance in sowing than the large marrowfats, as this sort requires considerably more room to grow, and taller sticks for the plants to run upon to their full length, otherwise they do not succeed in good perfection; but with such assistance, however, they bear wonderfully; so that where there is every convenience, it is proper to sow both these sorts; and as many of the approved kinds of the others as may be thought expedient, either as general or secondary crops.

According to the different seasons of sowing for the several crops, different exposures and situations should be observed as much as conveniently practicable; such as, for the earlier sowings in October or November, and December, should allot some warm south borders under walls, palings, or hedges, &c.

or some similar warmest dry compartments; and for sowings after Christmas, may generally allot more open situations, except where no sowings were performed before that period; in which case it will be proper to have the first sowing on a warm border, &c. as above, that the crop may come in as forward as possible according to the time of sowing; but for the general or larger forward and great main crop of any of the varieties of Peas to sow in January, or February and March, &c. should be principally in the open main quarters of ground; and generally in, at least, doubly larger portions, than the earlier crops.

And, as before observed, as a crop of Peas generally continues but a fortnight or three weeks in full production, proportionable frequent repetition of different sowings every month is indispensably requisite, especially in principal family gardens where a constant daily supply is demanded; but in considerable large crops in market gardens and fields for public supply, where required only during the principal Pea season of June and July, &c. probably about four, five, or six different sowings, from November, December, or January, &c. till April, may be sufficient; however, where a regular succession of Peas is required from the earliest to the latest season, should repeat the sowings every month in open weather, before Christmas; or even at intervals of only three weeks; if began sowing at the earliest period, in order thereby to have the greater chance against accidents from inclement weather in winter, and the depredation of vermin during that season; but from about Christmas till March, sow in open dry weather, once or twice every month, and from that time once a fortnight or every three weeks, till the middle of May, or in that month and June, moderate sowings once a fortnight, for late crops; making also trial of a small sowing the early part of July for a latest produce in September; and sometimes, in fine autumns, continue in a small production till October.

But where it is only required to have moderately forward, and some good general crops in regular succession during the principal season, the proper time for sowing, and the most certain and successful for good plentiful production, is from December, or beginning, middle, or anytime in January, when open temperate weather, continued every three weeks till the end of April, which will afford plentiful crops of peas in June, July, and greatest part of August: or February, March, and April, is a most successful season for sowing general full crops, for plentiful bearing two or three months

months in the principal season of Peas, June and July till the middle of August; after which, the produce is generally less abundant, and inferior in growth.

When, in the main crops of Hotspurs and the Marrowfats, &c. it is required to have the latter succeed the former regularly in bearing, both sorts being sown on the same day, or within a day or two of each other, the Hotspurs will come in soonest about a fortnight, and the Marrowfats will arrive to bearing in regular successive order accordingly, in proper growth for gathering: and, if Marrowfats and Rouncivals are sown in the same order, they will advance to production nearly in similar succession, the Marrowfats a week before the others.

In all the different sowings in the general varieties, the plants are always to remain where sown, to attain perfection in their general growth and production, though sometimes a few are transplanted, on particular occasions, for early production; such as either when the main earliest sowings are cut off by the severity of the winter, &c. or omitted sowing an early crop at the proper season; or sometimes, exclusive of any of these occurrences, a small portion is sown early, or a little before or after Christmas, either occasionally in a moderate hot-bed, or in a bed or border of natural earth, under a frame, &c. or sometimes sown thick in one or more large pots, and placed in a hot-house, forcing-house, or any common hot-bed, just to raise the plants as forward as possible, about an inch or two in growth, when, in either method, inuring them gradually to the free air, generally every mild day, giving protection of cold nights, frost, and other inclement weather, until the season commences somewhat settledly temperate in January, or early in February, &c. then, being thus defended over the inclement season, transplant them into some warmest south border in a row close along under the wall, or other similar fence, equally in a small neat shallow drill: they thus have a chance of coming into bearing at the most early period of the natural ground crops. Likewise for raising the most early crops of Peas in frames by hot-beds, &c. the plants being previously raised by sowing, as above, in November or December, &c. and when an inch or two high, are transplanted into fresh-prepared hot-beds of dung or tan-bark, under frames and glasses; or sometimes, when raised as above, are transplanted into beds of natural earth under frames and lights, but are obtained much forwarder in hot-beds; however, either of which are only practised occa-

sionally for a small earliest crop, in places where there are all proper conveniences, and that a few young Peas are in particular request as early as possible, March, or April, &c. But, as before observed, all the general crops of Peas, early, middle, and late, are always sown in the full ground in rows to remain for full growth.

The whole in the different crops being always necessarily cultivated in rows, as observed before, by sowing the seed or Peas in drills drawn in the earth with the corner of an hoe, these should be drawn about one to two inches deep, or but little more, according to the sizes of the Peas, seasons of the year, and nature of the soil, generally shallower in winter and wettest ground, than in the advanced warmer season, and dry light soils; and being careful to allow requisite abundant space between the lines or ranges, according to the growth of the different sorts of Peas intended, for the free admission of sun and air, as well as for performing the necessary culture, and room to go between to gather the produce without breaking down the plants. Allow, therefore, the smaller kinds not less than two feet, or two and a half, between the rows; but if intended to give them sticks to run upon, allow three feet at least, or rather three and a half, between the lines in rich ground; and the larger kinds should be allowed a yard or more between the rows even when no sticks are intended; but if designed to stick them, four or five feet is requisite for the largest sorts, such as the tall Marrowfats and Rouncival kinds. For it is most necessary, where practicable, to allow all the sorts sticks: placing a range of any sort of tall branchy sticks, or brush-wood, along each row of plants, when about half a foot high, for them to climb upon for support, whereby they will produce double the quantity of Peas, as when suffered to trail on the ground. This, however, though not generally practicable where large quantities are raised in fields for the supply of market; yet for moderate quantities in private gardens, where sticks can be readily obtained, it should never be omitted, as the advantage will be more than double.

Observe always to allow more room by a foot, between the rows for those crops that you design shall have support of sticks, than those that are not; for Peas that have support always grow strongest; and if they have not proper room, the plants of the different lines will interfere, and both interrupt the growth of each other, exclude the necessary influence of the sun and air, and not admit of room to gather the Peas without breaking the plants,

to

to the great diminution of the crops; but give them proper room and support, and you will reap the advantage in proportion.

But when intended to allow Peas support of sticks, some may be sown in double rows, with very wide intervals between, that is, beginning at one end of the ground, sow two rows together, only a foot asunder; then, if for the Hotspur kinds, leave a space of four feet, or if the large kinds, five feet, and sow two more rows a foot apart; then allow another wide space, and sow other two close rows, &c. and so proceed throughout: by this practice you have the ground equally filled as if the rows were single and closer; and by the abundant room in the wide spaces, it admits all the advantage of sun, air, and of gathering the produce freely without incommoding the plants.

Seed Peas of all the sorts are sold at all the seed-shops and nurseries at moderate rates, commonly by measure, as by the bushel, peck, &c. or in smaller quantities for private gardens, by the quart or pint.

Their Propagation and General Mode of Culture.

As to propagation, all the sorts are raised from seed, i. e. the Peas sown annually: the plants being but of one season's duration, an annual repetition of sowing is consequently necessary; and as those of one sowing continue but a short time in bearing, several sowings are requisite each season, to continue the succession for the table all summer; each sowing to remain where sown, choosing a warm border, &c. for the earliest crops; and for the succeeding ones, any of the common open quarters are the most eligible, in a free exposure, distant from shade of trees, &c. and open to the free air and sun; fixing on the driest warm soil for the forwarder crops, any common soil for the main crops, and the moistest parts for the late crops.

The general season for sowing is any time in open weather, from the latter end of October, or any time in November, until May or June; but remarking, that during the above period several different sowings are necessary, in order to keep up a constant succession of young Peas for gathering several months in summer, i. e. from May until September; for those sown in October or November, if they survive the winter, come into bearing in May and June, and by repeated sowings at a month, three weeks', and a fortnight's interval, till May, as we before remarked, they will furnish a constant supply of Peas all the summer; and those sown late in May and in June, or occasionally the beginning of July, very often

continue a moderate supply in autumn till the end of September, and sometimes a few in October. With regard, however, to the earliest sowings, from October or November till the beginning of January, they are liable to accidents from the severity of the weather; and if they all stand the winter, those sown in October or November will scarcely be a fortnight earlier in bearing than those sown six weeks or two months after: it is, nevertheless, proper to begin early, and repeat the sowings at the intervals before mentioned, that there may be a sufficiency for substitutes in case of accidents; and also, if they all survive, that there may be a regular succession of crops coming into bearing, to afford a daily gathering through the whole season.

But, in order to have green Peas as early as possible, recourse is had to the assistance of hot-beds, by the aid of which, young Peas are obtained in March and April, and continued till the coming in of the natural ground crops in May or June.

We, however, will first proceed with the culture of the several principal crops in the natural way; then by hot-beds.

Hotspur Kinds for the early and first general Crops.—In the latter end of October, or in November or December, as may be convenient, begin to sow the earliest crops; though in warm gardens it is always advisable to sow a few in the two former months; but in general, or especially in open grounds, November and December is time enough to begin any principal sowing, choosing the earliest Charlton or Golden Hotspurs; and for their reception prepare a warm south border, or some other dry, sheltered, sunny situation; and in a dry day draw drills by line, ranging south and north, to enjoy the greater advantage of the sun's influence, making the drills an inch and a half deep, and two feet and a half at least asunder; but if designed to allow them sticks, three feet and a half will be the more eligible distance, as we before observed: then having the seed, or Peas, scatter them evenly along the middle of each drill, rather somewhat thickish at these early sowings in winter, because they are liable to accidents from the attacks of vermin, and the inclemency of the season; covering them in evenly with the earth, either with a rake or hoe, or turned in with the feet; being careful that they are all equally covered the depth of the drills; and then with a rake lightly trim the surface smooth, which finishes the work of sowing. The seeds will begin to germinate in a fortnight, if mild weather, and will come up in three weeks or a month, seldom in less time
at

at this season ; when the plants are to be managed as hereafter directed.

Having thus performed the first sowing of the Hotspur kinds, then, agreeable to the aforementioned rules, another sowing should be performed in three weeks or a month after ; but if you sowed in October or early in November, it is advisable to repeat the sowing in a fortnight or three weeks, for fear the first should fail ; and after this continue sowing once in three weeks or a month all winter in mild weather, the same kinds, not forgetting towards spring to sow a principal crop of the Reading and other large Hotspurs ; observing, as the season advances, the sowings may be in more open exposures, and more in quantity than the early sowings ; and as the spring draws on, the sowings should be repeated oftener ; as, for instance, from about Christmas till the beginning of March or April, it should be once in three weeks ; and from that time till May, once a fortnight will be necessary, especially as the warm weather increases, in which it will be particularly eligible. It must be observed, however, these frequent sowings are principally to be understood for practice in private gardens, for the supply of such families that require a daily succession of young Peas during the whole season ; but for large quantities in fields, where only a succession of general crops are required just during the principal Pea season, June, July, and August, three or four to five or six different sowings from November or December until March or April may be sufficient, as before intimated.

All the different sowings will come up regularly in successive order ; but the winter and spring sowings differ materially in the time they require to germinate and come up ; those sown any time in winter are sometimes three weeks, or near a month, before they come up ; but those sown towards spring come up sooner ; and March and April sowings will often rise in less than a fortnight, especially those sown in April ; and sometimes sowings performed in April and May will come up in a week.

In the above sowings may introduce some of the dwarf Peas any time from December, January, or February, in small or moderate portions till May or June ; and of which the Leadman's-Dwarf, before observed, is also very successful both for middle and late crops.

Any of the other Peas of the first class may also be sown as above for variety.

According as the plants of each sowing come up, and have advanced two or three inches high, it is proper to begin the first culture by drawing a little earth with a hoe, or small

rake, lightly up to their stems on each side of every row, to strengthen them and forward their growth ; repeating the earthing once or twice at proper intervals, more or less as occasion may require ; at the same time cutting down all advancing weeds : and when the plants are six or eight inches high, those you design for sticks should then be stuck.

But as the earliest crops, that come up in November or December, are often in danger from the severity of frosts, it is, therefore, proper, when the plants are about an inch or an inch and a half high, to draw a little fine earth lightly up to their stems, in a dry day ; likewise it will be of much advantage to give occasional protection to the earliest plants in severe weather, by covering them lightly with long, light, dry litter, of the straw kind, or with mats ; which, in private gardens, where there is but a moderate quantity in warm borders, might be more easily effected : this need only be practised in very rigorous frosts ; but be sure to uncover them every fine day in temperate weather ; and the moment the frost breaks, discontinue the covering entirely ; for they must by no means be kept too close, which would draw them up weak and tender ; but by a judicious protection, the crop is often preserved in tolerable condition, and forwarded much sooner to bearing than if it had been left entirely exposed ; observe, also, that according as the plants advance, repeat the earthing up a little at a time in dry mild weather, two or three times till spring ; it will protect them the better from frost, strengthen, and forward their growth : this is all they require during the winter. In spring hoe up all weeds, and give them a final earthing, an inch or two up their stalks ; and then, if intended to allow them sticks, let it be done when the plants are six or eight inches high : having branchy sticks of three or four feet length, stick a range of them along by each row of Peas, on the southerly side of each row ; the plants will readily catch hold, and gradually ascend by their tendrils, blossoming as they advance ; if, when in blossom, the weather should prove dry and warm, some good waterings in a morning will be beneficial culture ; and when the blossoming plants are advanced some considerable height, if they are then topped, it will promote the pods setting more expeditiously, and arriving sooner to perfection.

As to the other succeeding crops of the Hotspur and other kinds, all they require is hoeing up the earth to their stems, and cut up all weeds when they appear ; and those designed for sticks, should always be stuck as soon as they are half a foot high, or a little more, before

fore the plants begin to fall down to one side; providing sticks for this purpose, about four or five feet long, and place one range to each row of Peas: placing them principally on the south or most sunny side of the rows, because the plants naturally incline towards the sun, and thereby more readily attach themselves to the sticks.

Larger Kinds for successional and general Crops.—With respect to the larger kinds, such as the Marrowfats, Spanish Morattos, &c. we may begin sowing in January, the dwarf Marrowfats first; though February, March, and April, is a very eligible season for sowing the general crops of all the large kinds; observing to chuse a free exposure in the most open quarters, there drawing drills by line, about an inch and a half or two inches deep, and not less than a yard asunder; but if to be stuck, four feet, and for the largest sorts four feet and a half to five feet, in single or double rows, agreeable to former intimations: sow the seed thinly along the middle of each drill, and draw the earth evenly over them with the rake, hoe, or feet, covering them equally the depth of the drills, and rake the surface smooth. Repeat the sowings once a fortnight or three weeks; though as the spring and the warm season advance, once a fortnight will be proper, especially from the beginning of April until the end of May; or in May and June may sow a few once in ten or twelve days: late sowings, however, performed from the middle of May till about the middle of June are seldom very fruitful, being often attacked with the mildew; but in family gardens it is proper to endeavour to have some as long in the season as possible.

When the different crops of these are come up about three inches high, hoe up earth to them on each side of the row; and cut down all weeds, repeating the hoeing occasionally according as the growth of weeds shall require; and when they are half a foot, or eight or ten inches high, those you intend sticking should have the sticks placed to them: observing, these large sorts require sticks six or seven feet high at least, placing them on the sunny side of the rows, as we said for the Hotspurs.

Late Crops.—Any of the sorts, either Hotspurs or larger kinds, that are most approved of, may be continued sowing all May and until the middle or latter end of June; likewise in May and June, and beginning of July, may sow some of the dwarf Peas before mentioned for late production; and I would observe of the larger kinds of Peas of the second class, designed for late crops, it would be proper to sow a larger portion of the Rouncivals

for the latest crops of all, on account of their being rather the hardiest to struggle with the summer's heat and drought; and thereby generally most to be depended on for a late production, in any tolerable abundance: though Peas of any sort that are sown after May is out, are rarely so successful as the preceding crops, they being liable to be much retarded by the heat and drought of the season, and frequently attacked by the mildew, &c. it is, however, worth the trial, and if they bear but a few after the general season, they will be a rarity; observing generally, for late crops, to allot some of the moistest ground, especially where there is choice of soil and situation; and in sowing the later crops in May and June, if the weather should prove very dry and hot, it will be of importance to soak the Peas in soft water six or eight hours previous to sowing, otherwise water the drills well; either of which will promote their rising very expeditiously and more regularly together.

Other general Remarks relative to all the Sorts.

I have observed, in performing the different sowings of Peas, with respect to the intervals of time between the sowings, it was a good rule, in the different principal sorts, that as soon as one crop appeared fairly above ground, to sow another to succeed it, of the same kind, such as Hotspurs to succeed those of that class, and the same of the marrowfats, and other large sorts, whether in winter, spring, or summer; so continuing it to every crop, which will be found an infallible rule in sowing, so as to have a regular succession of crops following one another in bearing.

And if a crop of marrowfats, &c. and another of Hotspurs are sown on the same day, the Hotspurs will come into bearing a fortnight the soonest, and the marrowfats will arrive to a bearing state about the time the others are going out, just in due time to succeed them: mark this, therefore, when intended to have these sorts, form a regular succession to each other.

Such crops of Peas that you design to assist with sticks for support, should always have the sticks placed when the plants are from about six to eight or ten inches high, whilst they maintain their upright position of growth; and as at that height they begin to emit tendrils, they will very readily attach themselves to the sticks.

With regard to the sticks proper for sticking Peas, it is incumbent on us to procure such that are branchy, or furnished with many side shoots, and of proper length, according to the sorts of Peas they are intended to support;

port; they may be either the loppings of trees, or any bushy underwood that is well feathered with small lateral branches the whole length, for the plants to run upon; observing, that if for the Hotspur Peas, to prepare them about four or five feet long; but for the large kinds, six or seven feet length will be requisite, or more for the largest marrowfats, &c. trimming them all somewhat fan-fashion, so as the branches may spread only two ways, to range the way of the rows of the plants, and sharpen the lower end of each: being thus prepared, place one row of sticks to each line of Peas; which will be sufficient, especially if placed on the most sunny side of the rows, because the sun's influence will incline all the plants that way, and thereby more readily encounter with the sticks; placing the sticks about a foot asunder, or a little more or less, so as the branches of the different sticks meet; and as soon as one row is stuck, then with a hoe draw a little earth up to the opposite side of the rows of plants, to lay them towards the sticks: when the whole is stuck, if the tops of the sticks appear very straggling and very unequal, you may run over them with your knife or garden-shears, just topping them to some little regularity.

In gathering the product of Peas, both hands ought always to be employed, one to hold the peduncle, or foot stalk of the fruit, while the other pulls the pods, otherwise the stem or main stalk of the plant, being slender, fragile, and weak, would be liable to be broken.

The gatherings should always be regular; according as the pods fill, never let them stand to grow old, but gather them whilst young and green, as they are then in greatest perfection for eating, and the plants will continue longer in bearing.

A crop of Peas continues only about a fortnight in full bearing, during which time they will furnish a plentiful gathering of pods in their ultimate perfection; though in moist showery weather they sometimes continue shooting and flowering three or four weeks; but the produce after the first fortnight is generally inferior both in quantity and quality; hence the necessity of repeated sowings every three or four weeks.

As soon as any crops of Peas, that have been stuck, are past bearing, take up all the sticks, and tie them in bundles, and set them upright in any dry corner; they will serve another year.

Early Culture by Hot-beds.

By Hot-beds.—Where it is required to have a few green Peas as early in the year as possible, recourse is had to the assistance of hot-beds, as we before said, and the proper sort

of Peas for this purpose are the early dwarf kinds, which by this aid may be brought to bearing in March and April, and the following is the method.

It must be previously observed, that it is rather most eligible to raise the plants first in the natural ground, sown in October or November, having occasional protection from frost; and when one or two inches high, then transplant them into the hot-bed, in January or beginning of February; for by this practice the luxuriant growth of the plants is somewhat checked by removal, so as they will shoot moderately within due compass, and thereby will blossom and bear sooner and more abundantly.

In October or November, therefore, prepare to sow in a warm, dry, south border, or otherwise in some similar dry sheltered compartment of light good earth, formed into an oblong bed of proper dimensions to have protection of a frame, &c. in rigorous weather: then having some early dwarf peas, sow them in drills about a foot asunder, in the manner as for the common crops, when the plants are come up, and advanced a little in growth, then in a dry day draw some fine earth up to their stems, as you shall see occasion; observing, if the frost should set in severe, you must afford them protection, either of frames or coverings of mats, or else some long strawy litter; being careful, however, to expose them every favourable day; and they will thus be continued in free growth, and good strength for transplanting.

Or if omitted sowing as above, or when desirous to have some plants with greater certainty as soon as possible in the proper season for hot-bed planting, they may be forwarded by sowing the Peas in a moderate hot-bed in December or January, under Frames, &c. and when the plants are up, admit plenty of free air every temperate day, and defended of nights, and from frost, snow, and cutting cold;—or some sown in large pots, may be placed in a hot-house, &c. to bring up the plants quickly for transplanting into the intended hot-bed in January,—or sometimes Peas are sown at once in a hot-bed in December or January, finally to remain for bearing; but it would be generally more eligible to have the plants previously raised an inch or two high, either by early sowing in the full ground, or forwarded under frames, or in a hot-bed, &c. as above, for transplanting at once in a fresh-made final hot-bed, which will be the most successful for a prosperous earlier production.

Therefore, by either of the above methods of raising the plants for transplanting in the hot-bed culture, they, when advanced one or

two inches in growth, or but little more, are of proper size for transplanting into the allotted hot-bed finally to remain for fruiting.

Then in mild weather, towards the middle or latter end of January, or beginning of February at farthest, prepare a hot-bed for one or more of the large three-light frames and glasses; the hot-bed may be either of dung or tan; the latter where it can be obtained easily at a moderate expense, is considerably the best hot-bed for this purpose: however, of either of these materials make the hot-bed two feet and a half or a yard thick, and cover it with frames and lights, and when arrived to a moderate temperature of heat, put on the earth for the reception of the plants (see HOT-BEDS). Chuse any light good dry earth, and lay it eight or ten inches thick all over the bed; then in a dry mild day, take up the plants, raising them with their roots as entire as possible, with what earth will readily hang about the fibres; and drawing small drills in the earth of the hot-bed, from the back to the front of the frame, a foot and a half asunder, and about an inch deep, put in the plants in the drills, not more than an inch apart, covering in the earth close to their roots and stems, and give a very light watering, just to settle the earth; which done, put on the lights; being careful to raise them occasionally at the upper end to give vent to the steam, &c. observing at first planting, if in sunny days the plants should flag, give a moderate shade in the middle of the day till the plants have taken root.

After this you will admit fresh air to the plants daily in fine weather to strengthen them, by tilting the upper end of the lights according to the temperature of the bed and outward air; but keep them close in cold nights, and cover also with mats; give occasional moderate waterings in fine days; and as the plants advance in growth draw a little earth up to their stems once or twice; repeating the moderate refreshments of water frequently as the warm season advances; which may be given more freely when the plants are in bloom: observing according to the advanced growth of the plants and increased warmth of the weather, to give a larger share of fresh air in proportion; and when they are in blossom, observe if the sun at any time appears too violent for them through the glasses, it is advisable to give a very slight shade an hour or two in the heat of sunny days; likewise when in full blossom and fruiting, be sure to admit plenty of free air, even sometimes in fine days shove the glasses entirely off; still also continue the waterings more abundantly during the time of

setting and growth of the pods, and indulge them with the benefit of warm showers.

Thus the plants may be brought to bearing in March or April, and by a succession of two crops, in hot-beds made at three or four weeks interval, and managed as above; you may continue a supply till the natural ground crops come into bearing in May.

Sometimes for early forced Peas, where there is the accommodation of fruit forcing-houses, hot-walls, &c. of any sort in cultivation in January, &c. a few earliest kinds, either previously raised in young plants an inch or two in growth, as in the hot-bed culture, or in default thereof seed sown; and either of which being in pots, are placed in the said departments; or sometimes, where there are internal borders of earth, some young plants, as above, may be placed therein where room admits: the internal moderate heat of the above departments, effected either by bark-beds, &c. or fire, or both occasionally, in a requisite degree for forcing the fruit-trees to early production, will forward the Peas proportionally, as to have some for gathering in the most early season, in a small portion. The general heat of a pine-apple hot-house or stove, is rather too strong for the above occasion in early Peas.

Hints respecting the Culture in Fields.

In the field culture of Peas, where designed to raise crops in order to gather the produce green and young for the supply of markets, November, or rather December, is time enough to begin the first sowings, especially in open exposed grounds; choosing a dry light soil for the forward sowings.

As to the sorts of Peas, any of the Hot-spurs for the forward crops, as observed in the garden culture, and for a general crop the Reading Hotspur is excellent; and secondary to that sort, the Master's and Ormrod's, &c. but of the large kinds, choose the marrowfats and Spanish morattoes for the main crops.

The ground for their reception is prepared by proper ploughing and harrowing; drills are then to be drawn with a hoe cross ways the lands, or if with a drill-plough lengthways, two feet at least, or two and a half asunder for the Hotspurs, and three for the larger sorts; no sticks being intended for these large field crops; and having sown the seed, cover them in either with a hoe or rake, though this is sometimes performed with a harrow; but the hoe or rake will cover them more evenly, and almost as expeditiously.

When the plants come up they must be kept clean from weeds, by broad-hoeing; but this is sometimes performed in fields by horse-hoe-

ing for the sake of expedition; which having hoes fixed in a sort of plough horizontally, is drawn by a horse between the rows, a man holding the plough-shafts to guide it; but as this can only cut down the weeds, a common drawing man-hoe must be used to earth up the plants; though this is often disregarded in the field-culture, it however proves very beneficial to the crop.

Saving Seed of all the Varieties.

To save seed Peas of the different varieties as perfect each in its kind as possible, some of each sort should be suffered to stand entirely for that purpose, or rather sow some of each purposely in different parts, and suffer the whole produce to remain and ripen for seed: this, however, in private gardens is rarely well attended to, for it is a very common practice to gather all the prime whilst young and green for the table, and let the gleanings remain for seed, which, although they will grow very well, and bear in tolerable plenty, yet the produce for the generality will be more scanty, smaller, and tend to degeneracy.

Observing, however, that when intended to raise a quantity purposely for seed, they should be sown in February in some open ground, in rows two or three feet asunder, no sticks being required, and when the plants come up, keep them clean from weeds by hoeing, and hoe the earth up to their stems once or twice.

When they are in bloom, examine them row by row, to see if there is any degenerate sort to pull it out, or if any improved variety is discovered, to mark it; which is the only method to preserve both the purity of the known sorts, and to procure new varieties; for example, if amongst the Hotspurs any large sorts appear, remove them directly; removing also any Hotspurs, &c. from amongst the large kinds, and different sorts of any of these from each other; and if any new sort discovers itself either by flowering earlier than all the rest, or possessing some other singularity, or noticeable merit for culture, it being carefully marked, the seed thereof may be saved separate, to sow also separate to furnish a proper increase.

According as the seeds of all sorts ripen in July and August, which is discoverable when the pods change brown, and the seed becomes a little hard, let the haulm be cut or pulled up in dry weather, and exposed in heaps in the sun, turning them every day; and when the seed is become perfectly dry and hard, it may either be threshed out directly, or stacked up in the dry till another opportunity; but whenever it is threshed, keep each sort

separate, and when properly cleaned, put them up also separate, in bags or sacks, with a label to each, expressing the variety.

PLANTATIONS, Plantations of trees, woods, &c.

Plantations of trees, &c. greatly embellish and improve estates, as well as ornament the adjacent country; and those formed into woods for timber-trees, prove not only very beneficial to the owners, but may be said to be a public convenience to the country around, to have the opportunity of purchasing wood in the neighbourhood, for the various purposes of buildings, fencings, making all sorts of husbandry implements, as carts, waggons, ploughs, &c. and for innumerable other uses; also for furnishing fuel, a very essential article.

In former ages this island abounded in natural plantations or forests, which spread themselves over the surface of the country, to a very considerable extent, and composed of various sorts of lofty trees of prodigious magnitude, all blended promiscuously together, and all of spontaneous growth. Those vast forests were never planted by any human hand, such only have been employed for ages in cutting them down, for in many places there were such a profusion of useless wood, that large tracts were obliged to be cleared by degrees in order to cultivate the ground for other purposes; which, together with the necessary demands for the timber from time to time for buildings, &c. and that owners of estates, reaping considerable advantage from the sale of their timber, continued by degrees, one generation after another, grubbing up their timber without measure; and few ever planted any in lieu of what they cut down; so that in many parts there is almost a general demolition of woodland, and many considerable estates have scarcely any timber of value left standing.

Every possessor of estates, either of large or moderate extent, will reap great pleasure and advantage in dedicating some share of his land to plantations; for in estates of whatsoever extent, they give grandeur and ornament to the premises, as well as an air of fertility and riches; and those large plantations designed for woods, will, after the first eight or ten years, bring in great profit by a gradual thinning of the underwood, besides leaving a sufficiency of standards to attain full growth: in the mean time the plantations in general will contribute exceedingly to the beauty of the estate; for how delightful it is for travellers to behold the noble plantations in groves, thickets, clumps, &c. variously disposed

in

in parks, and on the boundaries of spacious lawns, and the like places, formed of a great variety of beautiful trees and shrubs, and to see grand avenues of lofty growth, leading to or from a stately mansion, or some main road, or adjacent town; and in the out-grounds to observe the Plantations of woodlands, &c. ranging along the sides of hills, plains, and other grounds occasionally; but in estates how fertile soever the soil, yet it appears naked and barren without a proper share of Plantations; on the other hand, when estates are beautifully diversified with Plantations, the whole may be said to form a sort of pleasure-garden; especially as in the home-ward Plantations we may have commodious walks of gravel and sand, both private, shady, and sheltered, some straight, others disposed in varied winding turns in the serpentine way, bordered with hardy shrubs and flowers, which will afford most agreeable walking at almost any season of the year, as in summer they afford a screen from the vehement heat of the sun, and at other times shelter from boisterous winds, and cold piercing blasts; there may be also here and there recesses or places of retirement, leading by private turnings from the principal walks; with glades or openings of grass-ground in the midst of the most extended parts of the Plantations. See PLEASURE-GARDEN.

No land-holder, therefore, let the extent be almost ever so moderate or considerable, but ought to appropriate a proportionable share to commodious Plantations as soon as possible, either for ornament or emolument, or both, where the extent will admit, as there is hardly any estate that does not afford soil and situation proper for the cultivation of all our hardy trees, &c. and in many places, some estates often furnish particular soils improper for grass and corn, yet adapted to the growth of many sorts of trees, which would form good Plantations.

In short there is hardly any soil so barren and untractable but what will rear a growth of trees and shrubs of some species or other, both for ornament and advantage; and there is scarcely any kind of tree so bad but may be raised to one or other of those purposes: any very poor ground, or such that lie waste, or at a great distance, cannot be better improved than in Plantations; even although a tract of land should be so poor as to rear nothing but a crop of aspen trees, alder, and willows, yet the profits even of these productions will exceed what many may think.

So that there is a great number of examples to encourage, and warrant success in

Plantations, to reward the possessor not only with the pleasure of ornamenting his lands, and that of beholding their growth, but also with profit sufficient to compensate for the tract of land occupied, and labour in planting.

But to many persons, the necessary expense attending the making a Plantation, and knowing that they must wait several years before the trees have made any considerable progress, or can reap any advantage therefrom, often proves an obstacle in attempting the prosecution of that business; but as to the expense of planting, if you raise the plants in your own grounds, it will not prove near so great as many might imagine, especially as a small spot of seminary or nursery-ground will raise plants enough in three or four years to plant a great many acres of land, both ornamental and woodland; and by the latter, the expense of raising and planting them, together with the loss of time in waiting a few years till the plants attain some growth, will be compensated by the first fall or thinning of the underwood, in eight or ten years after planting; and the stools or roots remaining shoot up again, in many of the deciduous kinds, and afford a lopping every eight or ten years, exclusive of the due portion of standards left at proper distances, to attain full growth for timber, as aforesaid.

One particular precaution in making Plantations, is the judicious choice of such trees as are the best adapted to the nature of particular soils, which may vary exceedingly in estates of great extent; however, such trees as we find daily growing by road-sides, hedge-rows, and in any adjacent grounds, are rough sketches of what the land will produce.

As to the sorts of trees and shrubs proper for Plantations in general, there is a vast variety, both of the deciduous and ever-green tribes, that will prosper in the open ground in any common soil. See DECIDUOUS and EVERGREEN TREES, &c.

It is of importance, in making any considerable Plantation, to choose principally young plants, of from about two or three to five or ten feet stature, which always prove more successful than older trees; for although some persons, being in haste to have Plantations as forward as possible in a few years, transplant tall trees, perhaps twelve or fifteen feet high or more, particularly for ornamental Plantations; yet younger growth always take root sooner, and more firmly establish themselves, so as to form considerably the finest Plantations at last, and be of longest duration; for although large trees of fifteen to twenty feet height, especially of the deciduous kind, may with care

be transplanted, so as to grow, and probably thrive tolerably for some years, yet trees more than ten, twelve, or fifteen feet high, often fail, by not rooting firmly like young plants, and after some years standing, have hardly made any shoots, and at last gradually dwindle and perish; therefore large trees should never be employed for Plantations only on particular occasions, where a few may be necessary to form an immediate shade or blind, &c. in some particular place; but for general work, be persuaded to employ chiefly young plants, either of your own raising, or purchased from the nurseries. And for principal timber Plantations in particular, I would choose such plants as are only from about two or three, to five or six feet in height, or eight or ten at most; generally having those of the same Plantation, nearly of equal growth. See PLANTING.

All the different sorts of trees and shrubs proper both for ornamental and timber Plantations, may be had at all the public nurseries moderately reasonable; though persons accommodated with scope of ground, may easily raise many sorts for their own private use, by the methods directed under the respective genera: a small nursery will raise trees and shrubs enough to plant many acres of land. See NURSERY.

Observe, that where Plantations are intended principally for ornament, as great a variety as possible of the different sorts of hardy trees and shrubs should be employed, to afford the greater source of entertainment; and should consist both of lofty and middling trees, down to the humblest shrub. See DECIDUOUS and EVER-GREEN TREES. Disposing the deciduous and ever-green plants principally in separate compartments; sometimes arranging the tree-kinds by themselves, some in running varying Plantations, towards the boundaries of spacious lawns, parks, paddocks, &c. others in avenues, groves, thickets, and clumps, as aforesaid, variously disposed in different parts; and sometimes arranging the trees and shrubs together, in forming shrubberies, wilderness, shady walks, and wood-works; placing the taller growth backward, and the lower in front; bordering the whole with the most beautiful flowering shrubs, and showy ever-greens, especially next the principal walks and lawns; observing to vary the form of all the several compartments, sometimes by moderate sweeps and curves outward and inward, of different dimensions, other parts in long easy bends, varied projections and breaks, so as to diversify the scene in some imitation of natural Plantations. Allow proper distances, in planting, which may be from

five or ten to fifteen or twenty feet; for example, the tall trees designed for continued Plantations may be from ten to fifteen or twenty feet, varying the distance in different parts, according as light and shade, &c. may be proper; and those in groves, may, if open groves, be fifteen or twenty feet distance, and close groves ten or twelve; for thickets, five or six feet, or closer in particular places where a very dark shade, or thick coverture of wood is required; and in clumps of trees, may allow from five or ten to twenty feet between the trees in each clump, varying the distance occasionally, as also the sorts and numbers of trees in each, from two or three, to five, ten, or more; likewise the form of the clumps; some may be triangular, others quadrangular, pentagonal, &c. and some in curves, others in straight lines, to cause the greater variety. And as to the shrubby clumps, and wilderness compartments, where the trees and shrubs are employed promiscuously together, they may be planted from five to ten feet distance; the taller growth being placed backward eight or ten feet asunder, placing the lower plants gradually forward according to their gradation of stature, to the lowest in front, as above observed, at four or five feet distance: and if the trees and shrubs of the plantations in general are disposed somewhat in the quincunx way, they will appear to the greater advantage.

But when designed to form large Plantations into woods, &c. composed principally of forest and timber-trees for profit, particular sorts must be chosen, consisting both of deciduous and ever-green trees. Of the deciduous kinds choosing the oak, elm, ash, beech, chestnut, hornbeam, birch, alder, maple, sycamore, plane-tree, poplar, lime-tree, walnut-tree, wild cherry-tree, mountain-ash, larch-tree, willow-tree, hazel tree, &c. and of the evergreens, the pine-trees, firs, cedar of Lebanon, holly-tree, bay-tree, laurel-tree, yew-tree, ever-green oak, box tree, and some others. See FOREST TREES. The particular description and culture of all of which sorts, deciduous and ever-greens, are exhibited in their proper genera. They are all hardy, and will grow in almost any common soil, rich or poor, and mostly also in dry or moist ground, high or low; allotting, however, particular sorts to very low marshy soils, such as the willow, fallow and osier, poplar, alder, and other aquatics, which will prosper in places that are in a manner covered with water, and are the most proper sorts for the embellishing and improvement of such grounds: all the other sorts will succeed in any

any other more upland places out of water; observing, with respect to disposition; the deciduous and ever-greens should generally be separate, as observed for the ornamental Plantations. But the trees of the same tribe may sometimes be intermixed, and sometimes different sorts in separate divisions or quarters, as oaks in one, elms in another, &c. remarking likewise in timber Plantations, that all the trees should be planted pretty close together, i. e. not more than three, to four or five feet distance, in order that they may mutually draw each other up tall, more expeditiously, and to allow for a gradual thinning, as hereafter directed.

In forming woods, however, or Plantations of timber-trees, the following hints in respect to planting them are proper to be observed.

Let it therefore be remarked, that there are two methods practised in forming Plantations of woodlands; one is by raising the trees from seed at once on the ground where the Plantation is intended to be, especially of the deciduous kind, and is effected by sowing the seed in drills, a yard asunder, and the plants always to remain where raised, thinning them gradually: the other method is by previously raising the plants in a nursery, till two or three feet high, then transplanting them into places allotted them, in rows the above distance, to allow also for gradually thinning.

Either of these two methods may be practised, as shall seem most convenient to the owner; but the former, i. e. raising the plants where they are to remain, that although it may be more expeditious, and that at once to get rid of the troubles of transplantation, yet they will require greater attendance for a few years, till the plants have shot up out of the way of weeds; but on the other hand, the trees always remaining where raised, not disturbed by removal, they probably may make the greater progress. The latter method, however, of raising the trees first in a nursery, is rather the most commonly practised, as being thought the least troublesome and expensive, with regard to the attendance at first of the young growth. However, every one is at liberty to make the experiment as it suits his convenience.

The preparation of the ground for the final reception of the seed or plants of these Plantations, is by deep ploughing and harrowing, upon such ground where the plough can be employed; where this, however, or any other tillage is not practicable, we must decline sowing seed, and use only young plants from the nursery, digging holes, &c. at proper distances, one for the reception of each plant: where, how-

ever, the ground can be tilled, it will prove very advantageous, performing it previously a year before; sowing it with a crop of turneps, or the like: when these come off, well plough and harrow the ground again, for the reception either of the seed or plants the ensuing season.

The most proper season to perform this planting, either by seed or plants, is any time in dry mild weather, from October or November till February, though November and February are rather the most eligible for most kinds of hardy tree seeds: however, where large tracts are to be planted, both methods must be pursued all winter, at every favourable opportunity.

If seed is intended, you must be well provided with seeds of the several deciduous trees in particular, which may be obtained at many of the nurseries and principal seed-shops; then, for its reception, draw furrows or drills one to two or three inches deep; and three or four feet asunder, scatter the seed along the middle of the drills, and cover the earth evenly over them, the depth of the drills or furrows; though sometimes seeds are scattered or sown promiscuously over the general surface, and harrowed into the ground; observing, in general, to place scare-crows and traps to guard against the insults of birds and vermin.

But if designed to form the Plantation with young plants, previously raised in beds in the nursery by the common method, let the following practice be observed: choose always young plants, only from two or three to five or ten feet high; and if very large Plantations are intended, you may, to save time and trouble, take the plants immediately from the seed-bed, when one or two feet high, without giving them any previous transplantation in the nursery; though, where the Plantations are but moderate, it is most eligible to plant them out previously in nursery-rows, to have two or three years growth: but for remarkable large Plantations, this would be a very great trouble and expense. Being, however, furnished with young plants, they are to be planted in rows, three or four feet asunder, as directed for the seed, and one or two feet apart in the lines; they may be planted either by opening small apertures or holes with the spade for each plant; or, if very small plants, it is sometimes performed by making only a slit or crevice with the spade for each plant; and sometimes by opening or forming small trenches the whole length, then one interts the plants whilst another trims in the earth about their roots: some again, in very large tracts, where the situation admits of previous ploughing

ploughing and harrowing to divide and break the earth into small particles, open furrows with a plough, two or more persons being employed in depositing the trees in the furrow, whilst the plough following immediately with another furrow, covers the roots of the plants with the earth thereof, and afterwards treading each row upright. See PLANTING.

The ground where the above Plantations are made should be previously fenced all round with a deep ditch, &c. to guard against the encroachments of cattle.

Whilst these plantations are young, they must have some attendance to destroy weeds, which may be expeditiously executed by hoeing between the rows in dry weather, or occasionally by horse-hoeing; and this care will be needful for two or three years, especially the seedling Plantations, till the trees are advanced out of the reach of weeds; after which no farther trouble will be required until the trees are ready for the first fall or thinning, for poles, faggots, &c.

In eight or ten years growth, they will be of a proper size to begin the first fall by a moderate thinning, which will serve for poles and faggot-wood, to pay towards the expense of planting, &c. but begin lopping only part of the plantation the first year; thinning out the weakest and most unpromising growth first; leaving a sufficiency of the most vigorous plants pretty close, to grow up for larger purposes; the year following begin thinning another part, and so continue an annual thinning-fall till got through the whole Plantation; cutting each fall down near the ground, leaving the stools to shoot out again, especially of the deciduous kinds, and by that time you have made the last fall, the first will have shot up, and ready to be cut again; so the returns of fallings may be contrived to be every six, seven, eight, or ten years, or more, according to the uses the poles or wood are wanted for: and if larger poles, &c. are wanted, the fall may be only once in fourteen, eighteen, or twenty years, still, at every fall, being careful always to leave enough of the most thriving plants for final standards; leaving them pretty close at first, that they may mutually draw each other up in height; but may be thinned every succeeding fall as they increase in bulk and meet, so as to leave a sufficient quantity of the principal trees at proper distances to grow up to timber, which in their turn, as they become fit for the purposes intended, may also be felled according as there may be a demand for them to the most advantage; having young ones from the stools

coming up in proper succession as substitutes, so as the ground may be always occupied.

PLANTING. Planting is the work of inserting plants, seeds, and roots, in the earth, for the purpose of vegetation.

There are various methods of Planting in practice for different sorts of plants, seeds, and roots; such as hole Planting—trench Planting—trenching-in Planting—slit or crevice Planting—holing-in Planting—drill Planting—bedding-in Planting—furrow Planting—dibble Planting—trowel Planting—Planting with balls of earth about the root—Planting in pots, &c. all of which methods of Planting are occasionally used by different practitioners in the several branches of gardening, according as the several methods shall seem most eligible for different or particular sorts of plants. Observing that although most of the different operations are hinted in many different parts of this work in the culture of the various species of each genus, we nevertheless judge it expedient under this head, to exhibit some general directions of the manner each method is performed; together with some hints of the kinds of plants, &c. that are commonly planted by the different methods, which may prove useful to young practitioners in performing the mechanical operations of Planting.

1. *Hole Planting.*—This is the principal method practised in the final Planting of all sorts of trees and shrubs in the full ground, by opening with a spade round holes in the ground, at certain distances, one for the reception of each plant. Each hole should be digged capacious enough to admit all the roots of the tree or shrub freely every way to their full spread, without touching the sides of the hole, and about one spade deep, or a little more or less, or according to the size of the roots, so as, when planted, the uppermost ones may be only about three or four inches below the common surface, or about as low as they were before in the ground, which is discoverable by examining the bottom of the stem of the tree; though in very humid soils, where the water is apt to stand, the holes should rather be shallow, so as the uppermost roots may stand full as high as the general level, or higher if it shall seem necessary, raising the ground about them, especially in winter Planting: let the holes, however, be of a proper width and depth, according to the above rules, loosening the bottom well; and if too deep, it is easily remedied in the time of Planting, by shaking up the tree as you shall see occasion; observing in digging out each hole, to lay

lay the earth in a heap close to the edge, in order to be ready to fill in again: the holes being ready, then having trimmed the roots, &c. of the trees, as hereafter directed, place one tree in the middle of the hole, making all its roots spread equally around; a person holding the plant erect by the stem, whilst another with his spade casts in the earth about the roots, taking particular care to break all large clods, and trim in some of the finest mould first all round about the roots in general, shaking the tree occasionally, to cause the fine soil to fall in close among all the small roots and fibres; at the same time if the tree stands too deep, shake it up gently to the proper height, and having filled in the earth to the top of the hole, tread it gently all round, first round the outside to settle the earth close to the extreme roots, continuing the treading gradually towards the stem, to which tread the mould moderately firm, but no-where too hard, only just to settle the earth, and steady the plant in an upright position: then pare in all the remaining earth evenly round the tree, to the width of the hole, raising it somewhat above the general level of the ground, to allow for settling, giving it also a gentle tread, and finish it off a little hollow at top, basin-like, the better to receive and retain the moisture from rains, and occasional waterings in spring and summer, particularly to the choicer kinds of trees and shrubs.

After performing this Planting, if in winter, or late in spring, it may be of advantage to the choicer kinds of trees and shrubs, to mulch them, i. e. to lay some long mulch at top of all the earth, both to keep out the winter's frost, and prevent the drying winds and drought of spring and summer from penetrating to the roots before the trees are well rooted in their new quarters (see MULCH). But some, instead of mulch, use grass turfs, turned topsy-turvy, especially when planting upon any grass ground, or any out-plantations where turfs of grass can be obtained; or in orchards, where the ground is grass; in which case it may be proper to bank some turfs round the sides and top of each hole, particularly for large trees; which will steady them more effectually, as well as preserve the moisture, if much dry weather should happen the succeeding summer.

The above work, however, of mulching or turving new-planted trees, is not absolutely necessary to our common hardy kinds of fruit-trees, forest-trees, and shrubs; though it may prove beneficial to all sorts, but more particularly to the more tender kinds of wall fruit-

trees, and more delicate sorts of flowering shrubs, choice ever-greens, and some kinds of herbaceous perennials.

2. *Trench Planting.*]—This method is sometimes practised in the nursery-way, in putting out seedling and other small trees and shrubs in rows; is also used for Planting box-edgings; sometimes likewise for Planting small hedge-sets, &c. and always in Planting *Asparagus*; and is performed by opening a long narrow trench with a spade, making one side upright, so place the plants against the upright side, and turn the earth in upon their roots.

If for young seedlings, or other small trees and shrubs, &c. the ground is previously trenched or digged; a line is then set, and with a spade held with its back towards the line, cut out a narrow trench, six or eight inches deep, turning the earth from the line, making the line-side nearly perpendicular; the plants are then inserted in the trench at small distances, close to the upright side, covering in the earth about the roots as you proceed in planting them; and having planted one row, tread the earth evenly all the way along, to settle it close, and fix the plants steady; and so proceed row and row.

But in planting larger trees in the nursery way by *Trench Planting*, a more capacious trench will be requisite; sometimes a trench one or two spades wide, with proportionable depth, according as the roots of the trees shall require; so having opened it all the way along the intended row, proceed to place the trees along the middle of the trench, filling in some earth to each tree as you place it, one person holding it erect whilst another throws in the earth; and having placed one row, trim in all the remaining earth evenly; then tread it closely all the way, to fix the plants steady and perfectly upright.

3. *Trenching-in Planting.*]—This is also sometimes practised in light pliable-working ground, for Planting young trees in the nursery-way, and sometimes in Planting hedge-sets, &c. and is performed by digging along by a line, about one spade wide, and Planting as you go on. The method is this: a line is set, then having the plants ready, and with your spade beginning at one end, and standing side-ways to the line, throw out a spit or two of earth, which forming a small aperture, another person being ready with the plants, he directly deposits one in the opening, whilst the digger proceeds with the digging one spade wide, covers the roots of the plants with the earth of the next spit; and another aperture being

being thereby also formed, place therein another plant; the digger still proceeding, covers its roots, as before, with the next spit of earth; and so on to the end of the row, placing them at about a foot, or fifteen or eighteen inches asunder, according to the size of the plants; observing, when Planting larger trees with more spreading roots, by this method, that instead of digging the trench only one spade wide, two may probably be requisite for the proper reception of the roots; likewise in forming the opening for each plant, make it capacious enough to receive the roots freely, digging the earth over them as above. After having planted one row, either small or large plants, tread the earth evenly along to settle it to the roots, and steady the plants all equally upright.

Another method of *Trenching-in Planting* is sometimes used for Planting some sorts of roots, such as horse-radish-sets, potatoes, &c. performed by common trenching, placing a row of sets in each trench. The horse-radish should be planted in the bottom of the open trench, this being twelve inches depth, turning the earth of the next over them; and the potatoe-sets place about four to five, or six inches deep, and cover them also with the earth of the next trench; but this method of planting potatoes is only practised occasionally. See *COCHLEARIA Armoracia*, and *SOLANUM tuberosum*.

4. *Slit Planting*.]—This method is performed by making slits or crevices with a spade in the ground, at particular distances for the reception of small trees and shrub plants. A slit being made for each plant, which is inserted as you go on; and is practised sometimes in the nursery-way, &c. in putting out rows of small plants, suckers, &c. at from about a foot to eighteen inches or two feet high, and that have but small roots: it is also sometimes practised for final Planting in out-grounds, where very large tracts of forest-trees are intended, and that they are to be planted out at the above sizes, and by the most expeditious and cheapest method of Planting; the following is the method.

A line is set, or a mark made accordingly; then having a quantity of plants ready, for they must be planted as you proceed in making the slits; a man therefore having a good clean spade, he strikes it into the ground with its back close to the line or mark, forms a crevice, taking it out again directly, so as to leave the slit open, gives another stroke at right angles with the first, then the person with the plants inserts one immediately into the second-made crevice, bringing it up close

to the first, and directly press the earth close to the plant with the foot; proceed in the same manner to insert another plant; and so on till all is finished: which is a very expeditious way of putting out small plants, for any considerable plantation. See *PLANTATIONS*.

A man and a boy by this method will plant ten or fifteen hundred, or more, in a day.

5. *Holing-in Planting*.]—This is sometimes used in the nursery-way in light loose ground; also sometimes in Planting potatoes, &c. in pliable soils.

The ground being previously digged or trenched, and a line placed, they proceed thus: a person with his spade takes out a small spit of earth, to form a little aperture, in which another person directly deposits a plant, &c. the digger at the same time taking another spit at a little distance, turns the earth thereof into the first hole over the roots; placing directly another plant in this second opening, the digger covers it with the earth of a third, and so on to the end of the row.

6. *Drill Planting*.]—This is by drawing drills with an hoe from two to four or five inches deep, for the reception of seeds and roots, and is a commodious method of Planting many sorts of large seeds, such as walnuts, chestnuts, and the like; sometimes also broad beans, but always for kidney-beans, and peas; likewise for Planting many sorts of bulbous roots, when to be deposited in beds by themselves.

The drills for all of which purposes should be drawn with a common hoe, two or three inches deep (see *HOE* and *DRILL-SOWING*): though, for large kinds of bulbous roots, four or five inches depth will be requisite, covering in the seeds and roots with the earth, always the depth of the drills.

7. *Bedding-in Planting*.]—This is frequently practised for Planting the choicer kinds of flowering bulbs, such as *Hyacinths*, &c. also for larger seeds of trees, as acorns, large nuts, and other larger kinds of seeds, stones, and kernels, and is performed by drawing the earth from off the tops of the beds some inches depth, then planting the seeds or roots, and covering them over with the earth, drawn off for that purpose. The following is the particular method.

The ground must be previously digged or trenched, raked, and formed into beds three or four feet wide, with alleys between bed and bed; then with a rake or spade trim the earth evenly from off the top of the bed into the alleys, from two or three to four inches deep for bulbous roots, and for seeds, one or two, according to what they are, and their

size ; then, if for bulbous roots, draw lines along the surface of the bed, nine inches distance, place the roots bottom downward, along the lines, six or eight inches apart, thrusting the bottom into the earth : but, if seeds, they may be scattered promiscuously ; and having thus planted one bed, then with the spade, let the earth that was drawn off into the alley, be spread evenly upon the bed again over the roots or seed, &c. being careful that they are covered all equally the above depth, and rake the surface smooth.

This method is in occasional practice, in planting several kinds of the larger prime sorts of bulbous-rooted flowers in beds.

The nurserymen also practise this method in Planting many of their larger seeds, nuts, &c.

Another method of *Bedding-in Planting*, occasionally practised in some parts, particularly for planting potatoes in low wet grounds, is by dividing the ground into beds, four feet wide, with alleys two or three feet wide between bed and bed ; then digging the beds, place the potatoe-sets in three rows along each bed, a foot asunder in the row ; this done, dig the alleys one spade, casting the soil upon the beds over the sets, so as to cover them four or five inches deep : thus, if the ground is very wet, the alleys will drain the moisture from the beds, so as sometimes to afford very great crops.

Sometimes, in the above method, it is practised in low moist grounds, that are in grass sward ; so marking out beds as above, and without digging the ground, placing the potatoe sets immediately upon the sward, then digging the alleys, first turn up the sward, and place this topsy-turvy upon the bed, sward to sward over the sets ; and then finish by applying more earth from the alleys, to cover in the sets, the proper depth of four or five inches. This method, in some counties, is called planting in lazy-beds, because the ground is not digged ; and often is productive of great crops of large potatoes.

8. *Furrow Planting.*]—This is by drawing furrows with a plough, and depositing sets or plants in the furrow, covering them in also with the plough ; and is sometimes practised for planting potatoe-sets in fields, and has been been practised in planting young trees for large tracts of forest-tree plantations, where the cheapest and most expeditious method is required ; but this method can be practised only in a light pliable ground, and is performed thus ; a furrow being drawn, one or two persons are employed in placing the sets or plants in the furrow, whilst the plough

following immediately with another furrow, turns the earth thereof in upon the roots of the plants.

We do not, however, recommend this method of Planting for general culture ; only persons that have scope of ground may try the experiment.

9. *Dibble Planting.*] This is the most commodious method for Planting most sorts of fibrous-rooted seedling plants, particularly all the herbaceous tribe ; also for planting slips, off-sets, and cuttings both of herbaceous and shrubby kinds ; likewise for some kinds of seeds and roots, such as broad-beans, potatoe-sets, Jerusalem artichokes, and horse-radish-sets, with numerous sorts of bulbous roots, &c. and is expeditiously performed with a dibble or setting-stick, therewith making a narrow hole in the earth for each plant, inserting one in each hole, always as you go on ; observe the following hints.

Having a dibble or setting-stick, it is used by thrusting it into the earth in a perpendicular descent, in depth as the particular plants, &c. may require ; directly inserting the plant, seed, or set, according as each hole is made, closing the hole immediately by a stroke of the dibble. So proceed dibbling the holes and Planting as you go on, at particular distances and depths, according to the nature of the Plants, &c. as exhibited in their respective genera : observing, in setting any kind of plants, slips, cuttings, and the like, having long shanks or stems, it is proper to make holes a proportionable depth, to admit them some considerable way in the ground ; for example, cabbage-plants, favoys, &c. should be planted down to their leaves ; slips and cuttings should be inserted two parts of three, at least, in the ground ; being particularly careful in dibbling-in all sorts of plants, to close the holes well in every part about the roots, by striking the dibble slantways into the ground, so as to strike the mould first firmly up to the root and fibres, at the same time bringing it close to the stem ; for in dibble Planting, many inadvertently only strike the earth about the neck of the plant, and the lower part of the hole is often left hollow about the roots ; but by striking the dibble first at the root-part, you fix the plant effectually, then a stroke of the dibble at the top of the ground finishes, by closing up every part of the aperture. In this manner continue planting and finishing each hole as you go on, perfectly close, that neither the sun, air, nor penetrating winds can enter, this being of much importance ; but often disregarded, as we may often see the holes that are necessarily made in fixing the plants, left

open, which may be easily closed as they go on, with the utmost facility, each hole at the insertion of its plant, at one stroke of the dibble, as above said.

For the sorts of dibble, and some other particulars in dibble Planting, see DIBBLE.

10. *Trowel Planting.*—This is performed with a garden-trowel, which being made hollow like a scoop, is useful in transplanting many sorts of young fibrous-rooted plants with balls of earth about their roots, so as they may not feel their removal. See *Planting with Balls of earth, &c.*

The trowel is employed both in taking up the Plants, and planting them; observing the plants having been previously pricked out from the seed-bed or elsewhere, at certain distances, and having been of some standing for their roots to have got good hold of the ground, they, by aid of the trowel, may be readily taken up, each with a good ball of earth about all its roots; and then with the trowel making a hole for its reception in the allotted place, insert it in the hole with the whole ball of earth entire, earthing it in properly, and give a little water: thus the plants will scarcely feel their removal, and often continue their growth without loss of time, as if they had not been transplanted at all.

11. *Planting with Balls of Earth about the Roots.*—This is the removing a plant with a large ball of earth about its roots, so as the plant by having its roots firmly attached to the surrounding ball of earth, it still, during the operation, continues its growing-state, as it were, without receiving any, or but very little check from its removal; and is often practised more particularly to the more delicate and choicer kinds of exotics, both trees, shrubs, and herbaceous plants: and is occasionally practised to many of the fibrous-rooted, flowery plants, both annuals, perennials, and biennials, even in their advanced growth and flowering state, when particularly wanted to supply any deficient compartments; though not so eligibly in bulbous-rooted kinds: likewise, when intended to remove any sort of tree or plant out of the proper Planting season, as very late in spring, or in summer, it is eligible to transplant it with a good ball of earth to preserve it more certainly in a state of growth. Observing, some trees and shrubs are more difficult to remove with a ball than most kinds of herbaceous fibrous-rooted plants, though many of the tree and shrub kinds, having very fibry roots, will also readily rise with good balls.

However, in transplanting any of the tree

and shrub kind by this method, if they grow in the full ground, we must be careful to begin to open a trench with a spade at some considerable distance from and round the stem, perhaps a foot, or two or three, according to the size of the tree and expansion of the roots, digging a sort of trench all round, a spade or two wide, or more if large trees, and in depth below all the roots; all the time having great care not to disturb the ball or mass of earth between the stem and trench, but preserve it as entire as possible; for if we loosen this part about the roots, the intended effect of still preserving the tree in a growing state, will fail. Having, however, dug down below the roots all round, you must then undermine the ball on every side, below all the roots, till the whole ball is detached from the main ground; then remove the tree with its entire ball carefully to its destined place, having a capacious hole ready opened, if for the full ground; or if for pots, have such that are some inches wider than the ball, to admit of a portion of fresh earth all round; in either method, however, plant the tree or shrub with its whole ball entire, and fill in the earth evenly all round it, pressing it gently down, and give a moderate watering round the outside, to settle the earth close to every side of the ball; then place a stake for support.

But when trees or shrubs, with balls to their roots, are intended to be sent to any considerable distance, they should be placed singly in osier baskets, in order to preserve the cohesion of the ball; having a basket for each tree; the baskets to be of an upright make, in width and depth in proportion to the ball, with two handles at top, especially if large baskets; and all generally worked rather open at the sides, because sometimes the basket and all is placed in the ground, when the plant cannot be readily removed without danger of breaking the ball of earth; so that the sides being a little open, the roots may have liberty to shoot out; most basket-makers know how to make them. Having, however, the baskets, put a little good earth in the bottom of each, then place the plant with its ball, fixing it properly in an upright position, observing likewise, in their carriage to the allotted places, to preserve them in an upright posture. In Planting them, if they cannot be readily moved out of the baskets without disturbing the ball of earth, plant basket and all, as aforesaid; cut it here and there in the sides, and throw some fine mould close all round so as to join with that of the ball, and give a watering to settle it more effectually close: the roots and fibres will readily make their way

way through the sides of the basket; besides the baskets will soon rot, without proving any obstruction to the growth of the plants.

But sometimes, instead of baskets, smaller young trees and other plants with balls, intended to be sent to any distance, are placed in pots, one plant in a pot, and if they are to be placed in the full ground, turn each out of the pot with the ball entire; or, if it seemingly will not readily quit the pot without separating, break the pot, to preserve the cohesion of the ball.

Many sorts of herbaceous fibrous-rooted plants, however, may readily be taken up with balls with very little trouble, by reason of their numerous fibres, to which the earth closely adheres in a compact lump all round the root; and with a spade or trowel may often be taken up with balls with the utmost facility, and in some sorts the earth of the ball will cling so close as to admit of being sent to some distance without being potted; others again, being less fibrous, require the assistance of a pot to preserve the ball entire till arrived at its place of destination.

And as to trees and other plants that have generally grown in pots, the transplanting them with balls is very easy, for if they have been of some standing in the pot, the whole earth thereof will, by means of the numerous fibres, be formed into one compact lump, as it were, that it will readily come out entire and firm; or to such as do not so easily quit the pot, thrust a long blade of a knife, or some other thin instrument, down between the outside of the ball and pot all round, it will then readily come out, either in drawing by the stem of the plant, or by striking the edge of the pot with something; or, if small plants, may turn the pot mouth downward, and strike the edge gently against any thing of firm substance: observe, in replanting those potted plants, that if the sides of the ball of earth is much matted with the fibres of the root, it is proper to pare off the grossest part, together with a little of the old earth, especially if to be planted in pots again; then planting it in a pot a size larger than before, filling up all round with fresh mould, and finish with a moderate watering. See *Planting in pots*, below.

The advantage in Planting with balls, either in the full ground, or in pots, is, the root of the plant being inclosed in the ball of earth, continues all the while drawing nourishment, and the growth of the plant is not retarded in waiting till it has taken fresh root in its new place, which may be of advantage

in many cases, particularly all tender plants, some of our choicest ever-greens, and many kinds of herbaceous flower plants.

But Planting with balls is not recommended for general practice, for in all the hardy tree and shrub kind it would be needless as well as very expensive and troublesome, and in which is only necessary on particular occasions, as before explained.

12. *Planting in pots.*]—This is practised to all tender exotics, in order for moving them to shelter occasionally, such as all kinds of green-house and hot-house plants; and it is likewise practised for many sorts of hardy flowering-plants, for the convenience of moving them occasionally to adorn any particular compartments; and for the convenience of moving some curious sorts when in flower to occasional shelter from the sun's rays, and excessive rains, in order to preserve their beauty and prolong the time of their bloom; such as the fine auriculas, carnations, &c.

In Planting in pots, it is highly requisite carefully to adapt the sizes to the size and nature of the different plants intended to be potted; if small plants, begin first with small pots, one plant only to each pot, especially if to remain; but according as the different plants advance in growth, shift them into pots one or two sizes larger, which may be requisite to many sorts once a year, to others once in two or three years, according to the nature and increased growth of the respective plants: though to some sort of tender annuals it may be necessary once or twice in the course of a season, when forwarding them by hot-beds: all of which is generally particularised in the culture of the various sorts. And by thus beginning first with small pots adapted to the size of the plants, it is not only cheaper and more commodious for moving and stowing them in different parts occasionally, till they gradually advance in growth, but by thus shifting them into pots a size larger, it admits of adding fresh earth, which proves highly beneficial to their growth.

Garden pots for the reception of plants are of several regular sizes, from two to sixty in a cast, so are distinguished at the pot-houses accordingly, as twos, sixes, twelves, sixteens, twenty-fours, thirty-twos, forty-eights, sixties, or sixty-fours, &c. in each cast; each pot having one or more apertures at bottom to discharge the superfluous moisture. They are sold by the potters at so much per cast, large and small, all of a price; those of only two in a cast the same as those of sixty; and from two shillings to half a crown or three shillings per cast is the general price. See *Pots*.

But

But with respect to the particular method of Planting in pots in general, the following particulars are necessary to be observed.

Having the pots and mould ready for the reception of the intended plants, observe, previous to planting them, to place some pieces of tile, potshards, or oyster-shell, &c. over each hole at the bottom of the pots, both to prevent the holes being clogged and stopped with the earth, and the earth from being washed out with occasional watering; also to prevent the roots of the plants getting out; then having secured the holes, put some earth in the bottom of each pot, from two or three to five or six inches or more in depth, according to the size of the pot, and that of the roots of the plant; this done, insert the plant in the middle of the pot upon the earth, in an upright position, making its roots, if without a ball of earth, spread equally every way; directly adding a quantity of fine mould about all the roots and fibres, shaking the pot to cause the earth to settle close thereto; at the same time, if the root stand too low, shake it gently up as you shall see occasion; and, having filled the pot with earth, press it gently all round with the hand, to settle it moderately firm in every part, and to steady the upright posture of the plant; raising the earth however within about half an inch, or less, of the top of the pot, it will settle lower; for some void space at top is necessary to receive waterings occasionally: as soon as the plant is thus potted, give directly a moderate watering to settle the earth more effectually close about all the roots, and promote their rooting more expeditiously in the new earth; repeating the waterings both before and after they have taken root, as occasion requires.

In transplanting plants in pots from one pot to another, they may for the general be shifted with the whole ball of earth contained in the pot about their roots entire, so as to preserve the plant all along in its growing state, as scarcely to shrink or retard its growth by the operation of removal; which to plants growing singly in pots, and of some standing, whose roots and fibres have established themselves firmly in the earth, they will readily remove out of the pots with the entire ball in one compact lump, surrounding all the roots and fibres, retaining their growing state by still drawing nourishment from the surrounding ball of earth.

The method of removing them out of the pots with balls, is generally easily effected to most potted plants. Sometimes, in small plants, it is performed by turning the pot mouth downwards, and striking the edge

against something; the plant will come clean out, with the whole ball about all the roots entire. Or, sometimes plants that are very well rooted, and its numerous fibres surround the outsides of the ball, it will often readily quit the pot by drawing it by the stem; or at least, if raised a little from the ground, and strike the edge of the pot or tub, the ball will often come out whole and compact. But if by either of the above methods the ball will not readily quit the pot, thrust some narrow thin instrument of iron, such as a long blade of a knife, &c. down round the sides, as already hinted, the ball will then come out with much greater facility. Sometimes, however, large plants of some years standing unshifted, will by their increased roots have so wedged themselves, as to require the pot to be broken in order to preserve the ball. And sometimes large plants in heavy tubs, such as American alocs, orange and lemon-trees, require to be flung by the stems upon some temporary erection, to draw them out of the tubs with the ball entire.

Having, however, removed any plant with its ball for replanting in a larger pot, observe, preparatory to Planting it, that as sometimes the numerous fibres will have so surrounded the outsides of the ball, as to form a sort of mat all around, it is proper to trim the grossest of them off close with a knife, all round the sides and bottom; together with some of the outward old earth of the ball; then having the pots of proper sizes, larger than the former ones, and having secured the holes at bottom, and put in some fresh compost, deposit the plant with its entire ball in the pot, minding that it stands erect, and just the proper depth; and fill up the interstice all round the ball with more fresh mould, pressing it down round the sides with your hands or a stick, adding more mould gradually; and raise the whole about an inch or two over the crown of the ball, and finish with a moderate watering to settle the new earth close in every part.

But in transplanting from one pot to another with balls, is in some cases to be avoided; for example, if a plant appears diseased or in a bad state of growth, it is most probable the fault is in the root or earth; therefore, in transplantation, it is eligible to shake the whole entirely out of the earth, in order to examine its roots, and trim off all decayed and other bad parts; then, having a fresh pot, and some entire new compost, replant your tree, &c. therein, as already directed.

In potting plants from the full ground, or beds of earth, &c. if they have been previously pricked out certain distances, and have stood

stood long enough to fix their roots firmly, many sorts may also be potted with balls, particularly most of the herbaceous, fibrous-rooted kinds, and many of the shrubby tribe, by taking them up carefully with the garden-trowel, or with a spade, as may be most convenient, according to the size of the plants; and, if necessary, pare the balls round to fit the pot, planting them as above.

Potting of seedling plants, however, immediately from seed-beds, that, by their growing so close together, rarely admit of potting with balls to their roots; so that when intended to pot such, they must be drawn out of the earth with the root as entire as possible, and potted separately in small pots, shifting them occasionally into larger, as before observed.

Sometimes in Pot-Planting, we, to save room, and for other convenient occasions, plant several small plants in each pot, especially when designed as nursery-pots, to receive either small seedlings, off-sets, slips, cuttings, &c. just to strike them, and forward them a little at first, either in hot-beds, or for removing them to different situations, such as occasional shade, shelter, &c. and in which some sorts of small slips and cuttings are sometimes planted many together, in one or more wide pots, especially where large supplies of some particular sorts are required, such as myrtle cuttings and pipings of pinks, &c. planted sometimes to the amount of a hundred or two of these small sets in one capacious pot or wide store pan, so called by the myrtle gardeners about London, who raise amazing quantities annually for the markets (see POTS); however, this is not mentioned as generally necessary, only for occasional practice, where large supplies are raised on particular requests; so that observing, in the general way of planting a few or many together in pots, either small seedlings, slips, cuttings, off-sets, &c. when they are a little forwarded, or properly rooted, and shoot a little at top, they should be all potted off separate, in proper time, each in a separate pot, especially if plants of any duration; giving them small pots at first, and as they increase in size, shift them into larger pots accordingly.

When any large growing plants, such as orange and lemon-trees, or any other kinds, are become too large for pots, they should be shifted into tubs; these tubs should be made of full inch-thick staves, and adapted to the size of the respective plants; each tub well hooped with iron, and with two hooked or bow iron handles at top, by which to move them, either by hand, or, when very large tubs, to receive poles between two men for moving the

plants where occasionally wanted; having holes at the bottom of the tubs to discharge the superfluous moisture, as observed for the pots; placing some stones, &c. to prevent the holes being clogged with the earth; the method of planting and transplanting being the same as in Pot-Planting.

In the culture of all plants in pots it is proper to stir the surface of the earth now and then an inch or two deep, to prevent its binding or becoming mossy, and to promote the growth and health of the plants: likewise to such as are not shifted annually, it is also proper to add a little fresh mould in spring and autumn, previously stirring the old at top as above, and a little way round the sides; then taking out the loosened old, replace it with an equal portion of fresh compost, finishing with a moderate watering; this will prove a very beneficial dressing to the plants, and give an air of neatness, and a more lively appearance to the whole.

In all plants in pots or tubs great care is requisite in supplying them with water, which must be observed to most sorts the year round, but more particularly in summer; for the earth containing each plant being limited to the compass of a small pot or tub, it dries very fast in hot weather, so must be often moistened accordingly; which to some plants may be requisite three or four times a week in the summer season; and to some sorts in small pots every day, or even twice a day in very dry scorching weather: but as the autumn and cold season advances, give the waterings more seldom and sparingly; and in winter, plants that are exposed abroad in pots rarely require any water at all; but those in the green house or other place of shelter must be watered occasionally also during the winter; some probably once a week, or ten or twelve days, such as all the woody kinds; others but once a fortnight or month, particularly the succulent kinds; and some of the more tender very succulent sorts will require very little moisture at any time, but especially in winter; being careful, however, always to water all sorts in pots moderately in this season of the year, and, if possible, principally in temperate mild weather, and in sunny days, and give very little in frosty weather: at no time give too much to render the earth miry wet in winter, which would prove the destruction of most tender exotics; all that is necessary is to preserve the earth very moderately moist. Potted plants in hot-houses, however, will require more frequent supplies of water in winter than any other plants in pots.

To potted plants in general we must occasionally

sionally examine that the holes at bottom are sufficiently open to discharge the superfluous moisture from occasional waterings, &c. for if these are clogged up, and detain the moisture, the consequence will be bad, for it will rot the fibres, and even the main root, and soon bring on the decay of the whole plant; however, by turning up the bottom of the pot, the holes, if stopped, are easily cleared with the end of a stick or other instrument.

Other general Observations of Tree Planting in particular.

Having above given general intimation of the several different methods of performing the mechanical operation of Planting, we will next give some hints with respect to the preparation of plants previous to Planting, particularly tree Planting, which being of the greatest importance, shall first exhibit some general remarks on that head.

In the first place observe, with respect to Planting trees of all kinds, that it is of considerable importance to give them their final transplantation whilst they are young, i. e. from about two or three to six or seven years old, and in standards when of from about three or four to six, eight, or ten feet stature; especially for all kinds of fruit-trees and forest-trees for long duration; as at the above ages and statures they will establish themselves sooner and more firmly in the ground than trees of more considerable age and growth, and in the end make the most prosperous and durable trees.

Note, however, trees ten, fifteen, or twenty feet high are occasionally transplanted, especially some deciduous forest and ornamental trees in particular cases; such as in forming ornamental plantations, where persons are in haste to have any part thereof appear conspicuous as soon as possible, or to afford immediate shade or shelter, or to form blinds to any particular compartment.

But there are many sorts of trees and shrubs of eight, ten, or twelve feet stature, both deciduous and evergreens, that may be readily transplanted with tolerable success; as, if taken up with a good spread of roots, they will take root freely, and often assume a good free growth; those sizes, however, exceeding eight or ten feet, are more proper to be employed occasionally in ornamental plantations, to effect immediate show, than for any general plantations of fruit and forest-trees.

And as to trees above twelve or fifteen feet high, although they may on particular occasions in ornamental works be transplanted, by care in removing them with a good compass of roots, or sometimes with balls, as may oc-

asionally be practised to such in particular that happen to grow on grass ground; and are not to be removed to any great distance; yet the transplantation of these large trees should not be attempted for any general purpose, but only in cases where a few trees may be required to form an immediate show or prevent shade, shelter, or blind, as aforesaid, in some particular compartments, till younger trees grow up; for they rarely establish their roots like younger growth, but often assume a stunted habit, and frequently after a few years dwindle gradually off; so that when such are employed, it is proper to have some younger trees near them to be advancing as substitutes if any of the others should fail.

However, for any general plantations, either of fruit-trees, forest-trees, or ornamental trees and shrubs, let them be composed principally of young plants from about three or four, to six, eight, or ten feet height, as these sizes will be found to root more expeditiously and effectually, as well as shoot more freely at top than large transplanted trees, and sooner attain a state of perfection.

In fruit-trees, however, we may observe that common standards being generally trained with tall stems of four, five, or six feet, in which, if with heads branching out above, at these heights, and of two, three, to four or five years growth, they, in the whole, may probably be seven, eight, or ten feet high accordingly, and sometimes in those with three or four years' old heads, will have commenced bearers in a small production of their respective fruit; and, at which ages, sizes, and state of growth, are very eligible for Planting on most occasions, in gardens and orchards, especially when desirous of having trees commencing immediate bearers, as it were, probably in some, the first or second year of planting in small portions, as above intimated:—though, for a general plantation, trees with one, two, or three year-old heads are exceedingly proper.

Likewise in fruit-trees, of those trained in the dwarf order, both as dwarf standards, and for general wall trees and espaliers, almost generally with short stems and low branching heads, of one or two, to five or six years old, and of so many feet in extent of growth, are also of eligible sizes for Planting; and, in some sorts, those of two or three, to four or five years' growth have become bearers, as hinted of the common standards, and are proper to Plant where particularly required to have trees in bearing as soon as possible, especially as in the public nurseries proper trees of the above, trained in regular order

order for immediate bearers may be obtained; however, those with heads, of only one or two years' old, are also particularly eligible to plant for a general plantation, and so train them accordingly, from the beginning, under your care, for their respective different purposes, above mentioned: but wall trees are also sometimes trained with tall stems, as half or full standards, three, four, or five feet, branching out at that height, and the branches trained in the wall-tree manner, designed to cover the upper part of high walls, &c. and for which occasion they are also proper for Planting when of the abovesaid stages of growth.

But forest-trees in particular, that are intended principally for timber plantations, it is most eligible to plant them out finally when from two or three, to four, five, or ten feet high at most, that they may establish their roots firmly in their minor state, which is of considerable importance in promoting a flourishing and durable growth, so as they may sooner attain a great stature and magnitude.

In the work of Planting trees, &c. the choice of them in the nursery for furnishing the respective plantations should be particularly attended to; that, whether in your own ground, or in the public nurseries, always chuse the straightest, most vigorous, and thriving plants of the respective kinds.

Likewise in preparing for Planting, observe that in taking up the trees for that purpose out of the nursery, the greatest care is necessary in raising them with as great a spread of roots as possible; which, however, is often ill attended to, especially when large orders of plants are to be drawn in a hurry. The ground about the trees should always be opened with the spade widely round the roots, and deep enough to get to their bottom without hacking and cutting them with the spade, but so as to raise each plant with all its roots as entire as possible, for this is of much importance in the future prosperity of the trees and shrubs.

After having taken up the trees out of the nursery, &c. it is of great moment to have them replanted as soon as possible in the places allotted for them; for, although by properly covering the roots with litter, or, if sent to any considerable distance, that by tying them in bundles, and packing them up with plenty of straw about the roots, and afterwards closely matted round, they may be preserved in tolerable good condition a fortnight or longer; yet, where it is possible to plant them the same day, or in a day or two after, before the small fibres are shrunk or dried, it will be of much advantage in the first growth of the

trees; observing, however, after trees or shrubs are taken up in order for Planting, and that either the ground not being ready, or any other hindrance prevents their being planted soon after, they should as soon as possible be deposited in a trench of earth by the roots, which gardeners call *laying them by the heels*, and so take them out as they are to be planted.

Next, with respect to preparing the trees for planting, after being drawn out of the nursery.

In the first place with regard to the root;—this part must have an occasional trimming, not however to retrench or reduce any but the maimed and decayed parts; therefore previous to planting each tree, examine the root, and cut out all such parts as have been broken or damaged in taking up, and any casual decayed parts and other blemishes, being careful to leave all the sound roots every where entire; leaving also all the small fibres that are fresh and vigorous, and only trim off such as are become dry and mouldy; suffering all the main roots to remain, mostly at full length, except just to tip off their ends a little on the under side, sloping outward; and reduce any very long stragglers, and shorten long perpendicular tap-roots, more particularly of fruit-trees, to prevent their running down into a bad soil, and to promote their throwing out others horizontally into the good earth.

Some persons, however, make it a rule to retrench or thin the roots of transplanted trees very much, and shorten them also very considerably; but it will be found that trees planted with all their sound roots will be the most prosperous in growth; for the reducing the roots with too much severity, greatly weakens the tree; and, as every one must know, that all plants and trees receive invigoration, and their most essential nourishment from the roots and fibres, so that it is certainly an act of high imprudence to destroy the roots of any tree that are good and sound in every respect, and wait a considerable time for new ones, when we are actually possessed of a sufficiency that are good; it is therefore consequently the safest way to leave all the good roots, and only retrench blemished and decayed ones, as already observed.

And with regard to the preparation of the head of the trees previous to Planting, the principal care is to trim off straggling shoots and branches from the stem, leaving the head for the generality entire, only just retrenching very irregular branches, and shortening any very long stragglers; and always suffer the main or leading top shoot to remain at length, to aspire in height as fast as possible, particularly

larly forest-trees, and all others that we design shall grow to a lofty stature, for in this consists their beauty and worth.

With respect to fruit-trees, however, sometimes a more accurate regulation of the head preparatory to Planting may be requisite, more particularly dwarfs for espaliers and walls. For example, if the fruit-tree is taken from the nursery at one year old from the budding and grafting, and with its first shoot from budding and grafting entire, this first shoot must necessarily be shortened or headed down to force out lateral wood below, to furnish the bottom properly; but observing this heading down is not necessary at the time of Planting, and is most eligible to plant the tree with its said first head entire, to remain till spring, until the tree has taken fresh root and begins to shoot; for the head remaining will greatly promote the rooting: then in March or beginning of April, the tree having taken root, as you will observe by its effort for shooting at top, head it down within half a foot, or five or six eyes of the insertion of the bud or graft, and the shoot so headed will throw out, from its remaining lower eyes, several lateral branches the ensuing summer.

On the other hand, if the fruit-tree is two, three, or more years old from the budding and grafting, and the first shoots were headed down in the nursery at the proper time, and that in consequence thereof, produced several lateral shoots, to give the head its first formation; or even if the tree has stood long enough to form a good full head, it is proper in both cases to plant it with its whole head entire; only retrenching any irregular branch, or any very luxuriant shoot; or thin out the worst of such as are evidently too close or crowded, leaving however all the regular branches, suffering them to remain also at full length, except just to reduce any very long rambler consistent with the extent of the other branches.

For in new Planting trees it is very improper to retrench the branches too severely, and cut all that remains short, as is very often practised in transplantation, on a supposition to strengthen their roots, which however has often the contrary effect; for the branches and leaves imbibe the refreshing influence of the air, &c. which being conveyed to the roots, proves nutritive, and contributes exceedingly towards vegetation, and consequently promotes the rooting afresh more expeditiously and effectually; and until this is well effected, the tree will make but little progress in its top growth.

Besides, by a severe retrenching, and a ge-

neral shortening, of fruit-trees in particular, you would thereby, in most sorts, cut off the very parts where fruit would have been soon first produced; and probably cost the tree two or three years growth to furnish new branches equal to those cut away, as well as retard its bearing in proportion. And it often happens by such a general amputation of the branches of all new planted trees at the time of Planting, they, for want of branches to collect vegetative nourishment, either make very little progress in shooting for two or three years after; or sometimes, when they do shoot, throw out a profusion of unnecessary wood from the remaining eyes or buds.

For, as we formerly observed, that although shortening the branches of fruit-trees in particular is sometimes proper in young trees of one or two years old from budding or grafting, to force out a supply of lateral wood to furnish the first regular formation of the head, more particularly dwarfs for espaliers and walls, yet if you are about to transplant the tree, and the operation of heading being necessary as above, it ought not to be done till after the tree is planted, and has begun to take root and make an effort for shooting in March or beginning of April; for when headed down at Planting, they, for want of the head, rarely either strike root or shoot at top so freely.

Therefore if young fruit-trees at Planting, whether dwarfs or standards, are furnished with five or six or more good regular principal branches, of one, two, or more years' growth, it would be a great pity to retrench any part of them, and disfigure the tree, either on the consideration of strengthening it, or to force out more branches; particularly apples, pears, plums, and cherries, which should at all times be but sparingly shortened; and since several good branches being already obtained in the proper parts to give the head its first regular form, they will in their turn readily furnish more; and if there is a vacancy in any part, it will be better to endeavour to fill it by stopping some of the young shoots produced the summer after Planting, by either pinching or pruning them in May or June the same year to three or four eyes, or cut them down to that length in winter or spring following.—Some fruit-trees, however, such as peaches, nectarines, &c. against walls, require most of their young shoots to be shortened annually.—But for more particulars of all the sorts, see their respective genera.

Standard fruit-trees, when designed they shall form spreading heads, branching out near the top of the stem regularly all around, they,

they, if grafted high in the stem, must, like the dwarfs, have also the first shoot from the budding or grafting, headed down to four or five eyes, to force out a set of lateral branches near the insertion of the bud or graft; or, if the grafting and budding was performed near the ground, and the first shoot trained to a proper height for a stem, and if required to have a spreading head, it may also be topped at the desired height, to throw out a supply of lateral branches each way, near the head of the stem, as above said; but sometimes, when the first heading, in either of the above methods, does not furnish a proper supply of branches to give the head its first proper formation, a second heading is occasionally performed the next spring, upon the shoots produced from the first.

Observing, however, that all the above works of heading standard fruit-trees, in particular, should always be performed in the nursery, a year or two, or more, previous to final transplantation into the garden or orchard, that the trees may be furnished with several regular branches to form a head, at the time of Planting; and, as before observed, it is proper to plant it with all its said head entire; except reducing such irregular growths as already mentioned, so leaving all the regular branches at their length, suffering the whole to shoot up, and branch away in their own way; and they will annually advance in length, and gradually furnish laterals to fill and spread the head proportionably.

But remarking particularly, that standard-fruit-trees, having been previously headed in the nursery a year or two or more before, and in consequence are now furnished with several regular branches of one, two, three, or more years growth, they should on no consideration be either retrenched or shortened, neither at planting nor afterwards, for the reasons before given; and also that as most fruit-trees begin to blossom and bear first towards the upper parts of the branches, more particularly apples, pears, plums, and cherries, which always produce their fruit upon short shoots called *spurs* or *fruit-buds*, that mostly rise first towards the ends of the branches; but which in this shortening would all be cut away, and retard the bearing two or three years, besides all the other disadvantages above mentioned.

But when standard fruit-trees are required to aspire more considerably in height, rather somewhat pyramidal, or conic ways, than horizontally, no heading at all need be practised, neither in the nursery, nor at the time of final planting, but the whole, quite

from the budding or grafting, suffered to remain entire, and shoot up, and branch according to nature; and they will naturally form a regular head, some sorts hemispherically, others more of the pyramidal, or conic figure.

As to forest trees, &c. their preparation, previous to Planting, after being drawn out of the nursery, is only to trim the blemished roots, as before observed, and prune off all branches from the lower part of the stem, cutting the lower ones close, the others to two, three, or four inches, particularly the deciduous kinds, leaving the head always tolerably branchy, and mostly entire; not to trim away all the branches to one leading shoot only, as is often practised, but leave a proportionable share of the upper more erect branches, to form some tolerable head, and only just retrenching the lower stragglers, very long rambling luxurians, and very irregular growths, to preserve a little regularity; being particularly careful to leave always the top or leading shoot perfectly entire, unless it is decayed, or is very crooked, bending much downwards, &c. in which cases, if any straight shoot is conveniently situated, the crooked part may be retrenched down to the straight shoot, which leave entire to run up in height, as without a leader a tree can never aspire to any considerable stature; for the leader, by its annual erect shoot, gradually increases the length of the stem, and, as it advances, sends out a supply of laterals to furnish the head, branching and spreading in proportion, according to the natural growth of the respective sorts.

But in planting tall trees, where designed to form shade, shelter, or blind, as soon as possible, very little reduction of the branches of the head may be necessary, only to reduce any very irregular growers.

However, in removing pretty large trees of any sort, with considerable heads, especially of a very spreading or crowded nature, it may be proper to reduce the whole regularly, both in some proportion to the root, and that the winds may not have too much power to incommode it after Planting; in which cases, it may be necessary, as just above observed, to retrench, or reduce some of the most extensive lower branches, thin out some where much crowded, and reduce others down to some convenient lateral branch they may support, so as each reduced branch may, notwithstanding its reduction, terminate in a leader, having its top entire, not to exhibit naked ends of branches, standing up like stumps. Caring, however, in such large trees, that the above reduction should be so

judicious, as the remaining branches may still exhibit a moderately full, and somewhat regular head.

With respect to the preparation for planting of all the shrub kind, only just trim straggling under branches and shoots from the lower part of the stem, retrench luxuriant of the heads that seem to shoot away very irregularly and vigorously, at the expense of the neighbouring branches, and reduce long ramblers, &c. just to preserve a little regularity.

All new planted tall trees should generally be staked as soon as planted, in order to support them steady every where, till well rooted, and have somewhat established their roots, that tempestuous winds may not overset, or otherwise incommode them; particularly all trees of six, eight, or ten feet high, and upwards; one tall stout stake to each tree, or more, if the trees are of large size, sharpening the lower ends, and drive them firmly into the ground near the stem; or, if larger trees, place it slant-ways, at a little distance, so as its top reach the upper part of the stem, on the opposite side to that most exposed to the winds, in which it will have the greatest effect; but large trees, with full heads, should generally have very tall strong stakes, three to each tree, placed triangular ways, also in an oblique or slanting direction. Having, however, fixed the stakes in either of the methods, as the trees shall require, then directly proceed to bind the stem of the trees firmly to the stakes, previously wrapping some soft substance, such as hay-bands, &c. round the stem, at the part where it is to be fastened to the stakes, in order to save the bark from being rubbed off against the stakes, by the motion of the winds; which is more particularly necessary to tall plants that are much exposed: so having some strong bandages, such as rope-yarn, or the like, or for smaller plants some tough osier or other withy kind, then bringing the stem and stakes close, so as to preserve still the erect position of the plant, bind them firmly together, by drawing the bandage round the stakes, and about the stem, over the hay wrapping, if any, and fasten it so securely, as to admit of no motion between the stake and stem of the tree.

But large trees, of some considerable stature, with full heads, are often supported also with ropes suspended from the top of the stem, three different ways, straining them tight, and the end of each rope staked securely down to the ground; so that, whatsoever way the wind blows, the ropes will stay the tree still in its upright position.

Such new planted trees as are exposed to cattle, should each be well fortified all round the stem with thorn bushes.

The general Planting season, for all sorts of trees, is autumn and spring, i. e. the autumnal Planting being from the beginning of the decay of the leaf, in October, until December; though ever-greens may be begun to be transplanted towards the middle or latter end of September, and continued till December aforesaid. And for the spring Planting, February and March is the principal time, but may be continued occasionally until April; and several sorts of tender young ever-greens succeed best when planted the beginning of that month.

However, to those persons that have much Planting or other business in hand, I would observe, that Planting need not be confined particularly to autumn and spring; for all hardy kinds, both fruit-trees, forest-trees, shrubs, &c. may be planted occasionally, almost any time, in open weather, from October till March, especially in all moderately dry soils, with good success.

Planting, however, forward in autumn, is of some advantage, as the trees will have time to root more firmly, ready for the ensuing spring shoot, as well as be able to stand the drought of spring and summer somewhat better than those planted later.

But in very humid soils, where water is apt to follow the spade in winter, it is eligible always to plant forward in autumn, or not till spring; but rather principally the last mentioned season, toward the latter end of February, or in March.

Farther Observations, particularly in Planting herbaceous Plants.

In preparing to plant herbaceous fibrous-rooted plants, our first principal care is to remove them with good roots: young seedlings, &c. especially require particular care in drawing them with proper roots. When they are to be taken all clean up, they may be readily loosened and raised out of the earth with some instrument, with all their fibres entire; but when they are only to be thinned, they do not admit of this, because it would disturb the remaining plants, so must be drawn out by hand carefully, with as much root as possible.

Many sorts of fibrous-rooted plants, however, being so hardy, and apt to grow, that if taken up almost any how, with a little root, they will often strike: it is nevertheless advisable to use care in drawing all sorts for Planting, with tolerable roots, as they will in proportion make more progress in their future growth. And as to any trimming preparatory

paratory to Planting, very little is wanted, only in some sorts, just shortening very long naked spindly roots, and trimming any straggling fibres; though in numbers of plants of this tribe hardly any trimming at all is required, neither in root nor top; all of which however, you will be able to regulate according to observation, agreeable to the hints here exhibited, and in the culture of the respective articles.

The most commodious and expeditious mode of Planting herbaceous seedlings, slips, off-sets, cuttings, &c. is by dibble, as already observed in *Planting by Dibble*; and for such as have been previously pricked out in nursery-rows, many sorts may be drawn with little balls, when required, and holed-in with a trowel, especially numbers of the choicest flowery tribe; but almost all sorts of pricked-out herbaceous fibrous-rooted plants may either be drawn with full roots, and planted by dibble, or with balls of earth, and holed in by trowel, as shall seem most convenient according to the nature of the plants.

Many sorts of fibrous-rooted plants may be planted out at once, where they are finally to remain, particularly all long spindly-rooted kinds; likewise numerous others of the more fibry-rooted sorts may also be planted out finally from the seed-bed, provided the ground is ready for their reception: yet I would observe, when the ground is not ready to receive them for some considerable time, it will be eligible to thin out a quantity from the seed-bed, and prick them in nursery rows five or six inches asunder, to remain a month or six weeks, or some two or three months, or longer, till the ground is ready for their reception, whereby they will acquire good roots, and a robust firm growth, in order for final transplantation, in autumn or spring: whereas when they all remain long in the seed-bed, they, by standing so close, draw each other up very slender and weak, and never make near so good plants as those previously thinned and pricked out at small distances; which, after growing a month or two in nursery rows, will all readily rise with full roots for final Planting, and many sorts also with good balls of earth where necessary, which may be more particularly requisite to some of the choice, flowery tribe.

The season for Planting most herbaceous fibrous-rooted plants is any time in spring and autumn, also occasionally in summer, especially in pricking out young seedlings, both annuals and perennials, of the spring sowing, and in slips and cuttings of older perennial plants; and likewise, on particular occasions,

large plants of advanced growth might be transplanted in that season, according as they may be required for different purposes, as is always hinted in the culture of the various sorts; and many hardy kinds even in winter, in mild open weather, when occasionally wanted; for most of this tribe of plants readily and expeditiously take fresh-root at almost any season, in mild weather; chusing generally moist weather in spring and summer, but especially from April until September; and chiefly dry weather for winter Planting: observing likewise in the spring and summer Planting, it is proper always to give a moderate watering as soon as planted, but especially in summer, unless it should happen to rain hard enough to descend to the roots; otherwise a little water to settle the earth close to the roots is of very essential service.

As to planting herbaceous bulbous-rooted plants, such as hyacinths, narcissus, tulips, and all others of the bulbous tribe, they ought not generally to be removed but only in summer, when their stalks, leaves, and fibres of the bulbs decay; for these parts of bulbous plants always decay annually in summer, soon after they have flowered and ripened seeds; but the bulbs themselves are perpetuated; so that the above period is the most proper time to plant out seedlings and off-sets of these sorts previously into nursery beds for two or three years or more, to acquire a proper age and size for flowering, then transplanted finally: it is also the most proper period for transplanting full-grown bulbs, either from one place to another directly, or to take them up to keep for autumn and spring Planting.

For it should be observed of those bulbous kinds, that if removed for Planting out of the proper seasons as above, either before they flower, in spring or summer, &c. or after the flowering is past, in autumn or winter, if they have remained long enough to have struck fresh fibres into the ground, it would either greatly retard, or in several sorts entirely prevent their flowering the ensuing season; or others would not flower in tolerable perfection, so that where any, on particular occurrences are removed for Planting unseasonably, as above, they should be replanted again directly, or as soon as possible, for at this period of removal, if retained long out of the ground, they would shrink and diminish in size considerably.

All bulbous-rooted plants taken up at the above time of the decay of the stalks, leaves, and fibres, may either be planted again directly, or in most sorts, kept till September, October, or November, and then planted; which

which for the choicest kinds is the most eligible practice, as observed in their culture: and in order to have a late bloom a few may also be retained out of ground till spring, about January or February; but plant the principal always in autumn, about October and November.

Bulbous roots are planted two or three different ways, as by dibble, by drilling-in, and by hedding-in. See each of these methods as exhibited separately under this article, PLANTING. See also BULBUS.

Choose always dry weather for Planting most kinds of bulbs, especially all the choice kinds.

PLASHING HEDGES, the work of laying down the stems and branches of old run up open hedges horizontally, to close and thicken them below, &c.

This work, though rather more generally applicable in agriculture business than in gardening, is also sometimes necessary to be done in gardens, having outward hedge-fences that have been permitted to run up in rude growth, naked and open below; and which is reformed and reduced to order, by a proper trimming thinning, cutting and laying down the general stems and branches slantingly along according to the range of the hedge, between others left upright; assisting in this with the hedge-bill in occasionally cutting or gashing the larger stubborn growths, towards the lower parts on the upper side, by an oblique stroke of the bill, cutting them slantingly, less or more, according as it may seem necessary, in order to render them pliable or yielding to Plash, or lay down horizontally longways between others of the strongest stems left in upright growth in the order of stakes; and at the same time Plashing in all the smaller lateral branches; and thus proceeding in a regular manner, it closes all lower vacancies, and thickens the whole regularly from bottom to the top, in its proper moderate height of three or four feet, or a little more or less, according to the growth of the hedge in its disorderly state; which if run up tall, and naked below, is reduced lower accordingly in the Plashing in the above proportion; and hereby the whole, if the Plashing is properly executed, will form a close impenetrable hedge.

In performing this work, some of the main upright stems of the hedge are left in erect growth at small distances, as the Plasher proceeds in the business, as growing stakes, between which to plash, and lay the others and the general branches horizontally as before suggested, assisted occasionally by other stakes driven down in the hedge-row as required.

This work is performed occasionally to any sorts of common deciduous hedges: as white-thorn, black-thorn, elm, beech, &c. and the proper season is any time from the fall of the leaf in autumn till March or April, at farthest.

When proceeding in this business, it is often necessary, in very disorderly rough hedges, previously to trim or lop off much of the outward and over-growing rude branches, and large naked wood, and evidently superabundant growths, below and above; and as the Plasher goes on, fixing on some of the strongest upright hedge-stems to leave at moderate distances, for growing stakes as aforesaid, cut down to the proper height, proceeding at the same time in the plashing or laying the most branchy wood, and with the hedge-bill, cutting or gashing occasionally such of the larger stems and branches that are not otherwise pliant enough to admit of Plashing eligibly; bringing the whole down in a regular gradation one after the other, Plash or lay them properly along somewhat horizontally between the uprights, some nearly close down, or with the brushy parts more or less towards the ground to close the lower vacancies and fill the bottom properly, others over these; all arranged longways conformable to the range of the hedge, lopping off any very disorderly, or over abundant and impliable parts, either laterally or terminally; so continue the Plashing one over the other in the same regular order between the standing uprights, to the intended height, as the hedge admits, driving down other stakes occasionally in places where required; more effectually to fix the plashed stems and branches; and thus proceeding with some degree of regularity, the whole is formed equally close and full from the bottom upwards, three, four, or five feet high, as the nature of the hedge allows, or as may be thought necessary, whereby to have the whole the most effectually fencible.

Then the work is generally finished by trimming all irregularities at sides and top, with the proper hedge-bill, striking off all the too projecting and straggling parts below and above, both to give the hedge a close regular appearance, and that it may shoot more effectually in a close thickening growth.

PLATANUS, Plane Tree.

This genus consists of lofty deciduous trees, of high repute for their singularly beautiful growth and luxuriant foliage; being delightful trees for all ornamental plantations, and for affording shade; also as forest or timber-trees, they growing remarkably straight to a considerable height and magnitude; adorned with very large simple, palmated and lobated leaves,

leaves, from six to twelve or fourteen inches broad, but very small monœcious flowers, collected into close globular heads, succeeded by numerous seeds, digested into large round rough balls.

Class and Order, *Monœcia Polyandria*.

Characters.] CALYX, male and female, very small flowers apart on the same plant, the male florets digested into globular katkins, having very small cups; and females collected into a large roundish ball, having very small scaly calyxes. COROLLA in the males is scarcely discernible, and in the females each floret having many small concave petals. STAMINA, numerous, small, oblong, coloured filaments, having four-cornered antheræ. PISTILLUM, several subulated germina, having subulated styles, and recurved stigmas. PERICARPIUM, none; numerous roundish seeds, surrounded with down, and collected into round hard balls.

There are only two real species, which, however, comprise some varieties, all of which are deciduous, and of hardy growth.

The species are,

1. *PLATANUS orientalis*.

Eastern Asiatic Plane-Tree.] Rises with a very straight, smooth, branching stem, to a great height; palmated leaves, six or eight inches long, and as much broad, divided into five large segments, having the side ones cut into two smaller, green above, and pale underneath; and long pendulous pedunculi, each sustaining several round heads of close-sitting, very small flowers; succeeded by numerous downy seeds, collected into round, rough, hard balls.

It is a native of Asia, and many parts of the East, and grows in great plenty in the Levant.

Varieties of this are,

Spanish, or middle Plane Tree.—Having remarkably large leaves divided into three or five narrower segments or lobes.

Maple-leaved Plane Tree.—Having smaller leaves, somewhat lobated into five segments, resembling the greater-maple leaf.

2. *PLATANUS occidentalis*.

Western American Plane Tree.] Rises with a straight smooth stem, to a great height, branching widely around; lobated leaves, seven or eight inches long, and from nine or ten, to twelve or fourteen broad, divided into three large lobes; and very small flowers, collected into round heads, succeeded by round, rough, balls of seed. It is a native of Virginia, and other parts of North America, where it attains an enormous size, and is remarkable for having its stem all of an equal girth for a

considerable length; and we have an account of some trees being eight or nine yards in circumference, and when felled, afforded twenty loads of wood.

All these elegant trees are of hardy temperature; so as to prosper here in any common soil, and exposure in our open plantations, &c. and are some of the most desirable trees of the deciduous tribe; were in singular esteem among the ancients of the East for their extraordinary beauty and delightful shade they afforded by their noble foliage.

The leaves commonly expand in May, and fall off early in autumn; and the flowers appear in spring, a little before the leaves, being succeeded by seeds, which, in fine seasons, frequently ripen here in September, produced in round, rough, hard balls, suspended on long pendulous peduncles effecting a curious singularity.

As to the uses of these fine trees in gardening, they have singular merit for all ornamental plantations; their straight growth, regular branching heads, and lofty stature they attain, together with the extraordinary breadth of their luxuriant leaves, render them extremely desirable furniture to adorn avenues, lawns, parks, and woods; some disposed in ranges; some as single standards; others in clumps; some in groves, &c. and are most excellent for shade; for it is observable, that no tree is better calculated to defend us from the heat of the sun in summer, by its noble spreading foliage, and to admit the sun's rays more freely in winter, on account of the distance of its branches, which, in most different sorts of trees, is always in proportion to the size of the leaves.

They may also be employed in the collection of forest-trees, in woods, to grow up to timber, in which they will also prove advantageous in time.

In short, these noble trees claim the esteem of every one concerned in plantations of every kind; but more particularly in extensive works, where they may be so variously disposed, as to have a charming effect.

Their Propagation.

The propagation of these trees, is by seed, layers, and cuttings.

By Seed.—The seeds frequently ripen in these parts, and are also procured from other countries, and may be obtained of the nurserymen, or seedmen; observing, the best season for sowing them is autumn, if they can be then possibly procured, otherwise in the spring;—choosing a somewhat lightish, mellow soil; and having dug the ground, and raked it

it fine, form it into four feet wide beds, and either scatter the seeds evenly on the surface, and rake them in, or, previously with the back of a rake, turn the earth off the surface near half an inch deep into the alleys; then sow the seed, and directly, with the rake turned the proper way, draw the earth evenly over the seeds, and trim the surface smooth; many of the plants will rise in spring, and probably not generally till the spring following. When they are one or two years old, plant them out in nursery rows, two feet asunder, and about half that distance in the lines; here to remain till of a proper size for final transplantation.

By Layers.—This method of propagation is very commonly practised in the nurseries, in default of seed, and by which they most readily grow; for which purpose, some stout plants for stools must be planted, which in a year after must be headed down near the bottom, that they may throw out many shoots near the ground, convenient for laying; which, in the autumn after they are produced, lay by slit-laying; and by autumn after, they will be well rooted, and form plants two or three feet high, so may be separated, and planted in nursery rows, like the seedlings.

By Cuttings.—All the sorts will take tolerably by cutting off the strong young shoots; but the *Platanus occidentalis* more freely than the Oriental kind. Autumn, as soon as the leaf falls, is a proper season, or occasionally in the Spring; chusing strong young shoots, and plant them in a moist soil; many of them will grow, and make tolerable plants by next autumn.

It should be remarked, that in order to continue the distinction of the varieties more effectually, they should be propagated either by layers or cuttings: for when raised from seed, those of the respective species generally vary.

PLEASURE-GARDEN, or Pleasure-ground.

The district commonly called the Pleasure-ground, may be said to comprehend all ornamental compartments, or divisions of ground and plantation, surrounding a noble site, consisting of lawns, plantations of trees and shrubs, flower compartments, walks, pieces of water, &c. whether situated wholly within the space generally considered as the Pleasure-garden, or extended over ha-ha's, or by other communications, to the adjacent fields, parks, paddocks, or other out-grounds.

In designs for a Pleasure-ground, according to modern improvements, consulting rural

disposition, in imitation of nature, all too formal works being almost abolished, such as long straight walks, regular intersections, square grass plots, corresponding parterres, quadrangular and angular spaces, inclosed with high clipped hedges, &c. and other uniformities, as in ancient designs; and instead of which, consists now of rural open spaces of grass ground, of varied forms and dimensions, and winding walks, all bounded with plantations of trees, shrubs, and flowers, in various clumps, and other compartments, exhibited in a variety of imitative rural forms, in curves, projections, openings, and closings, in imitation of a natural assemblage; not forming inclosures of hedges, &c. but having all the various plantations open to the walks and lawns; for example: a spacious open lawn, of grass ground, being generally first presented immediately on the front of the mansion, or main habitation, sometimes widely extended in open space on both sides to admit of greater prospect, &c. and sometimes more contracted, towards the habitation widening gradually outward, and have each side embellished with plantations of shrubbery, groves, thickets, &c. in clumps and other compartments, in sweeps, curves, and projections, towards the lawn, &c. with breaks or opens of grass spaces at intervals, between the plantation; together with serpentine gravel-walks, winding under the shade of the trees; extended plantations, being also carried round next the outer boundary of the ground, in various openings and closings, having gravel-walks winding through them, for shady and private walking; and in the interior divisions of the ground is exhibited serpentine winding walks, and elegant grass opens, arranging various ways, all bordered with shrubberies, and other tree and shrub plantations, flower compartments, &c. disposed in a variety of different rural forms and dimensions, in easy bendings, concaves, projections, and straight ranges, occasionally; with intervening breaks or opens of grass ground, arranging between the compartments of plantations, &c. both to promote rural diversity, and for communication and prospect to the different divisions; all the plantations being so variously arranged, as gradually to discover new scenes, each furnishing fresh variety, both in the form of the design in different parts, as well as in the disposition of the various trees, shrubs, and flowers, and other ornaments and diversities.

So that in designs for a Pleasure-ground, according to modern gardening, a tract of ground of any considerable extent may have the

the prospect varied and diversified exceedingly, in a beautiful representation of art and nature, as that in passing from one compartment to another, still new varieties present themselves in the most agreeable manner; and even if the figure of the ground is irregular, and its surface has many inequalities, in risings and fallings, and other irregularities, the whole may be improved without any great trouble of squaring and levelling, for by humouring the natural form, may cause even the very irregularities to conceal their natural deformities, and carry along with them an air of diversity and novelty.

In these rural works, however, we should not abolish entirely all appearance of art and uniformity; for these, when properly applied, gives an additional beauty and peculiar grace to all our natural productions, and sets nature in the fairest and most advantageous light.

But some of our modern Pleasure-gardens, in which rural design is copied to an extreme, are often very barren of variety and entertainment, as they frequently consist only of an extensive grass lawn, like a great field, having a running plantation of trees and shrubs all round, just broad enough to admit of a gravel walk, winding through it in the serpentine way, in many short twists and turns, and bordering at every turn alternately upon the outward fence and the lawn; which are continually obtruded upon the sight, exhibiting the same prospect over and over, without the least variation, so as that after having traversed the walks all round this sort of Pleasure-garden, we find no more variety or entertainment than at our first entrance, the whole having presented itself at once at the first view; and we might often see as good a garden, sometimes in a common field, that is bordered with any kind of plantation.

Therefore, in laying out a Pleasure-garden, the designer ought to take particular care that the whole extent of his garden be not taken in at one view; only exhibiting at first a large open lawn, or other spacious open compartment, or grand walk, &c. terminated on each side with plantations of curious trees, shrubs, and flowers, in compartments, exhibiting only some opens at intervals; and behind these have compartments of the like plantations, with grass opens, gravel walks, water, and other ornaments; so that a spectator will be agreeably surprised to find what terminated his prospect was an introduction to new beauties and variety.

But it is impossible to exhibit any regular directions for planning a Pleasure-garden,

agreeable to the prevailing modern designs, being generally in some fancied natural imitation as aforesaid; as the plan may be varied exceedingly, according to the natural figure, position, and situation of the ground and taste of the designer, so we can only give some general hints.

General Sketch of the Design.

In this we can only give the following general sketch, which may be varied according to the situation and extent of the ground.

With respect to the situation; this must consequently be immediately contiguous to the main house, whether high or low situated; remarking, however, that a somewhat elevated situation, or the side or summit of some very moderate rising ground, is always the most eligible on which to erect the chief habitation, arranging the Pleasure-garden accordingly; such an exposure being the most desirable, both for the beauty of the prospect, and healthfulness of the air; a low level situation, neither affording due prospect of the garden, nor adjacent country, besides being liable to unwholesome dampness, and sometimes inundation in winter: there are, however, many level situations, forming plains or flats, that possess great advantages both of soil and prospect, and the beauties of water, without too copious moisture; there are also sometimes large tracts of ground, consisting both of low and high situations, as level plains, hollows, eminences, and declivities, and other inequalities, which may be so improved, as to make a most desirable spot for a Pleasure-garden, as the scene may be varied in the most beautiful manner imaginable. However, the choice of situation and scope of ground is not always attainable, so every one will regulate his plan in the most commodious manner possible, agreeable to the above hints.

The extent of a Pleasure-Ground may be various, according to that of the estate or premises, and of the quality and fortune, &c. of the owner; so may be from even a quarter or half an acre, to thirty or forty or more.

The ground should previously be fenced, which may be occasionally a wall, paling, or hedge, or some of each sort, as may be convenient, and in some parts a fosse or ha-ha, where necessary to extend the prospect, either at the termination of a lawn, walk, or avenue; observing, the close fences should generally be concealed within side, particularly the wall and paling fences, by a range of close plantation, unless where the wall may be wanted for the culture of wall-fruit. But sometimes, when a Pleasure-ground

ground adjoins to a fine park, paddock, or any agreeable prospect, the boundary fence on that side is often either a low hedge, or a ha-ha; but many prefer the latter, especially at the termination of any spacious open, both to extend the prospect more effectually, and give the garden an air of greater extent than it really has, at a distance, the ha-ha being sunk, nothing like a fence appears, so that the adjacent park, fields, &c. appear to be connected with the garden. See WALLS, HEDGES, FOSSE, &c.

But with respect to the arrangement of the several divisions, the following general sketches are on a supposition of a considerable tract of ground; and if the plat of ground is small, a greater simplicity of design must be observed in proportion.

First, a noble open lawn of grass ground is extended on one of the principal fronts of the mansion or main house, directed either towards the open fields, park, or adjacent country, or towards the garden, if the situation requires it; or may be extended a little more or less each way, according as the situation and extent of ground may admit, or require; but, if possible, always considerably the most extensive on the principal front; and should be considerably wider than the house, if possible, and twice as long as broad at least; or if the scope of ground admits it, may even be extended in length, as far as the extreme boundary of the garden; or carried over ha-ha's, to the adjacent park or pasture-grounds, &c. widening gradually in some varied order, from the house outward; having each side bounded by various plantations of trees, shrubs, and flowers; in groves, clumps, thickets, and other compartments, exhibited in a variety of rural forms, and dimensions, in moderate concave and convex curves, and projections, to break all appearance of too stiff uniformity; introducing also, between the plantations at intervals, breaks, or opens, of grass-ground, communicating with the lawn and internal divisions, in some places widely spread, in others more contracted; leaving also tracts for serpentine gravel-walks, some winding under the shade of the plantations, so conducted as to command views of the lawn, and the interior divisions occasionally; observing, the homeward part of the plantation should be inclined a little toward each wing of the house, that company may sooner arrive in the walks of the shrubbery, wilderness, and groves, under the shade and shelter of the trees; but the outward extension on each boundary should widen gradually towards the extreme termination, to give an air of grandeur, and

admit of a full prospect from and to the mansion. Each boundary being planted with a choice variety of ornamental trees and shrubs, deciduous, and ever-greens, arranged principally in separate clumps, and other compartments, alternately, some consisting wholly of lofty trees, arranged sometimes in regular groves, and some in groups or clumps, variously; other compartments being entirely of the shrub kind; and others consisting of trees, shrubs, and herbaceous perennials together: in all of which, arranging the taller growth backward, and the lower forward, according to their gradation of height; embellishing the fronts with the more curious low-flowering shrubs and ever-greens, interspersed with various herbaceous flowering perennials, all open to the lawn and walks; and the termination of the lawn at the farthest extremity, if extended considerably outward to some agreeable prospect, is generally continued open the whole width, by sinking a ha-ha at the limits of the garden, to unite the view with the adjacent pastures, plantations, and the open country, as well as admit of a grand view to and from the mansion. See LAWN.

But sometimes the termination of the lawn, in default of prospect beyond the limits of the garden, or that it is necessary to conceal the garden from the view of persons without, is by a plantation of stately trees, in gradual concave, and convex sweeps. Or small lawns that extend immediately towards the garden, may be terminated by elegant shrubbery clumps, continued to the interior division. However, for considerable lawns, extended outward to the utmost verge of the garden, that admit of any tolerable prospect of the adjacent fields, &c. a fosse or ha-ha termination, is, in some situations, the most eligible, in order to continue the prospect. See FOSSE and LAWN.

From the boundary plantation of the lawn, is continued the internal works, in a great variety of rural divisions, in spacious walks and open spaces of grass, bounded by shrubbery clumps, wilderness plantations, groves, thickets, &c. all in varied, elegant compartments, as before mentioned, to exhibit a grand rural imitation, diversified in a variety of forms.

In the general arrangement, the great art is to vary the prospect of the different divisions, so as they may variously present an air of novelty, and source of convenience and entertainment.

Around towards the outer boundary fence, is generally arranged a plantation of trees and shrubs, in varied, easy, concave sweeps, and

and projections next the garden, or lawn, &c. and broad enough to admit of a serpentine gravel-walk, winding through the whole extent, under cover of the trees and shrubs, for private and shady walking: varying the plantation in different degrees of thicket and openings occasionally, with here and there breaks and openings, for prospect from the walks to the different parts of the garden and open country; and with opening or concave grass spaces, bordering the walk at intervals for diversity, and as places for seats, &c. under shade of the plantation.

In the more interior parts are exhibited magnificent walks, avenues, and grass openings, some nearly straight, others more or less winding, arranging in different directions; and having each side embellished with plantations, in shrubby clumps, groves of trees, wilderness plantations, thickets, and flower compartments, distributed in various arrangements and distances, admitting intervals of grass ground surrounding and communicating with the various plantation divisions, in some places of considerable extent, in others more or less contracted, according to the distance and arrangement of the several clumps and other compartments of plantation, which should be exhibited in a variety of windings, openings, and closings, from one degree of light and shade to another; introducing also grand openings, at intervals, between the principal districts of plantation, for views or prospect, &c. and from the main walks and openings, have other smaller walks branching off at due distances, in a winding direction, to places of shade and retirement, amidst the plantation, and for communication from one division to another; exhibiting also opens of different figures and dimensions, surrounded by clumps of trees and shrubs, serving some for recesses, and places of shade, aforesaid, others for garden edifices, as temples, grottoes, rural seats, statues, &c. and sometimes for pieces of water; and if water from some upper spring or head, can be led in a winding course, through the lower parts, in gentle meanders, it will have a charming effect; other internal divisions appear with an air of grandeur and magnificence, by exhibiting a spacious opening of grass ground, bounded by the noblest trees and shrubs, in various elegant clumps, groves, groups, and straight ranges; and the opening terminated by some fine open prospect, noble piece of water, or ornamental building; and with gravel-walks, extending through the boundary plantations. Another part shall appear more gay and sprightly, displaying an elegant flower-ground, designed somewhat in the parterre

way, in various beds, borders, and other compartments, furnished with the most curious flowers; and the boundary decorated with an arrangement of various clumps, of the most beautiful flowering shrubs, and lively ever-greens, each clump also bordered with a variety of the herbaceous flowery tribe.

Another division sometimes presents a wilderness in irregular partitions of plantation, having intervening spaces of grass ground and gravel walks, extending in various directions, some by winding mazes or labyrinths, into openings formed in different parts amidst the plantation, and to a grand one in the centre; the boundary plantations of this division being generally in close assemblage, with tracts of serpentine walks between; some leading in private meanders towards the interior parts, or breaking out sometimes into other walks that are open and spacious, both of grass and gravel occasionally, conducted also in serpentine turns, to cause the greater variety, having each side bordered with plantations of trees and shrubs, the tallest behind, the lower growth in front; and from these grand walks, others more narrow and close, branch off at intervals, in various windings, in some places being closely bordered with tall trees, to effect a gloominess and perfect shade; the different walks leading now and then into circular openings of grass in different parts, each being surrounded with plantations as aforesaid; making also the principal walks terminate in a grand opening in the centre of the wilderness, in which may be some ornamental edifice, or fine piece of water, &c. furnishing all the plantation compartments, with a good variety of trees and shrubs; the deciduous and ever-green kinds principally in separate clumps, or quarters, interspersed with various wood flowers promiscuously, placing the more curious kinds of shrubs and flowers towards the fronts next the walks and openings, conspicuous to view. See WILDERNESS.

Straight ranges of the most stately trees are sometimes arranged on grass ground in different parts, in contrast with irregular plantations; and produce a most agreeable effect, which though prohibited in many modern designs, always exhibit an air of grandeur; being arranged sometimes in single rows, others double, or two ranges at certain distances, forming a grand walk or avenue; in other parts, several ranges together in the manner of groves: all of which being arranged on grass ground occasionally in different situations, will have a grand ornamental appearance. See AVENUE and GROVES.

Sometimes an outward division discovers a

close plantation of trees, like a thicket of woodland, arranged in irregular assemblage, mostly close and gloomy, resembling the internal arrangement of a wood; sometimes exhibiting sudden transitions of light and shade, by openings and closings, having serpentine walks winding through every part, and sometimes leading to openings in the midst of the plantation. Others breaking out suddenly from the thicket into open prospects of the other divisions; having all the walks bordered with flowering shrubs, hardy climbers, and various wood flowers that prosper under shade, and many common hardy shrubs, and herbaceous plants scattered promiscuously among the trees, to form more or less thicket, and cause diversity in the manner of a natural wood.

In other parts are sometimes discovered eminences, or rising grounds, as an high terrace, mount, steep declivity, or other elevated situation, having the sides covered with grass and compartments of plantation; and walks leading under the shade of trees by easy ascents, to the top, where is presented an extensive prospect of the adjacent fields, cottages, hamlets, and country around, as well as afford a fresh and cooling air in summer.

Regular compartments and figures, in various forms, are also sometimes introduced in some extensive grounds, for variety, in contrast with the irregular works, and still to preserve some appearance of the remains of ancient gardening; such as straight walks, verged with borders of flowers, &c. regular parterres, in flower borders; square spaces, circles, and octagons, &c. inclosed with low clipped hedges; hedge-work, formed into various devices; detached ever-greens, formed into pyramids and other regular figures; regular grass slopes, formed on the side of some declivity or rising ground: elevated terraces; bosquets of trees, surrounded with low ever-green hedges; straight avenues of trees in ranges, &c. a little of each being judiciously disposed in different situations, may prove an agreeable variety, by diversifying the scene, in contrast with the rural works aforesaid.

Sometimes a bleak declivity, or some rough hollow ground or vale, is made to exhibit a wild or uncultivated scene, by arranging some scattered clumps of trees in the most irregular assemblage; the intervals or spaces between being rough grass ground, and here and there tufts of shrubby bushes, with sometimes a gentle rill of water, winding along the bottom of the declivity, or twisting its course through the vale.

Towards the lower parts of the garden, pieces of water are always exhibited where

possible, in the most conspicuous points of view contiguous to the termination of the main lawn, or other spacious open, representing sometimes a basin, lake, &c. and sometimes a natural river, winding its course through different divisions, and its termination concealed by a curious turn, making it appear to lose itself in the adjacent plantations.

With respect to the walks, these may be both of gravel, sand, and grass, but principally gravel for common walking; and grass for occasional walking in the heat of summer, which in dry hot weather may be more agreeable than the hard gravel-walks: therefore some of each sort is proper both for convenience and variety.

Gravel-walks, however, should lead all round the garden and into the principal internal divisions, so as to have dry and firm walking at all times of the year; when the grass is too damp, as in winter and all wet weather.

These gravel-walks should be of proportional width, in different parts, according to the extent of the garden.

As to the distribution of gravel walks:—first a magnificent one, from fifteen to twenty or thirty feet wide, should range immediately close and parallel with the front of the house, and be conducted directly across the lawn into the nearest side shrubbery and general plantation; where each side being verged with spaces of grass ground, and shrubbery clumps, &c. from this main gravel-walk, other smaller ones, from five to ten or twelve feet wide, should branch off at proper intervals, directed in the serpentine way; some leading through the outer boundary plantation, as already hinted; others into the central divisions; and others carried along the front of the boundary plantation of the main lawn; all of which walks being conducted through and between the different principal plantation, is highly requisite, both for the convenience of shade, and retirement occasionally, as well as to enjoy the variety of the different sorts of trees, shrubs, and flowers, variously presenting themselves at different turnings: for the walks having various sweeps, and windings, discovering only a moderate length at once, every turning produces new varieties; and should likewise be so contrived, as at proper intervals to discover openings for prospect into different principal divisions of the garden; having in some places the plantation of trees, shrubs, and flowers, bordering close upon the walks; in other parts, have on one side of the walks considerable grass spaces, running into

into the adjacent plantation, in one or more concave curves, to form the greater diversity.

And in some places the windings of the walks should be gradual and moderate; in others exhibit sudden turns, and grand sweeps, each turning exhibiting sometimes a magnificent projection in the plantation, others some spacious opening, bordered with curious plants; other parts a close thicket, which sometimes may seem to terminate the walk, when by a sudden turn it breaks out all at once into some grand open division, spacious open walk, an avenue, or elegant piece of water, open grove, &c. And in other parts, a walk sometimes suddenly divides into two or three divisions, leading different ways, in gradual sweeps, each separation being formed by a projecting clump of shrubbery work, or group of trees, &c. and each division of the walk is conducted by varied serpentine turns, as soon to be concealed from the other, by the intervening plantation compartments.

Sometimes, similar to the ancient designs, a spacious gravel walk is extended in a perpendicular line, immediately from the front of the habitation, dividing the lawn, or extended on both boundaries, and in other situations; and with a wide border on each side, either straight, or sometimes a little serpentine, and planted with the most curious low flowering shrubs, ever-greens, and herbageous flowering plants.

All these gravel-walks should be laid with the best gravel, six or eight inches deep at least; but if more the better. See GRAVEL and GRAVEL-WALKS.

Grass-walks may be considered as all the open grass spaces, whether formed in the manner of walks, or as breaks or divisions between the various plantations, all of which serving both for communication to different parts, and to render the ground more rurally ornamental, and for occasional walking in dry weather in summer; but some tracts of considerable width and length, formed into grass-walks, leading to different divisions, having each side bounded with clumps of trees, shrubs, and flowers, gives an air of grandeur to the garden, allotting smaller breaks, or opens of grass, branching off between the plantation compartments, as formerly mentioned.

The grass ground of this garden may be formed, either by sowing grass seed, or by laying it with turf, cut from some common or downs; but in very extensive works turfing the whole would be a great expense; therefore seed is the most eligible for the principal spaces in very large gardens. For the

method, however of forming grass-ground, both by seed and turfing, and for keeping the grass in order, see GRASS.

Water being so ornamental in all garden designs, no pains should be spared to introduce it where possible; but where it admits of a constant running stream, from some adjacent upper spring, its beauties may be rendered admirably fine, as it may be conducted in meanders through the garden, so as to effect a beautiful assemblage of verdure and water together; and if it should be continued to any considerable length, one or more ornamental Chinese bridges may be carried over at convenient places, which will have a beautiful effect, and serve for communication with the opposite divisions, on each side of the rivulet.

Cascades, and other water-falls, have also a fine effect, where there are a constant plentiful stream, and the situation proper to give the water a due fall, from a higher to a lower part, upon a parcel of rugged stones, to increase the noise, and break and disperse the water.

In some grounds, by their natural situation, water may be obtained at a moderate expense; as sometimes a contiguous vale, or meadow, bounded by rising ground, and with a brook or rivulet constantly running through it, may be easily thrown into the most agreeable form; and sometimes large springs issuing from an upper ground, and running down a moderate descent between two rising grounds, to some vale below, may either form one entire lake, &c. or contrived, by making proper heads at distances, to form several lakes strung together, as it were, one above another, up to the beginning of the spring; each head may form a beautiful water-fall, or cascade; having the rising grounds on each side embellished with clumps of plantation.

Lakes and artificial rivers may also be contrived in a flat or level ground, where there are any contiguous brooks that can be conducted to supply them with water.

All pieces of water should generally be contrived in a natural imitation, as much as the situation will admit; and its boundary on all sides should be grass ground to some considerable width, sloped off as easy as possible, corresponding with the other adjacent grass ground, to admit of a prospect of the water at some distance.

On the verges of large compartments of water, some Babylonian, or Weeping Willows disposed in particular situations, singly at distances, sometimes in concave and projecting parts, terminations, &c. will have a very agreeable effect in their long, bending, arched branches, and numerous pendulous shoots,

shoots, suspended over the water, in a loose waving manner, sometimes sweeping the surface thereof; and when arrived to some considerable growth in their numerous low pendent branches, suspending all around, display an air of peculiar solemn grandeur.

The various compartments of ground intended for the different plantations, should be digged or trenched for the reception of the plants; particularly for all plantations of shrubbery, wilderness quarters, flower compartments, &c. and the ground for clumps should be raised above the common level, in a gentle swell; especially all detached compartments, such as shrubbery clumps, and flower partitions; and most other detached compartments of ground for any kind of ornamental plantation in gardens, should generally be raised in a moderate rounding swell, gradually from each side to the middle; or for any continued side plantation it may be raised in a gentle slope; for the swelling and sloping figure always strikes the eye the most agreeably, as well as shows the plants to the best advantage.

But where intended to have groves of stately trees, or any straight ranges of trees, either singly, or double lines, forming a walk or avenue, it is most in character to dispose them all on grass ground; in which they will appear the most rural and beautiful.

Likewise elegant ornamental trees, both as single standards, and in detached groups, or clumps, appear the most beautiful when disposed on spacious openings of grass ground.

However, for all kinds of shrubbery and wilderness plantations, &c. the compartments should generally be dug ground, as before observed.

All the plantation compartments of shrubbery, wilderness, &c. should be planted with some considerable variety of different sorts of trees, shrubs, and flowers, artfully disposed in varied arrangements; the taller behind, the lowest forward, and the different sorts so intermixed, as to display a beautiful diversity of foliage and flowers, disposing the more curious kinds contiguous to the principal walks and lawns.

For a list of the different sorts of trees, shrubs, &c. proper for embellishing the several divisions, see DECIDUOUS TREES, and EVERGREENS.

Observing, that as the trees and shrubs are of two different tribes, deciduous and evergreen kinds, those of each tribe should be mostly planted in separate clumps, in which they will effect the most agreeable variety; and in some places may exhibit clumps com-

posed of both sorts, to cause the greater diversity; and many of the most conspicuous deciduous compartments may be embellished towards the fronts, with some showy ever-greens thinly dispersed; which will appear ornamental and lively in winter, when the deciduous plants are destitute of leaves. In planting the several shrubbery clumps, &c. some may be entirely of trees; but the greater part an assemblage of trees and shrubs together; some entirely of the low shrub kind, in different situations, between and in front of the larger growths; likewise should intersperse most of the shrubbery and wilderness compartments with a variety of hardy herbaceous flowery plants, of different growths; having also here and there clumps entirely of herbaceous perennials: the distribution or arrangement of the clumps, and other divisions of the different kinds, both trees, shrubs, and flowers, should be so diversified, as to exhibit a proper contrast, and a curious variation of the general scene.

And in the disposing the various trees, shrubs, and other plants in their respective compartments, observe somewhat in the quincunx way, not exactly so, nor in regular ranges; and for the most part, place the tallest towards the middle or back part, and the lower forward towards the front, according to their natural stature of growth; observing also to intermix the different sorts in each clump, &c. in such order, as to display a diversity of different foliage and flowers, as aforesaid, as well as exhibit a conspicuous variety. Likewise placing the various sorts at such proportionable distances and dispositions, according to their various growths, as each may have full scope to spread its head; and so as the prospect of one may be no interruption or impediment to the growth and appearance of another, but all so judiciously arranged as to set off each other and appear distinct to proper advantage from the contiguous lawns, walks, and other divisions. See PLANTATION.

Observe, in planting any continued or running plantation where shady walks are designed, that particular care is requisite in arranging a due share of the taller trees and shrubs nearer the walks and in such order as to produce the desired effect, particularly in the continued plantation of shrubbery work around the outward boundary, and on the boundary of the lawn and other running plantations, through which serpentine walks are carried: planting many tall-growing trees and shrubs more or less towards the walk in such arrangement as to produce proper shade, shelter, and private walking, with occasional openings

openings and closing at intervals, as hath been already observed; interspersing also many smaller shrubs and hardy herbaceous plants between the larger growths; disposing the whole so judiciously as to afford also a source of variety in the excursion of the walks.

These plantations for shady walks are highly necessary to retire to occasionally, for shelter from the injuries of the weather: they afford shade from the scorching rays of the summer's sun, shelter from tempestuous winds and cold blasts, and for private walking when required. But where very close and gloomy shade is required in any particular parts for diversity, some trees and tall shrubs should be arranged nearer to the verge of the walks, backed and fronted with others, and a variety of hardy shrubs, in such order as to produce the proper effect.

In planting groves and avenues, they should be composed principally of the tree kind, and such as are of straight and handsome growth, with the most branchy, full, regular heads, and may be both of the deciduous and ever-green tribe; but generally arranged separately; which, for groves and avenues, should always be in some considerable open space, formed into grass-ground, either before or after planting the trees; and in planting the groves, it is most eligible to arrange the trees in lines, in some places straight rows, others in gentle bendings, or easy sweeps, having the rows at some considerable distance that the trees may have full scope to display their branchy heads regularly around; and in some places may have close groves to form a more perfect shade. And as to avenues and walks of trees, they may be formed either entirely of deciduous trees, or of ever-greens; but the deciduous kinds are in most estimation for forming fine avenues: however, avenues and grand grass-walks, planted with beautiful ever-green trees, make a fine appearance. In both the sorts, the trees are most commonly disposed in straight rows, one on each side of the avenue, though sometimes grand walks of trees may be both in single straight lines and in double rows, to exhibit the greater variety, planting the trees generally, both in the avenues and walks, at proper distances, to have full scope to branch out regularly around and display their beautiful heads. See AVENUES, GROVES, &c.

But thickets may be composed of all sorts of hardy deciduous trees, planted close and promiscuously, and with various common shrubs dispersed between the trees, as underwoods, to exhibit a more or less thicket occasionally in different parts.

Thickets may also be of ever-green trees, particularly of the pine and fir kinds.

Straight rows of beautiful ever-greens, as pines, firs, cypress, cedars, &c. forming magnificent walks, are very ornamental.

In some open spaces of grass-ground, such as spacious open lawns, or other considerable opens in parks, &c. should dispose some of the most beautiful trees and elegant shrubs detached, both separately as standards or single objects; and in groups or assemblages, from two or three to five or ten or more in different groups or clumps; some irregularly, others in curves, straight lines, &c. for variety, arranging both single standards, and groups a considerable way asunder, not to obstruct the prospect, and at such varied distances as if they had grown there by chance.

It sometimes happens that on the spot or tract of ground which is designed for a Pleasure-ground are found large old trees of considerable standing, properly situated to be introduced into the design, sometimes in proper assemblage for constituting a grove or a thicket, and some as single standards, groups, or clumps, &c. which will prove a considerable advantage; and should be preserved with the utmost care, as it would probably require an age or two to form the like with young plantations; and although the trees should stand ever so close, or irregular and straggling, they, with proper address of thinning or regulating where necessary, may be retained for purposes as above, so as to have a fine effect. See GROVES, &c.

A commodious space for a flower-ground, distinct from the other divisions as formerly hinted, is most necessary for the culture of the more curious and valuable kinds of flowers.

This principal flower-ground forming a distinct division, exclusive of the other flower compartments distributed in different parts in contrast with the shrubbery clumps, &c. should be allotted for a choice collection of the finest kinds of both bulbous and fibrous-rooted flowers. The form of this ground may be either square, oblong, or somewhat circular; having the boundary of the division formed by an arrangement of a curious shrubbery, embellished with a collection of the most beautiful flowering shrubs; and the interior part should be divided into many narrow compartments, either in the manner of a parterre, formed into straight borders, beds, &c. edged with box (see PARTERRE); or divided into plain four feet wide beds arranging parallel, having two-feet wide alleys between bed and bed;

bed; in either method having a walk carried all round next the outer boundary, then a border surrounding the whole division, and within this have the various division of beds, &c. as above, raising them generally in a gently rounding manner, highest in the middle, and edge the compartments principally with dwarf-box, and some with thurst and pinks by way of variety, laying the walks and alleys with the finest gravel.

In this division you may deposit the finest hyacinths, tulips, polyanthos-narcissus, jonquils, ranunculus, anemones, and all the other more curious, hardy, bulbous, and tuberous-rooted flowers; each sort principally in separate compartments, especially of the choicer kinds; which being necessary both for distinction sake and for the convenience of giving them occasional protection from inclement weather; but for particulars, in respect to the sorts, method of planting, and general culture, see the respective articles under their proper genera.

Likewise in this division should be planted a curious collection of the finest fibrous-rooted flowery plants, as carnations, polyanthus, auriculas, and many other curious sorts, arranging some of the most valuable in beds separately: others may be dispersed in different compartments, forming an assemblage of various sorts.

In other compartments may exhibit a variety of all sorts, both bulbous and fibrous-rooted kinds.

In some spacious Pleasure-grounds, various buildings and erections are introduced as ornaments to particular departments. For instance, light ornamental buildings, as temples, a banquetting-house, bowers, alcoves, grottoes, rural seats, cottages, fountains, obelisks, statues, and other edifices and devices, are often introduced in different parts in openings between and contiguous to the divisions of plantation and termination of grand walks, &c. Some of these kinds of ornaments, however, being expensive, are rather sparingly introduced; sometimes a temple is presented at the termination of a grand walk or opening, or sometimes a temple, banquetting-house, or bower is stationed in the centre of some spacious opening of grass-ground in the internal divisions; other parts present alcoves, bowers, grottoes, rural seats, &c. at the termination of different walks or openings, and with rural seats placed in different opens or breaks by the sides of long walks, under shade of trees, for places of rest, &c. Fountains and statues are generally introduced in the middle of spacious opens; statues are also of-

ten stationed at the termination of particular walks; sometimes in woods, thickets, and recesses, upon mounts, terraces, and other stations, according to what they are to represent.

Sometimes also there are exhibited root-houses, rock and shell-work, ruins, and other rustic devices, representing hermitages, caves, and the like; being generally stationed in some retired or private situation, and as these kinds of buildings being arched or vaulted, they are commonly covered with a coat of earth and turfed with grass, so as to appear like a sort of mount, hillock, or knoll, and planted with some little clumps of shrubs, &c. having private walks leading to the entrance.

Likewise in some parts is exhibited artificial rock-work, sometimes contiguous to some grotto, fountain, rural piece of water, &c. and planted with a variety of saxatile plants, or such as grow naturally on rocks and mountains.

Ornamental bridges over artificial rivers, or any rural pieces of water in some magnificent opening, so as to admit of a prospect thereof at some distance from the habitation, have a fine effect.

General Culture of the Ground.

With respect to the general culture of this ground, neatness must be ever observed in every part; the walks, lawns, shrubbery, clumps, &c. and the several compartments of trees, shrubs, and flowers, kept duly furnished with a proper stock of the various plants.

The gravel-walks must always be kept free from weeds and all sorts of litter, and should be rolled twice or three times a week in summer, particularly the principal walks, but never less than once a week; previously trim the edges close when necessary, especially if verged with grass-ground; pulling out all weeds, and lightly sweeping off all loose litter; and then roll them well with an iron or stone roller. The rolling in summer should be occasionally performed immediately after showers of rain, particularly the first after any continuance of very dry weather, to settle all the loose parts compact and smooth: in winter, the rolling should also be occasionally performed; observing, it is improper to break up the walks in that season in rough ridges as often practised, to remain in that unsightly manner till spring, whereby the walks are rendered useless at a time when there is hardly any dry or sound walking upon grass or other parts, besides their having a disagreeable slovenly appearance; I would therefore advise to have the walks remain undisturbed, at least till spring, when, if the surface is foul,

or mossy, they may be broken up, and turned the surface to the bottom, and the bottom to the top; directly tread, rake, and roll them smooth, proper for walking on. See GRAVEL WALKS.

All the principal grass lawns and walks within the limits of the Pleasure-garden should also be kept perfectly neat by frequent mowing in summer, to keep the grass short, close, and fine, like a fine pasture down or common; likewise poling it frequently with a long pole to scatter the worm-casts of earth which so greatly deface all grass; and give also occasional rolling both to clean up the scattered worm-casts to make the surface clean, and to render it firm and smooth. The poling and rolling of grass, where kept short in a close surface, should occasionally, in summer, be performed a day or two previous to mowing, whereby the mowing will be more easily, expeditiously, and effectually performed; observing, the mowing of grass-ground within the limits of the principal Pleasure-garden and home lawns, &c. will be necessary about once a week or fortnight, from March or April until September or October, choosing always dewy mornings, or moist weather, for this work, being careful to have each mowing performed with an even hand, not to score or leave the mark of the scythe at each stroke, which has a most disagreeable appearance; and directly after mowing sweep up all the swarths of grass as clean as possible into heaps and carry them away. See GRASS.

But rolling the grass should also be occasionally performed, sometimes with a heavy roller, at intervals, between the times of mowing, in order to continue the surface always firm, even, and of a close, smooth appearance.

In considerably extensive Pleasure-grounds, and large extended lawns, walks, &c. the rolling is sometimes done by horses, having a very large roller, furnished with horse-shafts; and the horses' feet occasionally muffled, especially when the ground is rather softish, to prevent their cutting the surface of the grass in holes.

Where numerous wild daisies deface the grass in May or June, as is sometimes the case, even often in a day after mowing, they may be headed down at a great rate with an old broad sword fixed in the end of a long pole.

Likewise keep all grass-ground clean from litter, such as fallen leaves of trees, &c. which may be expeditiously effected by a light broom or besom on a long handle. See BROOMS.

The edges of all principal grass-walks and those of grass-ground, next to gravel-walks in

particular, should always be kept close and even; which once a year in spring, when the gravel-walks are to be turned and new-laid, may be previously cut even slightly with an edging iron: after this, during the summer, they may be trimmed occasionally as the grass grows rank, either with the points of the garden-shears, with a pair of sheep-shears, or with the point of a knife; for if these edges are not kept close and even they have a slovenly appearance.

The shrubbery plantations should generally all be suffered to take their own natural growth, and branch out into full heads, only just giving a little occasional trimming to any very irregular growths, such as retrenching or reducing any very luxuriant rude shoots, or considerable ramblers, running wildly from all the other branches, and cut out all dead wood: likewise, for the general part, keep all the shrubs from interfering or intangling with one another, by shortening occasionally any straggling or rambling interfering branches, so as the head of each shrub may appear distinct, in which they will show themselves to proper advantage, and effect a more distinguishable variety.

Likewise in tree plantations some occasional pruning will also be sometimes necessary; such as trimming up the stems from low lateral branches, and pruning casual very irregular boughs above, long run-away ramblers, and very low overhanging branches of the head, reduced to order, either by lopping some more or less, or others cut clean out to their origin, as it may seem necessary; performed any time from the fall of the leaf in November till March; always cutting out decayed wood at any season when discoverable.

Observing, the best general season for performing those occasional regulations of pruning is, for the deciduous kinds, any time in winter or spring, when destitute of leaves, especially for any general trimming; though in particularly rambling growths, any time in summer, may also be pruned to order in that season, as required: but for the ever-green kinds, the most eligible season to give any principal pruning, is either summer, autumn, or in spring, about March or April, especially when any considerable trimming or cutting in may be occasionally required, as if performed in winter or very sharp weather, by laying the more interior tender parts immediately open to the cold, it often injures the leaves and young shoots; however, where only a little retrenching or shortening here and there a rambling shoot is necessary, it may be performed almost any time to any of the sorts;

but remarking, both of the deciduous and ever-green kinds, that when any general trimming is occasionally required throughout the different plantations, it is highly proper to perform it at the above-mentioned seasons, previous, in shrubberies, to giving the annual digging to the ground between the shrubs, &c. as directed below.

Where close thickets, however, are intended, no regulation in shrubberies, &c. need be observed, but let the various sorts run promiscuously.

The ground of the principal shrubbery plantations, in which the shrubs stand distant, not covering the surface, should generally be digged every year, in winter or spring; previously giving the shrubs any necessary pruning, as above observed; then dig the ground between neatly, one spade deep, trimming off any rambling suckers or spawn from the roots, leaving the surface of the ground level and smooth: this operation gives health and vigour to the plants, kills weeds, and gives the place an air of culture, and a lively neat appearance.

After this general digging the clumps, &c. the ground must be kept clean from weeds all summer, by occasional hoeing in dry weather, which with a Dutch scuffing-hoe may be expeditiously performed. See HOE and HOEING.

Great care is requisite to support with sticks all such plants as require it, particularly all such of the herbaceous tribe that are liable to be overturned by the wind, weight of wet, &c. for there is great merit in preserving all tall plants in an upright posture.

Keep likewise all the flower compartments in neat order by an annual digging, in autumn, winter, or spring; hoeing in summer to destroy weeds; at each hoeing always rake the surface smooth, particularly the principal borders and other compartments: likewise, according as the various plants grow up, let such as need support have sticks placed to preserve them upright; and as they have done flowering and their stalks decay, cut them down close, clearing off also all decayed leaves, and other rubbish, from time to time as they appear; taking up also the roots of curious bulbous flowers, as their leaves and stalks decay; and in autumn, about October or November, it is proper to give a general dressing, by cutting down all remaining decayed stalks, clearing off all weeds and litter, &c. and prepare to dig the ground: observing, if any manure or additional fresh earth is necessary, this is the time to apply it; so digging the ground neatly one spade deep, and then if any kinds of plants or roots are wanted, most of the

hardy kinds may either be planted now or in the spring; and finish with a neat raking, that the whole may lie clean and decent during the winter; and in spring stir the ground a little with a hoe or rake, or such as was not digged in autumn or winter, as above advised, must now be done; and finish putting in such plants that were omitted in autumn; then rake the ground smooth that every part may assume a fresh, neat, cultivated appearance in the spring and summer seasons.

All kinds of hedge-work and detached trained figures of ever-greens, should be shorn or clipped annually in summer with garden shears; but to keep them perfectly neat, twice every summer is necessary, the first in June, and the second in August or September. See HEDGES.

Also all edgings of box, &c. to walks, borders, and beds, should always be neatly clipped once or twice every year in summer; but to have them extremely neat, they should be clipped twice in that season, i. e. in May or June, and in August, or September, choosing principally moist weather, if possible, for if cut in very dry hot weather, the leaves change brown and unsightly: the same also happens if clipped in winter, or early in spring, while cold weather and frosty nights prevail, so should cut these edgings principally in summer. See BUXUS, article *Dwarf-box for edgings*.

All other edgings of thrift, pinks, daisies, London-pride, &c. should also be kept cut in on each side, every summer after the flowers are past, to keep them neat, and within due bounds, performing it in moist weather, as observed of the box edgings; likewise edgings of under-shrubby aromatics must have the operation of clipping annually performed at sides and top in summer: for all edgings should be kept low, narrow, and regular, otherwise they will appear clumsy and unsightly. See EDGINGS.

Likewise where edgings of box, thrift, daisies, &c. have become very disorderly, or grown rude, out of proper compass, or in any other considerable irregularity, they should, at a proper opportunity, be taken up, slipped, and replanted in regular order.

For particulars relative to the general culture of the various trees, shrubs, and flowers, see their respective genera.

Of Ancient Designs.

Designs, in ancient gardening, for a Pleasure-ground consulted uniformity in every part, exact levels, straight lines, parallels, squares, angles, circles, geometrical figures, &c. all corresponding in the greatest regularity, to effect an exact symmetry and proportion.

Straight

Straight walks were every where observed, and all arranged parallel, and crossing one another in regular intersections; generally a grand one of gravel was extended in a straight line immediately from the front of the main-house, having each side verged either with a regular straight border of earth, furnished with a variety of flowers, &c. and sometimes having a verge of grass three or four feet wide, then a border embellished as above with various plants; this main walk being often intersected by others at regular distances, so as sometimes to divide the space immediately in the front of the house into four, six, or more equal squares, some of which were sometimes formed into parterres, sometimes only naked grass-plats, or other uniform divisions; and often the whole garden was thus divided by straight, parallel, and intersecting walks, into many regular squares and angles, without any variation.

Grand parterres were very commonly presented immediately on the front of the main house, having a grand walk of grass or gravel directly from the house through the middle, or dividing the parterre ground into two divisions. See **PARTERRE**.

In the more interior parts, large tracts of ground were frequently divided by straight grass walks into many square and angular divisions of wilderness, each division surrounded by regular hedges of various kinds of trees and shrubs, kept in uniform order by an annual clipping; having the interior part of each quarter planted with trees and shrubs, which however were in a manner concealed by the hedges from persons in the adjacent walks, so that hardly any thing but close edges, the same thing over again, appeared to view, on each side of the walks; and all the walks generally led into uniform openings of grass, particularly to a grand circle or octagon, forming some central part.

Frequently there were partitions of regular hedge-work, particularly of ever-greens, surrounding large squares of grass ground, designed as pieces of garden ornaments, the hedge-work being often formed into various uniform devices; such as pilasters, arcades or arches, porticoes, galleries, amphitheatres, pavilions, cabinets, bowers, pediments, niches, and cornices; likewise regular arbors, having the sides formed into arcades, and sometimes the top vaulted; and with various other formal imitations, all performed in hedge-work, which were often so arranged and trained, as to effect an air of grandeur and art. High hedges were also in great repute, as boundaries to grand walks and avenues, sometimes

carried up from fifteen or twenty, to thirty or forty feet high; sometimes trained perfectly close from the very bottom to top, others open below a considerable way, and formed into regular arches, &c. all of which sometimes appeared magnificent and ornamental, but were troublesome and expensive to keep in order, on account of their great height: however, all sorts of hedge-work was generally esteemed so ornamental in ancient gardening, that almost every division was surrounded with regular hedges of one sort or other, presenting themselves to view in every part, shutting out all other objects from sight; but in modern designs hedges are rarely admitted; every compartment of plantation being left open to view from the walks and lawns, to have a full prospect of the various trees, shrubs, and flowers, which consequently are more beautiful than continual ranges of close hedges; but for the sake of variety, a little ornamental hedge-work might still be introduced in some particular parts of the ground. See **HEDGES**.

Wildernesses were always designed with the greatest uniformity, the ground being divided by walks into many squares and angles, all corresponding, and all the walks straight, and the principal ones all leading to some common centre or opening, &c. with all the quarters or divisions commonly surrounded with close hedges, as before observed.

Labyrinths or mazes of hedge-work, in the manner of a wilderness, also prevailed in many large gardens. See **LABYRINTH**.

Detached trained figures of ever-greens, as yew, cypress, juniper, holly, box, and various other close-growing ever-green plants, but principally yew, were also very predominant in ancient designs, and generally disposed in regular ranges along the borders and other verges of grand walks; being trained by clipping into various formal shapes, as pyramids, obelisks, columns, &c. in a variety of forms, with other formal figures, all placed in the most exact arrangement. Some also were often placed singly in the midst of some circle, octagon, or other open space, and were all kept in order by clipping once or twice every summer, and were considered as great ornaments.

Straight rows of the most beautiful trees, forming long avenues and grand walks, were in great estimation, which, though not often admitted in modern designs, were formerly considered as great ornaments, and no considerable estate and eminent Pleasure-ground were without several of them; but modern planners rarely introduce straight ranges of

trees for avenues or walks, but even often demolish old ones of a century or two standing, as being thought too formal; however, ranges of trees, forming spacious avenues, &c. about extensive grounds, always give an air of grandeur and dignity to the premises.

Regular grass slopes also greatly prevailed in most old gardens, as ornaments to particular divisions; sometimes were formed at the beginning of some rising ground, also sometimes at the termination, and frequently some low ground, canals, and other formal pieces of water, were bounded by a range of regular grass slopes; likewise, regular grass slopes formed the sides of terraces and other rising grounds. Moderate grass slopes also often formed a boundary to some open spaces, as a bowling-green, flower-garden, &c. forming a sort of terrace all round, having sometimes a gravel-walk at top; these slopes were always formed with the greatest regularity and exactness, which in some situations were very ornamental. They were of various dimensions in respect to height, from one foot to ten or twenty high, according to the nature of the situation and purpose they were designed for, in different parts; and some being ranged singly, others double, treble, or several one above another, on the side of some considerable rising ground, in a theatrical arrangement.

Regular terraces, either on a natural eminence or of forced ground, were also introduced for ornament, and for the sake of prospect, and of enjoying the fresh air in summer.

But as the above taste in the ancient style of designing gardens, being generally crowded every where with exact uniform divisions and formal figures, and the same thing often prevailing in almost every part, that even gardens of very considerable extent afforded very little variety; and the perpetual show of stiff formality of the same thing over again, together with the numerous surrounding hedges in every division, obtruding constantly upon the sight, obstructing that of other objects, becoming, at last, in a manner disgusting and unentertaining in the general appearance, to persons of taste and observation, most designs of that kind have been gradually discontinued and abolished from our principal English gardens; old gardens demolished and new modernised, often running into the contrary extreme in modern designs, by excluding all formal regularity and uniform appearances, and substituting various dissimilar arrangements in the general plan, in the formation of the different compartments in fancied imitations of natural rurality, as much as possible, as before observed.

However, for the sake of diversity, some of the more elegant regular works might still be admitted sparingly, in particular divisions, in contrast with the general rural performances, so as in some places to exhibit a grand straight gravel or grass-walk, in others a parterre, and in some places straight rows of the most beautiful trees, forming walks and avenues, and sometimes a range of hedge-work, and here and there a pyramid, &c. of some detached trained ever-greens; and sometimes a regular grass slope, formal terrace, &c. all of which, if judiciously disposed, might assist in diversifying the general scene.

PLENUS Flos, a full or most double flower; a flower having the greatest plenitude or multiplicity of petals, often to the diminution or entire exclusion of the parts of fructification.

Perfectly Full Flowers, whose multiplicity of petals obliterate the generative organs, consequently prove barren, *i. e.* rarely ever producing seed; but mostly all Full Flowers are varieties of singles, which are always the original species; so that the singles and half-doubles only produce the seed, and from which both double and single flowers are obtained; however, the full double flowers are esteemed the most beautiful, and are often the florist's and gardener's pride.

But all flowers of the above luxuriant nature are commonly called double flowers; observe, however, a Full Flower is to be considered as the highest degree of luxuriance or plenitude, as the petals are generally multiplied in many series to the very centre, so as frequently to choak up all the male and female organs, as sometimes happens in carnations, ranunculus, anemones, &c. a double flower, properly so called, may be said to have its series of petals only twice repeated; however, among gardeners and florists, all multiplied flowers, whether their petals are repeated but twice, thrice, or many times, are commonly all denominated double flowers, and are generally in the greatest estimation, as being the most delightful to the eye, in the opinion of gardeners, to cultivate for ornament.

But although full and double flowers are often the most beautiful to the eye, as just observed, yet they are to be considered as an unnatural increase and monstrous production; by Linnæus called vegetable monsters, because double flowers are only varieties of singles, varying by culture from their natural single or *characteristic* state; for the *characters* of the genera are always drawn from single flowers, never from full or double ones, whose number of petals often vary more or less by culture,

ture, and are never to be depended on to establish the *characters*.

Full or double flowers therefore, are varieties both of monopetalous and polypetalous flowers; for example, the hyacinth, tuberose, primrose, &c. being all monopetalous, or of one petal only, in their natural or *characteristic* state, yet the increase or repetition of the petals one within another is often continued to the very centre, choaking up the organs of fructification aforesaid; though perfect fullness is less frequent in flowers with one petal than in those with several. Polypetalous flowers therefore, such as carnation, anemone, ranunculus, marsh-marigold, columbine, poppy, pœony, tulip, crown-imperial, &c. all having several petals, are liable to all degrees of luxuriance, from the lowest to the greatest fullness.

The mode of luxuriance is effected either by a multiplication of the division of the limb or upper part of the petal, or of the petals entirely; and in flowers having nectariums, the impletion is often formed by a multiplication of the nectarium, as frequently occurs in columbine, narcissus, larkspur, &c.

Compound flowers are also liable to various degrees of luxuriance; as in African marigold, sun-flower, garden-daisy, feverfew, &c. For an account of this mode of impletion, see *COMPOSITUS flos*.

PLINIA, pedunculated Myrtle.

Comprises an exotic shrub for the stove, garnished with oval leaves and icofandrious flowers.

Class and order, *Icofandria Monogynia*.

Characters.] *CALYX*, a monophyllous cup divided into four or five parts. *COROLLA*, five or sometimes but four oval, concave petals. *STAMINA*, twenty or more capillary filaments, topped with small antheræ. *PISTILLUM*, a germen within the corolla, awl-shaped style, and simple stigma. *PERICARPIUM*, a large globose, furrowed drupe, containing large globose smooth seeds.

The species is,

PLINIA pedunculata.

Peduncled Brazilian inodorous Myrtle.] Rises with a branching stem, having a whitish bark, broad, oval, shining, opposite, scentless leaves, and naked pedunculi, sustaining solitary flowers with ciliated petals, succeeded by large globose fruit.

This plant flowering here in January and February, when few others are produced, recommends it for ornamenting the stove. It is propagated by seeds procured from abroad, which sow as soon as possible after their arrival in pots of rich mould, and plunge them

in the bark-bed, and they will come up the same season, or they may be increased by cuttings, in May or June, of the young shoots: plant them in pots of good earth, which plunge in the bark-bed, covering them with hand or bell-glasses, and giving occasional waterings, they will be fit to transplant separately the same year.

PLUMBAGO, Lead Wort.

This genus consists of some flowery perennials, of which, one is herbaceous, for the open borders, and the others are ligneous, or under-shrubby plants, for the stove; have fibrous roots, sending up slender stalks, three or four feet high, adorned with oval-spear-shaped leaves, and terminated by clusters and spikes of small monopetalous flowers.

Class and order, *Pentandria Monogynia*.

Characters.] *CALYX* is monophyllous, tubular, pentagonal, quinque-dentate, and permanent. *COROLLA* is monopetalous, funnel-shaped, divided above into five oval, spreading segments; and a nectarium of five very small valves, including the germen. *STAMINA*, five subulated filaments sitting on the nectarium, and small versatile antheræ. *PISTILLUM*, a very small oval germen, simple style, having a slender five-pointed stigma. *PERICARPIUM*, none; a single oval seed lodged in the permanent calyx.

There are, in our gardens, about four species, which are the following.

Hardy Herbaceous Kind.

1. *PLUMBAGO europæa*.

European Plumbago.] Hath thick, fibry, descending roots, sending up many slender, channeled stems, branching a yard high; spear-shaped, rough, amplexicaule leaves, and all the stalks and branches terminated by bunches of blue flowers in October.

Varieties.] With purple flowers — with white flowers.

They are all perennial in root, and annual in stalk; natives of Italy, &c. but succeed in the open ground.

Ligneous Stove Kinds.

These are somewhat under-shrubby, and are natives of India and America.

2. *PLUMBAGO zelanica*.

Ceylon Plumbago.] Hath a thick, juicy, acrid root; ligneous, very slender, branchy stalks, rising three or four feet high; oval, smooth leaves, having short foot-stalks; and the branches terminated by spikes of white flowers, appearing great part of the year.

3. *PLUMBAGO rosea*.

Rose Plumbago.] Hath slender ligneous stems, with gibbous or swelling joints; oval smooth leaves, having foot stalks; and all the branches

branches terminated by spikes of red flowers, great part of the year.

4. *PLUMBAGO scandens.*

Climbing American Plumbago.] With flexuose climbing stalks, and petioled, ovate, smooth leaves.

All these plants merit culture, to increase the variety of the flowery tribe; the first sort for the pleasure ground, and the other three to plant in pots, and place in the hot-house collection.

Their propagation is;

The first sort, by parting the roots in autumn, when the stalks decay.

And the second, third, and fourth sorts by seed, in a hot-bed, in the spring: they may also be tried by slips and cuttings, assisted by the same artificial heat.

PLUMERIA, Red Jessamine.

The plants are woody, succulent, flowery exotics, of South America; retained here in our hot-house collections for variety, rising several feet high; ornamented with oval, oblong, and spear-shaped leaves, and beautiful monopetalous, funnel-shaped, five-parted flowers, terminating the branches in clusters.

Class and order, *Pentandria Monogynia.*

Characters.] *CALYX* is small, obtuse, and five-parted. *COROLLA* is monopetalous, infundibuliform, with a long tube, widening upwards, and the top divided into five oblong, oval, erect, spreading segments. *STAMINA*, five awl-shaped filaments, having connivent antheræ. *PISTILLUM*, an oblong, bifid, germen, scarce any style, but a double, acute stigma. *PERICARPIUM*, two long, ventricose, acuminate, nutant, unilocular, and univalvular folliculi, having numerous oblong, imbricated seeds.

The species are;

1. *PLUMERIA rubra.*

Red Plumeria.] Rises with a woody, thick, succulent, branching stem, eight or ten feet high; large oval-oblong leaves, having short, biglandular foot-stalks; and the branches terminated by clusters of elegant, red, odoriferous flowers.

Variety.] With pale-red flowers.

2. *PLUMERIA alba.*

White Plumeria.] Rises with a woody, thick, succulent, branchy stem, eight or ten feet high; spear-shaped, pointed revolute leaves, and the branches terminated by clusters of white odoriferous flowers, with the pedunculi having tuberosc swellings above.

3. *PLUMERIA obtusa.*

Obtuse Plumeria.] Hath a woody, thick, succulent, branchy stem, rising ten or twelve feet high; spear-shaped, short, obtuse leaves;

and the branches terminated by clusters of fragrant white flowers.

4. *PLUMERIA pudica.*

Modest, or closed-flowered Plumeria.] Having all the flowers closed at the border.

All these plants flower here in our stoves, in summer, about July and August, but never produce seeds in England.

They being all exotics of the hot parts of America, require the indulgence of a hot-house all the year in this country; and are retained here in many curious gardens, as plants of variety and ornament, for the beauty of their stems, leaves, and flowers, particularly the latter, which rising in large clusters, make a fine appearance, six weeks or two months in summer, and have great fragrance; but those of the *Red Plumeria* are considerably the most beautiful.

All the three species are of a very succulent quality, both in stem, branches, and leaves; replete with a milky juice of a very caustic and poisonous nature.

As being all of the above succulent temperature, and exotics from the hot parts of the world, they must be potted in light, dry, sandy earth, and placed almost constantly in the stove, and supplied with proper waterings, which, however, as being succulents, must be applied with great moderation, particularly in winter, and they must be shifted occasionally into larger pots.

They are propagated by seeds and cuttings of their branches.

By Seed.—This is procured from the West Indies: sow it in pots of light sandy compost, and plunge them in a hot-bed under glasses, or in the bark-bed in the stove; they will readily grow; and when the plants are two or three inches high, prick them in separate small pots, which plunge also in the bark-bed, &c.

By Cuttings.—Any time in summer, take off some cuttings of the branches, which, previous to planting, as being very succulent, should be laid in the stove, or some dry place, a week, or more, as it shall seem necessary, till the wound made by the amputation from the parent plant is perfectly healed and dried over, to prevent their rotting; then plant them in pots of light dry earth, and plunge them in the bark-bed, giving occasional shade from the mid-day sun; and very moderate waterings; and they will be rooted in a month or six weeks.

POINCIANA, Barbadoes Flower-Fence, or Spanish Carnation.

It consists of shrubby flowering exotics of the Indies, proper for our hot-house collections; of upright branchy growth, garnished with decomposed pinnated leaves; and the branches

branches terminated by long spikes of beautiful pentapetalous flowers.

Class and order, *Decandria Monogynia*.

Characters.] CALYX, five oblong, concave, deciduous leaves. COROLLA is pentapetalous, four of the petals roundish, and nearly equal, and the fifth is larger, deformed, and crenated. STAMINA, ten very long, bristly, declinated filaments, having oblong antheræ. PISTILLUM, a long, awl-shaped, declinated germen, long style, and obtuse stigma. PERICARPIUM, an oblong compressed pod, having tranverse partitions, containing many plane nearly oval seeds.

The species are,

1. *POINCIANA pulcherrima*.

Fair Poinciana, or Double-spined Barbados Flower-Fence.] Hath a shrubby, upright, straight stem, branching ten or twelve feet high, armed with double spines, at each joint; large decompound, pinnated leaves, of numerous, oblong, obtuse folioles; and the branches terminated by long loose spikes, of large golden-yellow, beautifully variegated flowers.

2. *POINCIANA bijuga*.

Bijugated Single-spined Poinciana.] Rises with a shrubby, upright, straight stem, dividing into spreading branches, armed with short single spines; decompound pinnated leaves, of numerous, roundish, emarginated lobes; and the branches terminated by loose spikes, of yellowish purple flowers.

3. *POINCIANA elata*.

Loftier Spineless Poinciana.] Hath a shrubby, spineless stem and branches; bipinnated leaves, of many small oblong, oval, entire lobes; and loose spikes of flowers, having leathery cups, and very long, dark purple filaments.

These beautiful shrubs flower here in our stoves, in autumn, or beginning of winter, very ornamentally, imparting an agreeable fragrance; and are sometimes succeeded by ripe seed in England.

As they are exotics of both Indies, they must be always kept in pots, and placed constantly in the hot-house.

Their propagation is by seed, which we receive annually from the West Indies. Sow it in pots of light earth, and plunge them in any hot-bed, or in the stove bark-bed; they will soon come up abundantly, which when about three or four inches high, prick them into separate small pots, plunging them also in the bark-bed, till larger, giving occasional waterings, and they will make great progress. As they advance in growth, shift them with balls into larger pots; and grant them supplies of water, plentifully in summer, but

always very moderate in winter. Thus they will grow freely, advance fast in height, and in a few years begin to exhibit their elegant flowers.

POLEMONIUM, Greek Valerian, or Jacob's Ladder.

The plants are herbaceous, fibrous-rooted, flowery perennials, for the pleasure-ground, sending up annual stalks from about ten or twelve, to eighteen inches high, adorned with pinnated leaves, and terminated by bunches of monopetalous, rotated, five-parted flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is monopetalous, five-parted, and permanent. COROLLA is monopetalous and wheel-shaped, divided at top into five parts. STAMINA, five short inclined filaments, having roundish antheræ. PISTILLUM, an oval acute germen, filiform style, and a trifid revolute stigma. PERICARPIUM, a three-cornered, trivalved, trilocular capsule, having many irregular seeds.

The most noted species are,

1. *POLEMONIUM caruleum*.

Blue Greek Valerian, or common Jacob's Ladder.] Hath fibrous roots, crowned by a cluster of pinnated, many-lobed leaves, and upright, channeled, hollow stalks, about half a yard high; garnished with pinnated leaves, of several pair of alternate lobes, terminated by an odd one; and the stalks terminated by clusters of blue flowers, having the calyx larger than the corolla.

Varieties.] White-flowered — variegated-flowered — woolly-cupped.

2. *POLEMONIUM reptans*.

Creeping Greek Valerian.] Hath very creeping roots, upright branchy stalks, about a foot high, pinnated leaves, of several pair of narrow alternate lobes; and the stalks terminated by bunches of light blue flowers, nodding or drooping downwards.

Both the species flower in May and June; the flowers are always collected into bunches; and are succeeded by plenty of seed in autumn.

These plants are hardy: the first grows wild in thickets, in some parts of England, and other parts of Europe; and the second in Virginia; and both the sorts are cultivated in gardens for ornament, in the flower-compartments of the pleasure-garden; are abiding by the roots, and send up stalks annually in spring, for flowering.

Their propagation is by seed, and by parting the roots; but the seedlings are generally the finest plants: parting the roots, however, is the only certain method to continue

the

branches terminated by spikes of red flowers, great part of the year.

4. *PLUMBAGO scandens*.

Climbing American Plumbago.] With flexuose climbing stalks, and petioled, ovate, smooth leaves.

All these plants merit culture, to increase the variety of the flowery tribe; the first sort for the pleasure ground, and the other three to plant in pots, and place in the hot-house collection.

Their propagation is;

The first sort, by parting the roots in autumn, when the stalks decay.

And the second, third, and fourth sorts by seed, in a hot-bed, in the spring: they may also be tried by slips and cuttings, assisted by the same artificial heat.

PLUMERIA, Red Jessamine.

The plants are woody, succulent, flowery exotics, of South America; retained here in our hot-house collections for variety, rising several feet high; ornamented with oval, oblong, and spear-shaped leaves, and beautiful monopetalous, funnel-shaped, five-parted flowers, terminating the branches in clusters.

Class and order, *Pentandria Monogynia*.

Characters.] *CALYX* is small, obtuse, and five-parted. *COROLLA* is monopetalous, infundibuliform, with a long tube, widening upwards, and the top divided into five oblong, oval, erect, spreading segments. *STAMINA*, five awl-shaped filaments, having connivent antheræ. *PISTILLUM*, an oblong, bifid, germen, scarce any style, but a double, acute stigma. *PERICARPIUM*, two long, ventricose, acuminate, nutant, unilocular, and univalvular folliculi, having numerous oblong, imbricated seeds.

The species are;

1. *PLUMERIA rubra*.

Red Plumeria.] Rises with a woody, thick, succulent, branching stem, eight or ten feet high; large oval-oblong leaves, having short, biglandular foot-stalks; and the branches terminated by clusters of elegant, red, odoriferous flowers.

Variety.] With pale-red flowers.

2. *PLUMERIA alba*.

White Plumeria.] Rises with a woody, thick, succulent, branchy stem, eight or ten feet high; spear-shaped, pointed revolute leaves, and the branches terminated by clusters of white odoriferous flowers, with the pedunculi having tuberosc swellings above.

3. *PLUMERIA obtusa*.

Obtuse Plumeria.] Hath a woody, thick, succulent, branchy stem, rising ten or twelve feet high; spear-shaped, short, obtuse leaves;

and the branches terminated by clusters of fragrant white flowers.

4. *PLUMERIA pudica*.

Modest, or closed-flowered Plumeria.] Having all the flowers closed at the border.

All these plants flower here in our stoves, in summer, about July and August, but never produce seeds in England.

They being all exotics of the hot parts of America, require the indulgence of a hot-house all the year in this country; and are retained here in many curious gardens, as plants of variety and ornament, for the beauty of their stems, leaves, and flowers, particularly the latter, which rising in large clusters, make a fine appearance, six weeks or two months in summer, and have great fragrance; but those of the *Red Plumeria* are considerably the most beautiful.

All the three species are of a very succulent quality, both in stem, branches, and leaves; replete with a milky juice of a very caustic and poisonous nature.

As being all of the above succulent temperature, and exotics from the hot parts of the world, they must be potted in light, dry, sandy earth, and placed almost constantly in the stove, and supplied with proper waterings, which, however, as being succulents, must be applied with great moderation, particularly in winter, and they must be shifted occasionally into larger pots.

They are propagated by seeds and cuttings of their branches.

By Seed.—This is procured from the West Indies: sow it in pots of light sandy compost, and plunge them in a hot-bed under glasses, or in the bark-bed in the stove; they will readily grow; and when the plants are two or three inches high, prick them in separate small pots, which plunge also in the bark-bed, &c.

By Cuttings.—Any time in summer, take off some cuttings of the branches, which, previous to planting, as being very succulent, should be laid in the stove, or some dry place, a week, or more, as it shall seem necessary, till the wound made by the amputation from the parent plant is perfectly healed and dried over, to prevent their rotting; then plant them in pots of light dry earth, and plunge them in the bark-bed, giving occasional shade from the mid-day sun; and very moderate waterings; and they will be rooted in a month or six weeks.

POINCIANA, Barbadoes Flower-Fence, or Spanish Carnation.

It consists of shrubby flowering exotics of the Indies, proper for our hot-house collections; of upright branchy growth, garnished with decomposed pinnated leaves; and the branches

branches terminated by long spikes of beautiful pentapetalous flowers.

Class and order, *Decandria Monogynia*.

Characters.] CALYX, five oblong, concave, deciduous leaves. COROLLA is pentapetalous, four of the petals roundish, and nearly equal, and the fifth is larger, deformed, and crenated. STAMINA, ten very long, bristly, declinated filaments, having oblong antheræ. PISTILLUM, a long, awl-shaped, declinated germen, long style, and obtuse stigma. PERICARPIUM, an oblong compressed pod, having tranverse partitions, containing many plane nearly oval seeds.

The species are,

1. POINCIANA *pulcherrima*.

Fair Poinciana, or Double-spined Barbados Flower-Fence.] Hath a shrubby, upright, straight stem, branching ten or twelve feet high, armed with double spines, at each joint; large decomposed, pinnated leaves, of numerous, oblong, obtuse folioles; and the branches terminated by long loose spikes, of large golden-yellow, beautifully variegated flowers.

2. POINCIANA *bijuga*.

Bijugated Single-spined Poinciana.] Rises with a shrubby, upright, straight stem, dividing into spreading branches, armed with short single spines; decomposed pinnated leaves, of numerous, roundish, emarginated lobes; and the branches terminated by loose spikes, of yellowish purple flowers.

3. POINCIANA *elata*.

Loftier Spineless Poinciana.] Hath a shrubby, spineless stem and branches; bipinnated leaves, of many small oblong, oval, entire lobes; and loose spikes of flowers, having leathery cups, and very long, dark purple filaments.

These beautiful shrubs flower here in our stoves, in autumn, or beginning of winter, very ornamentally, imparting an agreeable fragrance; and are sometimes succeeded by ripe seed in England.

As they are exotics of both Indies, they must be always kept in pots, and placed constantly in the hot-house.

Their propagation is by seed, which we receive annually from the West Indies. Sow it in pots of light earth, and plunge them in any hot-bed, or in the stove bark-bed; they will soon come up abundantly, which when about three or four inches high, prick them into separate small pots, plunging them also in the bark-bed, till larger, giving occasional waterings, and they will make great progress.

As they advance in growth, shift them with balls into larger pots; and grant them supplies of water, plentifully in summer, but

always very moderate in winter. Thus they will grow freely, advance fast in height, and in a few years begin to exhibit their elegant flowers.

POLEMONIUM, Greek Valerian, or Jacob's Ladder.

The plants are herbaceous, fibrous-rooted, flowery perennials, for the pleasure-ground, sending up annual stalks from about ten or twelve, to eighteen inches high, adorned with pinnated leaves, and terminated by bunches of monopetalous, rotated, five-parted flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is monopetalous, five-parted, and permanent. COROLLA is monopetalous and wheel-shaped, divided at top into five parts. STAMINA, five short inclined filaments, having roundish antheræ. PISTILLUM, an oval acute germen, filiform style, and a trifid revolute stigma. PERICARPIUM, a three-cornered, trivalved, trilobular capsule, having many irregular seeds.

The most noted species are,

1. POLEMONIUM *caeruleum*.

Blue Greek Valerian, or common Jacob's Ladder.] Hath fibrous roots, crowned by a cluster of pinnated, many-lobed leaves, and upright, channeled, hollow stalks, about half a yard high; garnished with pinnated leaves, of several pair of alternate lobes, terminated by an odd one; and the stalks terminated by clusters of blue flowers, having the calyx larger than the corolla.

Varieties.] White-flowered — variegated-flowered — woolly-cupped.

2. POLEMONIUM *reptans*.

Creeping Greek Valerian.] Hath very creeping roots, upright branchy stalks, about a foot high, pinnated leaves, of several pair of narrow alternate lobes; and the stalks terminated by bunches of light blue flowers, nodding or drooping downwards.

Both the species flower in May and June; the flowers are always collected into bunches; and are succeeded by plenty of seed in autumn.

These plants are hardy: the first grows wild in thickets, in some parts of England, and other parts of Europe; and the second in Virginia; and both the sorts are cultivated in gardens for ornament, in the flower-compartments of the pleasure-garden; are abiding by the roots, and send up stalks annually in spring, for flowering.

Their propagation is by seed, and by parting the roots; but the seedlings are generally the finest plants: parting the roots, however, is the only certain method to continue the

the variegated kind, and any other singular variety.

By Seed.—Sow it in spring, in any bed or border of common earth, and rake it in; the plants will soon come up abundantly, which, when two or three inches high, prick out a quantity in nursery-rows, six inches asunder, to remain till autumn; then may be transplanted, where they are finally to remain; and they will flower the following summer.

By parting the Roots.—Autumn, when the stalks decay, or early in spring, before new ones begin to shoot, is the proper time; and is performed in the common way.

POLLEN, Meal, the prolific powder, or fecundating dust contained in the antheræ, or tops of the stamina in flowers.

This Pollen is generally a very fine meal or powder, being the male dust in vegetables, corresponding to the seminal fluid in animals; is very generally of a yellow colour; and being discharged, and dispersed by the bursting of the antheræ, upon the stigma of the pistillum or female organ, impregnates the ovary of the germen, or seed-bud below, which then, in the progress of vegetation, swells, becomes a fruit or seed-vessel, furnished with fertilised or prolific seeds.

The dust in question is very conspicuous in many flowers, as tulip, lily, cucumber, &c. and is supposed to contain a fine liquid substance, not distinguishable by the naked eye, and discharged by elastic force in its dispersion, for the impregnation of the female.

This said Pollen, or male dust, in its fecundating office, is generally effected by nature, for the impregnating the female organs; though it may be proper to remark, that in one particular instance, it is sometimes effected by art, such as in the culture of early cucumbers in frames, in which the impregnation is very generally accomplished by detaching some of the male blossoms, and applying the antheræ, thereof, loaded with its yellow powder, to the stigma of the female or fruit blossom, and a sufficiency of the Pollen adhering thereto, the young fruit under the corolla being then fertilised, it, in two or three days after, will discover its impregnation by its advancing growth.—See CUCUMERS.

POLYANTHES, Tuberose, or Indian tuberous Hyacinth.

It is an herbaceous, bulbo-tuberous-rooted, beautiful flowery perennial, an exotic of India, rising with annual stalks, three or four feet high, terminated by a long spike of many large monopetalous, six-parted, liliaceous flowers, of great beauty, and delightful fragrance.

Class and order, *Alexandria Monogynia*.

Characters.] CALYX, none. COROLLA is monopetalous, infundibuliform, with an oblong incurved tube, divided above into six oval spreading segments. STAMINA, six thick obtuse filaments, terminated by very long linear antheræ. PISTILLUM, a roundish germen, slender style, crowned by a thick trifid stigma. PERICARPIMUM, a roundish, obtusely trigonal capsule, with three cells, having numerous, plane, semi-orbicular seeds, in a double range.

There is but one species, consisting of some varieties, all of which being exotics of tender quality, requiring aid of artificial heat, under shelter of frames and glasses, or in a hot-house, &c. to bring them to flower in perfection in this country.

The species is,

POLYANTHES *Tuberosa*.

Tuberosa or *Tuberoſe*.] Hath an oblong, bulb-like, tuberous, white root, crowned with a few long very narrow leaves; amidst them an upright, straight, firm stem, three or four feet high, terminated by a long spike of large white flowers, arranged alternately.

Varieties.] Common Tuberose, with single flowers, —double-flowered, —dwarf-stalked, —variegated leaved.

They all flower here in June, July, and August: the flowers are funnel, or bell-shaped; garnish the upper part of the stem, in a long spike, consisting from ten to twenty or more separate flowers, in alternate arrangement; the lower flowers opening first, which are succeeded by those above, in regular order, making in the whole a most beautiful appearance, highly enriched with a most fragrant odour.

The common single-flowered Tuberose is the sort the most commonly cultivated, as it generally blows the most freely, and possesses the finest fragrance.

The double-flowered kind, also highly merits culture, as when it blows fair, it makes a singularly fine appearance.

The dwarf, and the variegated kind, are inferior to the other two, but may be cultivated for variety.

All the varieties being exotics from warm countries, although they are made to flower in great perfection in our gardens, by assistance of hot-beds, they will not prosper in the open ground, and do not increase freely in England; so that a supply of the roots is imported hither annually from Genoa, and other parts of Italy, by most of the eminent nursery and seedsmen, and the Italian warehouse-keepers; generally arriving in February or March, time enough for the ensuing

ensuing summer's bloom; and are sold commonly at the rate of twelve or fifteen shillings per hundred, being careful always to procure as large roots as possible, for on this depends the success of having a complete blow.

They requiring artificial heat to blow them in this country, are planted in pots, and plunged in a hot-bed, under a deep frame, furnished with glass lights; or placed in a hot-house, where they may be blowed to great perfection, with little trouble.

The principal season for planting them is March and April; observing, however, that in order to continue a long succession of the bloom, it is proper to make two or three different plantings, at about a month interval; one in March, another in April, and a third the beginning of May; whereby the blow may be continued from June until September; observing, as above mentioned, they may be flowered either by aid of a common dung, or bark hot-bed, or in a hot-house; and the following are the methods.

First - by common Hot-beds.—In March or April, &c. as above observed, make a moderately substantial hot-bed of dung or tan, in dimensions suitable to any of the deepest hot-bed frames; and when the bed is become of a proper temperature of heat, prepare to put in the roots, previously planting them in pots, as directed below; observing, that if a dung hot-bed, lay in six inches depth of earth, or old tan, in which to plunge the pots, but if of bark or tan, no earth is necessary, as the pots may be plunged immediately into the bark.

The hot-bed being ready, and having procured the roots, and some proper sized pots, twenty fours, one for each root; then having light rich earth, fill the pots therewith; and, after having divested the roots of all loose outer skins, and all off-sets, plant one in each pot, in depth, so as the top of the root be about an inch below the surface of the earth: this done, directly plunge all the pots in the hot-bed close together, or so as the bed may contain the number required; and as soon as they are all thus placed, put on the lights of the frame.

Being thus planted and placed in the hot-bed, observe their culture as follow: admit a portion of fresh air daily, by tilting the upper ends of the lights; but keep them close down on nights: give also moderate waterings, which however apply very sparingly, till the roots begin to shoot; then repeat the waterings moderately as you shall see occasion; likewise observing, that when the shoot be-

gins to advance, to admit fresh air more freely, in proportion, to strengthen the stems, according as they advance in height: and when they have risen near the glasses, it is proper to deepen the frame, either by the addition of another at top, or by raising it at bottom six or eight inches, in order to give the stems sufficient room to shoot to their full stature, repeating this, once or twice, as the growth of the plants renders it necessary, still also assisting them with plenty of water, and a large portion of fresh air daily, either by raising one end of the lights as above-said, or that when the plants are advanced some tolerable height, and the warm season also a little advanced, the lights may be taken away entirely occasionally in fine mild days, which will strengthen and inure them gradually to the full air: but always draw the lights on again towards the evening, or at the approach of a sharp air, cold blast, or heavy rains; observing, towards the middle or latter end of May, or beginning of June, according to the temperature of the season, to begin to expose them fully, only giving occasional shelter in cold nights, or very wet weather, either of the glasses, or mats supported on hoop arches, till they begin to flower, which will be about the middle or latter end of June, or beginning of July; when the plants in their pots may be removed where wanted; either to adorn any of the garden compartments, or any apartment of the habitation.

Place to each plant a tall straight stake; to which fasten the stem for support.

They must still be duly supplied with water all the time of their bloom; they will require it every other day, or oftener, in very hot dry weather.

Observe, as aforesaid, that, in order to continue a long succession of bloom of this flower, two more parcels of roots should be planted at about a month's interval, in April and May, &c. each planting to be in pots, as already directed; and plunged in a hot-bed under shelter of frames and glasses, or an awning of mats every night and cold weather: those, however, planted late in April or in May, will need only a moderate hot-bed, just to let the roots going at first, and will succeed tolerably, with only a protection of hoop arches across the bed, for the support of mats occasionally in cold nights.

Sometimes roots planted in May in the full ground, will shoot tolerably strong, and produce flowers in autumn.

It is however the most eligible way to allow them the assistance of a hot-bed as above, otherwise of a hot-house, as directed below;

for one or other of these aids is the only method by which we can blow these flowers in full perfection.

By assistance of a Hot-house.] Where there is the convenience of a hot-house, we may blow tuberoses in great perfection with very little trouble. Plant the roots any time in spring, March, April, or May, in pots as above advised; and if there is room in the bark-bed, plunge them to their rims; if not, place the pots any where towards the front of the house; but they will shoot more freely if plunged in the bark-bed; give occasional waterings as directed in the hot-bed culture, and they will shoot and flower strong in their due season; and by a repetition of planting a few at three or four weeks interval, you may continue a bloom from April or May, until autumn.

Method of Propagation.

With respect to the propagation of these plants, it is principally by off-sets of the roots.

The blowing roots that are brought annually from abroad, for sale, are often furnished with off-sets, which ought to be separated, previous to planting; those also that are planted here in our gardens, frequently furnish off-sets, fit for separation in autumn when the leaves decay; they must then be preserved in sand all winter in a dry sheltered place; and in the beginning of March, plant them either in a bed of light dry earth in the full ground, or to forward them as much as possible, allow them a moderate hot-bed, and in either method indulge them with shelter in cold weather, either of a frame and lights, or arched with hoops, and occasionally matted; but let them enjoy the full air in all mild weather, giving also plenty of water in dry weather, during the season of their growth in spring and summer.

Thus let them grow till their leaves decay in autumn; then take them up, clean them from earth, and lay them in a box of dry sand to preserve them till spring, at which time, such roots as are large enough to blow may be planted and managed as already directed, and the smaller roots plant again in a nursery-bed, to have another year's growth; afterwards plant them for flowering.

POLYGALA, Milk-wort.

This genus furnishes for our garden collections, several species of herbaceous, and ligneous, under-shrubby perennials, mostly as ornamental flowering plants, for the pleasure-ground and green-house, and of which one in particular is peculiarly valuable in some medicinal applications, all of which rising with slender stalks of moderate growth, from about eight, or ten, to eighteen inches and two

or three feet high, in the different species, adorned with small spear-shaped, oblong, and oval leaves, and large irregular papilionaceous flowers in lateral and terminal spikes in May, June, &c.

Class and Order, *Diadelphia Octandria*.

Characters.] **CALYX**, a small cup of three oval, acute, permanent leaves. **COROLLA** is papilionaceous, with two large oval, plane wings, placed beyond the other parts, a short tubulous vexillum a little reflexed and bifid at top, and a concave, compressed carina, ventricose towards the apex. **STAMINA**, diadelphous filaments crowned with eight simple antheræ. **PISTILLUM**, an oblong germen, simple erect style, and bifid stigma. **PERICARPIUM**, a turbinate, heart-shaped, compressed capsule, bivalvous, with two cells, each containing one oval seed.

The most material species are,

1. **POLYGALA vulgaris.**

Common Milk-wort.] Hath a long white root, sending up slender herbaceous stalks, inclining to the ground, six or eight inches in length, narrow spear-shaped, pointed smooth, bright-green leaves; and the stalks terminated by crested spikes of flowers in June, succeeded by ripe seeds in August.

Varieties.] Blue-flowered,—red-flowered,—white—violet-coloured,—striped.

2. **POLYGALA amara.**

Bitter Milk-wort.] With large oval radical leaves, erect herbaceous stalks, six to eight or ten inches high, terminated by crested spikes of blue, and other coloured flowers, in the different varieties, in June, &c. succeeded by ripe seeds in autumn.

3. **POLYGALA senega.**

Senega Rattle-snake root.] Hath a thick, fleshy perennial root, consisting of many jointed tubercles, striking deep in the ground, from which arise three or four herbaceous stalks, about half a yard high, garnished with broad spear-shaped leaves, placed alternate, and terminal spikes of smaller white flowers in July; but seldom succeeded by ripe seeds in this country.

This last species possesses peculiar medicinal virtues in its roots, particularly as a sovereign and infallible remedy for the bite of the rattle-snake, applied both outwardly and inwardly; and for which, in America, it has been long successfully used by the Senega Indians; also by the inhabitants of Virginia of late years with considerable success in many disorders; is said to be a powerful purifier of the blood, a fine diuretic, &c. and used in hydropic cases, and pleuritis.

All these three species are proper plants to be

be introduced in the pleasure-ground, and most of them will effect an agreeable variety; the first two sorts are hardiest to succeed always in the full ground, but some of the others should have occasional protection in severe winters from frost.

They are all propagated by seed, which in the first and second may be sown either soon after ripe, or in the spring; the plants will come up freely proper for pricking out or transplanting in summer and autumn; the third sort is also raised in the same manner, but require protection from the frosts in winter; and the seed, which is generally procured from America by the seed dealers, should be sown in a light, warm sandy soil; and have protection as above.

Tenderer kinds for the green-house, mostly under-shrubby.

4. *POLYGALA chamæ-buxus.*

(*Chamæ-buxus*)—*Dwarf-box Milk-wort, or Myrtle-leaved Polygala.*] Rises with slender, ligneous, under-shrubby stalks and branches of moderate growth, closely garnished with numerous small oblong, spear-shaped, bright shining-green leaves; and lateral and terminal crested or tufted flowers, white on the outside, and with a mixture of purple and yellow within; very odorous, appearing in May, or June and July.

5. *POLYGALA microphylla.*

Small-leaved, under-shrubby Portugal Milk-wort.] Having slender ligneous stalks branching ten or twelve to fifteen inches high; minute, oval awl-pointed, sessile leaves, and terminal short spikes of large flowers, often of different colours, appearing in May and June; and the seeds ripen in August.

6. *POLYGALA spinosa.*

Thorny African Milk-wort.] With shrubby stem and branches, oval, acute-pointed leaves, and lateral flowers.

7. *POLYGALA chinensis.*

Chinese Decumbent Milk-wort.] With under-shrubby, short decumbent stalk and branches; ovalish leaves, and axillary spikes of flowers.

8. *POLYGALA histeria.*

(*Histeria*)—*or, triangular-leaved African Milk-wort.*] With a shrubby tree-like stalk, and triangular, sharp, thorny-pointed leaves.

Of these green-house kinds the first and second are the principal sorts in our English green-house collections, they being curious little shrubby ever-greens, very closely set with their numerous leaves, and they flower very ornamentally in the principal summer months; any of the others are also proper to introduce in the same collection, to increase

the variety: one mode of culture is applicable to the whole, being the same as for other shrubby exotics of the green-house.

They are raised from seed, and occasionally by cuttings: sow the seed in autumn or spring in pots, and protected from inclement weather; or may be sown in March and forwarded in a hot-bed; and by the same assistance may raise some from cuttings and slips, &c. in spring and summer.

POLYGAMIA, the name of the twenty-third class in the Linnæan sexual arrangement of plants, expressive of the polygamy, (many marriages) or inter-communication of different sexes in the plants belonging to that class, by means of their flowers, being both hermaphrodite, and also male or female flowers, or both, on the same or different plants of the same family.

All polygamous plants, which constitute this class, are distinguished by bearing always hermaphrodite flowers, and flowers either male or female, or of both these sexes, either in some all on the same plant, or in others, on two or three distinct plants in the same genus; and from these different circumstances of polygamy, this class is divided into three orders. See **CLASSIS**.

This polygamy of plants occurs variously in different genera in this class.

For instance—in the first order, *Polygamia monœcia*, the polygamy in one habitation, consisting of hermaphrodite and male flowers on the same plant, as in *acer*, *atriplex*, *celtis*, &c. hermaphrodite and females on the same plant, as in *mimosa*: male hermaphrodites and female hermaphrodites on the same plant, as in *musa* only, being such as, although the flower contains the parts proper to each sex, have one of the said sexual parts reciprocally abortive or ineffectual; which, if in the stamina or male, is styled a female hermaphrodite; and if the defect is in the female, is a male hermaphrodite; according as either sex is predominant in all its parts.—In the second order, *Polygamia diœcia*, the polygamy in two habitations or distinct plants, comprehending such as are hermaphrodites and females, on two separate plants of the same species, as in *fraxinus*: hermaphrodites and males on two different plants, as in *diospyros* and *nyssa*, &c. hermaphrodites and males, and females on two distinct plants, as in *gleditsia*; having the hermaphrodites and males on one plant, and the females on a distinct one; and by androgynous and males on two separate plants, as in *panax* and *anthospermum*, &c.—Third order, *Polygamia triœcia*, the polygamia in three habitations

tions or distinct plants, being such as have androgynous, and male and female; in three separate plants of the same species, as in *figus* and *ceratonia*; in which one plant has the female flowers, another the male, and a third is androgynous, i. e. producing both male and female flowers distinct. See *Ficus*, &c.

Polygamy also relates to the inter-communication of the different florets which compose a compound flower, as prevail in most of the orders in the class *Syngenesia*, each main flower consisting of many smaller ones called florets; and are frequently of different sexes, as in *tanacetum*, *aster*, *tagetes*, *chrysanthemum*, *xeranthemum*, *calendula*, &c. which in some are hermaphrodite and females, in others males in the disk and females in the radius, all, in both cases, in the same general flower. See class *Syngenesia*, under the article CLASSIS.

POLYGONUM, Knot-grass.

This genus consists of herbaceous perennials and annuals for adorning the pleasure-garden, and for medical and other uses; rising from about six inches to ten feet high, in different sorts, garnished with oval and spear-shaped leaves, and terminated by branchy spikes of small but numerous apetalous flowers.

Class and order, *Ostendria Trigynia*.

Characters.] CALYX is divided into five oval segments, coloured within, and permanent. COROLLA, none; there being no petals. STAMINA, eight very short filaments, crowned with roundish antheræ. PISTILLUM, a triquetrous germen, three very short styles, and simple stigmas. PERICARPIUM, none; each floret having a single triquetrous seed wrapped in the permanent calyx.

The principal species for our purpose are two perennials, and two annuals.

Perennial Kinds.

These are cultivated in many gardens for variety, but their chief merit is for medical use.

1. POLYGONUM, *Bistorta*.

Bistort or Greater Snake-weed.] Hath a thick oblique intorted root, blackish without, and red within; a simple round slender stem near two feet high, oval leaves, having decurrent foot-stalks, and the stalk terminated by thick short spikes, of whitish-red flowers.

2. POLYGONUM, *viviparum*.

Viviparous Polygonum, or smaller Bistort.] Hath a thickish root, a simple slender stem, half a foot high, spear-shaped leaves, and the stalk and branches terminated by long spikes of whitish-red flowers.

Both these perennials flower in May and June, succeeded by ripe seeds in August.

They grow wild in England, &c. the first in moist places, the other in mountainous situations; are in great estimation for medical purposes; the root being the part used.

Annual Kinds.

The first of these is a noble ornamental plant, commonly called *Perficaria*; the other is an esculent.

3. POLYGONUM *orientale*.

Oriental Polygonum, commonly called Perficaria.] Hath fibry roots; an upright, strong, jointed stem, rising eight or ten feet high, dividing at top into several branches; very large oval-lanceolate alternate leaves, on broad foot-stalks half surrounding the stem; and all the branches terminated by long, slender, hanging spikes of reddish-purple heptandrous and digynous flowers, from July till October.

Variety.] White-flowered oriental *Perficaria*.

They are noble annuals for the decoration of the large compartments of the pleasure-garden.

4. POLYGONUM *Fagopyrum*.

Buck-wheat, or Brank.] Rises with an upright smooth branchy stem, from about a foot and a half to a yard high, heart-shaped-sagittated leaves, and the branches terminated by clusters of whitish flowers, succeeded by large angular seeds; excellent for feeding pigeons, and most sorts of poultry.

All these plants are hardy, and succeed in almost any soil and situation; the two first are perennial in root, and the third and fourth are annual, wholly decay at the end of summer, or early in winter.

As to their merit in gardening, the following are the particulars:

The first two sorts are retained in some curious gardens, for variety; but their chief merit is for medical purposes: they are powerful astringents, and are used both internally and externally; esteemed very efficacious in hæmorrhages, and other fluxes; and good to heal sore mouths.

Third sort *Oriental Polygonum*, or *Perficaria*, is a most elegant annual for the embellishment of the pleasure-ground; it assuming a majestic tree-like growth by its erect luxuriant stem, and branchy head; which being garnished with noble large foliage, and numerous pendulous spikes of flowers, in constant succession three or four months, exhibits a very ornamental appearance from June or July, until October, and is so easy of culture, that from its scattered seeds in autumn young plants rise spontaneously in abundance the ensuing spring, and also from seeds regularly sown

sown in those seasons, or more generally the latter, both in the full ground in patches to remain, and for transplanting, or likewise forwarded by sowing in a hot-bed in March, &c. for transplantation into the borders; and thus raised by either method, the plants shoot up so rapidly, as to attain six or eight feet stature by July or August, when they generally begin flowering, and continue till attacked by the frost, then totally perish; so that a fresh supply must be raised from seed annually.

The fourth sort (*Buck-Wheat*) is a sort of corn, and is frequently cultivated both by way of fodder, cutting its stalks while young and green to feed cattle; and for its grain to feed pigeons, poultry, hogs, &c. it flourishes in any soil and situation, but generally thrives best in light dry earth; and the driest seasons seldom retards its growth.

Method of propagating all the Sorts.

The first and second sort are easily propagated in plenty, by parting the roots in autumn.

The third sort, *Oriental Polygonum*, being annual, is always propagated from seed annually; either in the full ground, or by aid of hot-beds.

By sowing in the full ground.—Some seed may be sown both in autumn, as soon as ripe, and in spring, some scattered thinly about the borders, and the principal part sown regularly in patches; the autumn-sown plants, although they rather rise sparingly, yet those that succeed, generally rise earlier and stronger in the spring following, than the spring-sown plants; it is however proper to sow in both seasons; some of which may be in a warm border for transplanting; and others about the borders in patches, finally to remain, covering the seed half an inch deep; they will come up about April or May, if a fine season; which, when three or four inches high, those designed for transplantation should be planted out singly, about the different compartments; and of those sown in patches, thin out the weakest in moist weather, leaving only one of the strongest plants in each patch; and those thinned out, may also be planted singly where they may be required. According as the plants in general advance some considerable height, place a stout stake to each for support, which is all the culture they require; and they will flower in due season, and furnish plenty of seed.

From the scattered or self-sown seed in autumn, many young plants often rise in spring, and flourish without any trouble.

By hot-beds.—As sometimes in bad seasons, or in cold wet soils, the sowings in the

full ground either rise but sparingly, or not till late in spring, probably May or June; it is therefore proper also to sow some in a hot-bed in March, with other annuals, such as African and French marigolds, China asters, &c. for transplantation, which will forward them considerably; but they must be planted out in May or June before they draw up; or if previously pricked upon another hot-bed, six or eight inches asunder, and arched over with hoops, and sheltered with mats in cold nights; and here to have three or four weeks growth, it would bring them more considerably forward, and they may readily be moved with large balls of earth about their roots, for their final transplantation.

The fourth species, *Buck-Wheat*, is also propagated by seed annually, in any open ground, which sow in April or May, either broad-cast, and raked, or harrowed in, or in shallow drills, ten or twelve inches asunder, the plants will soon come up, and be fit to mow for cattle in eight or ten weeks, or if to stand, will produce a crop of grain in three or four months.

POMUM, Apple, a fleshy fruit, and species of seed-vessel both of many sorts of trees, and some herbaceous plants.

Of this kind of seed-vessel is all the Apple and Pear kind, quince, medlar, pomegranate, gourd, &c. composed of a succulent fleshy pulp, generally of a round, globular, oval, turbinate form, in that of different species of trees and plants, without any valve or external opening, inclosing in the middle a membranous capsule of several cavities or cells for containing the seeds; which in the natural order are confined to their cells till the fruit decays, as this kind of seed vessel has no opening for their dispersion, there being only in some sorts a small close cavity or *umbilicus*, the navel or eye of the fruit at one end, as in apple, pear, quince, &c.

POPULUS, Poplar-tree; comprehending the Abele, and Aspen-tree, &c.

This genus is composed of hardy deciduous trees, valuable for ornamental and forest-tree plantations; they rising to a considerable height and magnitude, garnished with large roundish angulated and heart-shaped simple leaves, and dioecious apetalous flowers, collected into long amentums.

Class and order. *Diæcia Octandria*.

Characters.] CALYX, male and female flowers on two separate trees, collected into oblong, loose, imbricated amentums, composed of oblong scales, each scale forming a cup to a single floret. COROLLA, no petals, but a monophyllous nectarium. STAMINA, eight filaments,

filaments, having large four-cornered antheræ. PISTILLUM, an oval acuminate germen, very short style and quadrid stigma.—PERICARPUM, an oval bilocular capsule, and numerous oval pappous seeds.

There are several species, all of the tree kind, deciduous, and of hardy temperature; will thrive in almost any soil and situation, but are the most prosperous in moist grounds, particularly the first three sorts, which thrive exceedingly in marshy or boggy land, or any similar situation.

The species of most consideration are,

1. *POPULUS alba*.

White Poplar, commonly called Abele-tree.] Rises with an upright straight trunk, and regular branchy head, to a great height, having a whitish smooth bark, roundish leaves, indented into several angles, of a dark-green above, and are downy and white underneath.

Comprises these Varieties.] Large-leaved White Poplar — small-leaved — variegated-leaved.

2. *POPULUS nigra*.

Black Poplar.] Rises with a straight trunk, and full branchy head, to a considerable height; having deltoid-heart-shaped, acuminate, serrated, light-green leaves.

3. *POPULUS tremula*.

Tremulous Poplar, or Aspen-tree.] Rises with an upright large trunk, and a full branchy head, many feet high, having a grey bark, roundish leaves indented into angles, smooth on both sides, with a constant tremulous motion.

The leaves of this species having long slender foot-stalks, are rendered so very tremulous, that they have a constant wavering or trembling motion; hence the name *Populus tremula*.

4. *POPULUS angulata*.

Angulated Carolina Poplar.] Rises with an upright large trunk, and a large regular branchy head, to a great height, having a whitish smooth bark, and the young shoots cornered or angulated; large almost heart-shaped, indented, light shining-green leaves.

This is a very elegant species of *Populus*, of very free growth, and the leaves remarkably large and ornamental.

5. *POPULUS heterophylla*.

Heterophyllous, or variable-leaved Virginia Poplar.] Rises to a great height, having large heart-shaped and roundish leaves, hairy at their first appearance.

6. *POPULUS candicans*.

Tacamahac Poplar, or Balsam-tree.] Is of moderate growth, branching out into a full regular head, having middling-sized leaves,

some ovalish, others somewhat heart and spear-shaped, whitish underneath, and of a very balsamic odoriferous nature. In this species of Poplar, the early buds and young leaves abounding in a very balsamic substance of salutary medical property, is exceedingly efficacious in immediate application to fresh cuts and green wounds.

7. *POPULUS (italica) dilatata*.

Lombardy Poplar.] Rises with a very straight stem, branching erectly, forming a regular pyramidal head, and grows to some considerable height; having large, roundish, acuminate, smooth, light-green leaves: is a remarkable fast shooter.

8. *POPULUS canadensis*.

Canada round-leaved Poplar.] Rises with a straight erect stem, regularly branching to a considerable height, covered with a whitish bark, and garnished with roundish light-green leaves, terminating in an obtuse point, and the border waved.

9. *POPULUS græca*.

Grecian, or Athenian Poplar.] Rises with a straight upright whitish stem, branching swiftly, four or five feet in a year, to a lofty growth; garnished with large heart-shaped leaves, remotely crenated, and glandulous at the base.

In all these trees the leaves are universally of the simple kind, moderately large, and form a distinguishable diversity in plantations in summer; they expand in spring and decay in autumn, like the rest of the deciduous tribe.

All the sorts flower annually in the spring, but the flowers being only small katkins, make no ornamental show; they are all of the class *Diacia*, i. e. male and female on two separate trees, collected into oblong imbricated amentums or katkins, two or three inches long, the flowers being small florets without petals, situated under the scales of the amentum, appear commonly in March or April; the males come out first, and the females in a week after, and in about five or six weeks are succeeded by ripe seed, which is frequently disseminated by the winds all around to a considerable distance, and often productive of many young plants.

These trees are all of remarkably quick growth, often making shoots whilst young, from three or four to eight or ten feet long in one summer; they are mostly of the large tree kind, and some rise swiftly to a considerable altitude in their general growth; are principally somewhat of the aquatic tribe, delighting to grow in humid soils, in which, at least, they are generally the most prosperous in swiftness and magnitude of growth; they however,

however, succeed almost any where, not reluctant to any soil or situation, moist or dry, low or elevated, as it happens; so may be planted accordingly as required; and in most soils, they will shoot freely and run up very expeditiously; but of which the Lombardy Poplar is superior as the swiftest shooter, and peculiar regularity of growth, in its numerous erect branches generally in a pyramidal form, and in a few years advancing to a considerable height, for which particularities, where a defensive plantation is required in haste, in any particular district, this sort is preferable on that occasion, though I would not advise its use so predominantly as now introduced in many places, in continual outward ranges next road sides, and in front of houses and fore-courts, &c. in which hardly any thing of the tree kind is seen but Lombardy Poplars without variation.

But with respect to the general utility of the different species of Poplar in gardening and planting, they may be employed in assemblage for ornament in out-grounds, not near fine lawns and walks, on account of the great litter the falling of their catkins in some sorts occasion; but are excellent for planting towards the boundaries of parks, paddocks, and fields, the sides of rivers and brooks, and to interperse with other trees in large plantations in any interior parts. The White Poplar or Abele, the Carolina, Tacamahacca, Lombardy and Athenian Poplar, are proper to introduce as ornamental trees, and are finely adapted to be employed in assemblage in forming large avenues, open groves, and clumps in parks, &c. though any of the sorts are eligible on the same occasions to increase the variety; and all the sorts may be employed to advantage in any large tracts of plantation.

If required to ornament any marshy grounds with plantation, no trees are better adapted for that use than Poplars, especially the first three species, all of which thrive remarkably in moist situations, and will readily grow by cuttings, either of young shoots or in truncheons.—See their *Propagation*.

As forest or timber trees, the following sorts, White, Black, Tremulous, and Lombardy Poplar are proper to be employed for that purpose, especially in any moist marshy ground, where few other trees will thrive: they however will succeed in any other common soil poor or rich, but in a very moist ground they will be so expeditious in growth as in six or seven years will afford a considerable advantage, especially if planted close to allow of thinning, for a fall of poles, spars, and for

fire-wood, &c. besides leaving a sufficient number of standards at proper distances to grow up to timber, and the stools of the first fall remaining, shoot up again and afford a fall every four, five, seven, or ten years, as may be required, still leaving the timber standards.

And marshy land may be improved to much advantage by coppices of these trees, to cut every four, five, or six years for poles, and other small purposes; being planted in rows a yard asunder, and in seven years they will be fit to cut for many small uses, and the stools shooting up again strong, will afford a cutting every four or five years after. See *PLANTATIONS*.

Some sorts may also be planted occasionally to form hedges in moist or other situations, more particularly the Lombardy Poplar, as this sort is peculiar in branching out numerously from the bottom upwards, and may be planted hedge fashion along the sides, or top of outward watery ditches, in large plants as at once to form a hedge; they being topped to five, six, or seven feet, and they will thus shoot out laterally more effectually close.

For all the above purposes young trees are propagated and raised, as directed below in their propagation.

Method of Propagation:

All the sorts of *Populus* are easily propagated by cuttings, layers, and suckers.

By Cuttings.—October and November is a good season for this work, or even any time in winter until March, in open weather. This is the most expeditious mode of propagating all these trees, for cuttings thereof grow freely without any trouble; either cuttings of the young year-old shoots, a foot and half long, planted a foot deep; or large truncheons of two, three, or more years growth, from about a yard to five or six feet long, planted in moist places: though these large cuttings or truncheons are not proper for any general plantation, only just in some particular parts, in a marshy or watery situation, where shade and shelter, &c. may be required as soon as possible, in which may be planted a quantity finally to remain; planting them about one to two feet deep.

But, in order to raise plants for any regular plantation, or for a quantity of handsome standards, it is the most eligible to raise them principally from young cuttings of one year's growth, or two at most; procure therefore a quantity of these young cuttings, about fifteen or eighteen inches long, and plant them in nursery-rows two feet asunder, placing each cutting two parts or half-way in the ground, and about

about a foot distance in the lines, they will readily take root, and make good shoots the following summer, being careful to trim off straggling laterals in order to encourage the leading shoot to grow straight, and aspire more expeditiously in height; and after having from two to four or five years growth here, they may be transplanted finally for the purposes above-mentioned.

By Layers.—In autumn choose any lower young shoots conveniently situated, lay them by slit-laying, they will be well rooted and fit to transplant by autumn following, in nursery-rows, to have two or three years growth.

By Suckers.—Some of the sorts send up abundance of suckers from the roots, which may be taken up after the fall of the leaf, and planted in nursery-rows, as directed for the cuttings; they will form good plants in two years.

The plants raised by all the above methods, will, after having obtained from two or three to five or six years growth, be of proper size for furnishing any of the aforementioned plantations.

These trees may also be raised from seed, if care is taken to gather a quantity as soon as ripe; and sow it in autumn in beds either broad-cast or in drills, half an inch deep.

PORTLANDIA, comprises large trailing and other exotic, ever-green plants for the stove.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX, a five-leaved cup, above the germen. COROLLA, monopetalous, long, funnel-shaped tube, and border cut in five acute segments. STAMINA, five awl-shaped declining filaments, from the bottom of the tube, and near the length of the corolla, topped with linear erect antheræ. PISTILLUM, a roundish pentagonal germen below the flower, a single style, and oblong blunt stigma. PERICARPIUM, a five-cornered retuse two-celled capsule, crowned with the cup and containing many roundish compressed seeds.

1. PORTLANDIA *grandiflora*.

Great-flowered Portlandia.] Hath long rooting stalks, running many feet high, garnished with oval, pointed leaves, on short foot stalks, five or six inches long, and three or four broad, and placed opposite the flowers: come out singly from the axilla of the leaves: towards the extremity of the branches they are white; eight or ten inches long, and make a noble appearance.

This elegant plant is a great ornament to the stove, and is commonly trained along the back part, and exhibits its large flowers in July and August. Its propagation is by cut-

tings in the spring, which must be planted singly in pots and plunged in the bark-bed, and afterward shifted into larger pots and replunged in the bark, where they must constantly be retained: it is also sometimes propagated by seeds obtained from abroad.

The two following species are also retained in some stove collections.

2. PORTLANDIA *hexandria*.

Hexandrous or six-male Portlandia.] With ovate leaves, equal at the base; and flowers having six stamina.

3. PORTLANDIA *tetrandria*.

Tetrandrous, or Four-male Portlandia.] With oblong obtuse leaves, broad stipulæ, and flowers having four stamina.

The propagation and culture of these two species is the same as the first sort.

PORTULACA, Purslane.

Two species are found in our gardens; one a low herbaceous succulent annual, a salad herb; the other a low shrubby perennial for the green-house, or stove collection; both rising only six or eight inches high, garnished with small succulent leaves, and small pentapetalous flowers.

Class and order, *Dodecandria Monogynia*.

Characters.] CALYX is small, bifid, and placed on the germen, and permanent. COROLLA, five plane, obtuse, erect petals. STAMINA, from twelve to nineteen short capillary filaments having simple antheræ. PISTILLUM, a roundish germen, short simple style, and five oblong stigmas. PERICARPIUM, an oval covered capsule, of one cell, having many small seeds.

There are several species but the two following are the most noted.

1. PORTULACA *oleracea* (Annual.)

Common culinary Purslane.] Rises with herbaceous, low, succulent, branchy stalks, six or eight inches high, garnished with wedge-shaped, thick, succulent leaves, and small close-setting flowers.

Comprises two Varieties.] Green Purslane, having deep-green leaves.—Golden Purslane, having yellowish leaves; both the varieties rising from the same seed.

These herbs are excellent to mix in summer salads.

2. PORTULACA, *Anacampseros* (Perennial.)

(Anacampseros) — or Shrubby ever-green African Purslane.] Rises with a shrubby branchy stalk, about six inches high, oval, gibbous, succulent leaves, and the stalks terminated by small clusters of red flowers.

Both these plants are of a succulent nature; the first is an herbaceous annual, for culinary uses; and the second a shrubby perennial, cultivated

about a foot distance in the lines, they will readily take root, and make good shoots the following summer, being careful to trim off straggling laterals in order to encourage the leading shoot to grow straight, and aspire more expeditiously in height; and after having from two to four or five years growth here, they may be transplanted finally for the purposes above-mentioned.

By Layers.—In autumn choose any lower young shoots conveniently situated, lay them by slit-laying, they will be well rooted and fit to transplant by autumn following, in nursery-rows, to have two or three years growth.

By Suckers.—Some of the sorts send up abundance of suckers from the roots, which may be taken up after the fall of the leaf, and planted in nursery-rows, as directed for the cuttings; they will form good plants in two years.

The plants raised by all the above methods, will, after having obtained from two or three to five or six years growth, be of proper size for furnishing any of the aforementioned plantations.

These trees may also be raised from seed, if care is taken to gather a quantity as soon as ripe; and sow it in autumn in beds either broad-cast or in drills, half an inch deep.

PORTLANDIA, comprises large trailing and other exotic, ever-green plants for the stove.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX, a five-leaved cup, above the germen. COROLLA, monopetalous, long, funnel-shaped tube, and border cut in five acute segments. STAMINA, five awl-shaped declining filaments, from the bottom of the tube, and near the length of the corolla, topped with linear erect antheræ. PISTILLUM, a roundish pentagonal germen below the flower, a single style, and oblong blunt stigma. PERICARPIUM, a five-cornered retuse two-celled capsule, crowned with the cup and containing many roundish compressed seeds.

1. PORTLANDIA grandiflora.

Great-flowered Portlandia.] Hath long rooting stalks, running many feet high, garnished with oval, pointed leaves, on short foot stalks, five or six inches long, and three or four broad, and placed opposite the flowers: come out singly from the axilla of the leaves: towards the extremity of the branches they are white; eight or ten inches long, and make a noble appearance.

This elegant plant is a great ornament to the stove, and is commonly trained along the back part, and exhibits its large flowers in July and August. Its propagation is by cut-

tings in the spring, which must be planted singly in pots and plunged in the bark-bed, and afterward shifted into larger pots and replunged in the bark, where they must constantly be retained: it is also sometimes propagated by seeds obtained from abroad.

The two following species are also retained in some stove collections.

2. PORTLANDIA hexandria.

Hexandrous or six-male Portlandia.] With ovate leaves, equal at the base; and flowers having six stamina.

3. PORTLANDIA tetrandria.

Tetrandrous, or Four-male Portlandia.] With oblong obtuse leaves, broad stipulæ, and flowers having four stamina.

The propagation and culture of these two species is the same as the first sort.

PORTULACA, Purslane.

Two species are found in our gardens; one a low herbaceous succulent annual, a salad herb; the other a low shrubby perennial for the green-house, or stove collection; both rising only six or eight inches high, garnished with small succulent leaves, and small pentapetalous flowers.

Class and order, *Dodecandria Monogynia*.

Characters.] CALYX is small, bifid, and placed on the germen, and permanent. COROLLA, five plane, obtuse, erect petals. STAMINA, from twelve to nineteen short capillary filaments having simple antheræ. PISTILLUM, a roundish germen, short simple style, and five oblong stigmas. PERICARPIUM, an oval covered capsule, of one cell, having many small seeds.

There are several species but the two following are the most noted.

1. PORTULACA oleracea (Annual.)

Common culinary Purslane.] Rises with herbaceous, low, succulent, branchy stalks, six or eight inches high, garnished with wedge-shaped, thick, succulent leaves, and small close-setting flowers.

Comprises two Varieties.] Green Purslane, having deep-green leaves.—Golden Purslane, having yellowish leaves; both the varieties rising from the same seed.

These herbs are excellent to mix in summer fallads.

2. PORTULACA, Anacampseros (Perennial.)

(Anacampseros) — or Shrubby ever-green African Purslane.] Rises with a shrubby branchy stalk, about six inches high, oval, gibbous, succulent leaves, and the stalks terminated by small clusters of red flowers.

Both these plants are of a succulent nature; the first is an herbaceous annual, for culinary uses; and the second a shrubby perennial, cultivated

tivated by the curious for variety; are both exotics of a tender quality, of the temperature of green-house and stove plants.

The common *Culinary Purslane* is raised annually from seed for summer use, both as a salad and pot-herb, is of a moist cold-nature, and an excellent ingredient to mix in summer salads, but not so proper for winter use; the plant being tender must be raised either in a hot-bed, or in a warm border, in which latter it will not succeed before April or May.

The shrubby sort must be kept in pots of dry soil, and placed in the hot-house collection.

Method of Propagation.

The propagation of the *Common Purslane* is by seed annually in spring and summer; for, in order to continue a succession of young plants for use, it is proper to sow several different times from March or April until June, July, or August, at about three or four weeks interval; observing, if required to have it early, the first sowing may be performed in a slender hot-bed in February or March, and the other sowings may be in a warm border of lightish earth in April and May; though, as the warm season advances, the sowings may be in any open bed or border of light ground. The seed may either be sown in shallow drills, and covered about a quarter to half an inch deep, or all over the surface, covering it that depth, or may be raked in lightly: give occasional light waterings in dry weather, both before and after the plants come up, which are to remain where sown, and they will be fit to cut for use in three or four weeks. In gathering them for use, cut off their young tops with a knife: they will shoot out again after each cutting.

To save seed of this sort, leave some strong plants of the April sowing: they will flower and ripen seeds freely towards autumn.

The second sort is propagated by cuttings, any time from April till June or July; plant them in pots of light dry earth, and if plunged in the bark-bed they will root the sooner, giving occasional shade till rooted, and moderate watering.

PORTULACARIA, *Purslane-tree*.

This genus furnishes a shrubby succulent plant for the green-house.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX, a diphyllous, coloured, permanent cup, with a very spreading, obtuse, concave border. COROLLA, five oval, blunt, entire petals. STAMINA, five awl-shaped, erect, very short filaments, topped with ovate antheræ. PISTILLUM, a three-cornered germen, above the flower: no style; but the

germen crowned with three spreading stigmata. PERICARPIUM, none; but the cup and corolla contain an oval-oblong, three-sided, winged seed.

We know but of one species, which was formerly arranged with the crassulas, viz.

PORTULACARIA *afra*.

African Purslane-tree.] Hath a very thick, succulent, perennial stalk of a reddish colour, branching pyramidally three or four feet high, garnished with ob-oval, wedge-shaped, succulent, opposite leaves, and flowers growing in spikes, but rarely appear in England.

This plant is easily propagated by cuttings of their stalks and branches, cut from three to four or five inches long, in May or June: after lying in a dry place some days to heal over the wounded part, plant them in pots of sandy earth, placing them in a frame to be occasionally shaded in hot weather, and protected from wet; and in a few weeks they will be rooted: or they may be planted in a bark-bed, which will facilitate their growth. It must in winter be kept in the green-house, observing to be sparing in watering these plants at that time of the year.

POTENTILLA, *Cinquefoil*.

The genus consists of one noted shrubby species, and near thirty herbaceous kinds; the former is a hardy deciduous flowering shrub for the pleasure-ground; and the others having but little merit as garden plants, only a few of them are sometimes admitted in the herbaceous collection for variety. All the sorts are of moderate growth, some growing erect, others trailing, and garnished with pinnated and other compound leaves, and pentapetalous flowers.

Class and order, *Icosandria Polygynia*.

Characters.] CALYX is monophyllous, half cut into ten parts, alternately smaller, and reflexed. COROLLA, five roundish, spreading petals, inserted into the calyx. STAMINA, twenty or more awl-shaped short filaments, having elongated-lunulated antheræ. PISTILLUM, numerous small germina collected into a head, many slender styles, having obtuse stigmas. PERICARPIUM, none; a head of seeds placed on the common receptacle, which lodges in the calyx.

There are about six or seven species found in our gardens, one of which is shrubby, the others herbaceous.

Shrubby kind.

1. POTENTILLA *fruticosa*.

Shrubby Potentilla, commonly called Shrub Cinquefoil.] Rises with a short shrubby stem, dividing into a branchy full head, three or four feet high, closely garnished with pinnated leaves,

leaves, of five oblong, narrow, acute-pointed folioles, pale-green above, and whitish underneath; and the branches terminated by clusters of large, spreading, yellow flowers.

This is a beautiful deciduous flowering shrub, worthy a place in every curious collection.—It grows wild in Yorkshire and other northern parts of England, &c. but has been long a resident of gardens as an ornamental shrub.

Herbaceous perennial kinds.

There are about six or seven of these kinds common to our gardens; the first of which grows wild in England, and is rarely cultivated; the others are of foreign growth in different parts of Europe.

2. *POTENTILLA reptans.*

Creeping Common five-leaved Potentilla, or five-leaved grass.] Hath a thick fibry root, slender, trailing, repent stalks, digitated, five-lobed, petiolated leaves, and yellow flowers, singly.

3. *POTENTILLA rupestris.*

Mountain upright Cinquefoil.] Hath upright stalks, eight or nine inches high; pinnated, five and three-lobed, alternate leaves, having oval crenated lobes, and the stalks terminated by small white flowers.

4. *POTENTILLA recta.*

Erect, seven-lobed, Yellow Cinquefoil.] Hath erect stalks; seven-lobed leaves, having the lobes spear-shaped and serrated, green and hairy on both sides; and the stalks terminated by corymbose clusters of yellow flowers.

5. *POTENTILLA Fragaroides.*

Strawberry-like trailing Potentilla.] Hath a somewhat tuberous root, furnished with many long fibres, long trailing shoots, rooting at the joints; pinnated, mostly three-lobed leaves, having oval lobes, with the extreme lobe the largest, and clusters of small white flowers.

This species bears a great resemblance to the small sterile strawberry plants.

6. *POTENTILLA argentea.*

Silvery upright Potentilla.] Hath upright stalks, branching a foot high; and five-lobed leaves, having the lobes wedge-shaped, cut on the edges, hoary and white underneath, and the branches terminated by small yellow flowers.

7. *POTENTILLA grandiflora.*

Grandiflorous, or Great-flowered Potentilla.] Rises with upright stalks, eight or ten inches high; dentated, ternate leaves, downy underneath, and the stalks terminated by large yellow flowers.

All these *Potentillas* flower in June and July; the flowers are composed each of five roundish petals, and about twenty stamina.

They are very hardy plants, and may be employed in the different compartments of the pleasure-ground. The first species in particular, *Shrubby Potentilla*, merits a place in every shrubbery towards the front of the clumps, &c. and the herbaceous kinds may be dispersed about the common compartments to increase the variety.

Their propagation is very easy.

The *Shrubby Potentilla* may be propagated abundantly by suckers, layers, and cuttings; all of which will readily grow, and make plants in one year, which, after having two or three years' growth in the nursery, will be fit for any of the shrubbery compartments.

All the herbaceous kinds may be propagated by parting the roots in autumn or spring, or by seed in any of those seasons.

POTERIUM, Garden Burnet.

It consists of two herbaceous and one shrubby perennial: of the former, one is a kitchen-garden herb, the other for the pleasure-garden, and the shrubby kind for the green-house collection; they all rising with upright stalks from about a foot and a half to a yard high, in different sorts; having pinnated leaves, and the branches terminated by spikes of quadripartite monœcious flowers.

Class and order, *Monœcia Polyandria.*

Characters.] *CALYX*, male and female flowers on the same spike, each floret having cups formed of three oval leaves. *COROLLA*, in the males it is quadripartite, the segments oval, concave, and permanent, and in the females is monopetalous and wheel-shaped, with a short tube, divided above into four oval, plane, persistent segments. *STAMINA*, numerous capillary filaments, and didymous antheræ. *PISTILLUM*, two oval-oblong germens, two hair-like, coloured styles, and pencil-shaped, coloured stigmas. *PERICARPIUM*, a berry inclosed in the indurated corolla, having two seeds.

Herbaceous kinds.

The first of these herbaceous kinds is an esculent herb, the other for variety in the pleasure garden.

1. *POTERIUM Sanguisorba* (Perennial).

Common garden Burnet.] Hath fibry perennial roots, crowned by a large tuft of pinnated leaves, of six or seven pair of sawed lobes, terminated by an odd one; upright angular stalks, dividing, and branching a foot and a half high, terminated by oblong spikes of purplish-red flowers.

This species grows wild in England, in chalky soils, but has been long cultivated as a choice salad-herb, &c. for winter and spring use,

use, it being of a warm nature; the young leaves are the useful parts.

It is perennial in root, and retains its radical leaves all the year, but the stalks are annual.

2. POTERIUM *hybridum*.

Hybrid Agrimony-leaved Montpellier Burnet.] Rises with upright, taper, closely gathered stalks two feet high, pinnated odoriferous leaves, of three or four pair of sawed lobes, terminated by an odd one; and the stalks terminated by long foot-stalks dividing into smaller, each supporting a small roundish spike of flowers.

This species often proves biennial, but by cutting down some of the stalks before they flower, it will cause it to multiply at bottom, and become abiding.

Shrubby kinds for the Green-house.

3. POTERIUM *spinosum*.

Shrubby Spinous Burnet of Crete.] Hath a shrubby stem and branches, rising a yard high, armed with spines; small, pinnated, ever-green leaves, of six or seven pair of lobes, terminated by an odd one, and the branches terminated by small heads of greenish flowers.

All these three species flower in June and July, succeeded by ripe seeds in autumn.

They are all naturally perennial, but the two herbaceous kinds being abiding in root only; the other in root, stem, and branches; and the two former are hardy, and the third requires shelter in winter.

The first sort merits culture in every kitchen-garden for winter and spring fallads.

Some plants, both of the first and second sorts, may be introduced in the herbaceous collection in the pleasure-garden for variety.

Keep the third sort always in pots to have shelter in winter.

They are all easily propagated as follows.

The first sort by seed, and by parting the roots.—Sow the seed in autumn or spring, in a border of light earth, and rake it in; and when the plants are two or three inches high, plant them out in any bed or border, a foot asunder, finally to remain.—Parting or slipping the roots is performed also in the autumn or spring season, planting the slips as directed for the seedlings.

The second sort may also be increased by seed and slips of the root, as for the former sort.

And the propagation of the third is by slips or cuttings of the branches in spring and summer, planted in pots, and placed under glasses, giving shade and water; or might be forwarded more by plunging them in a hot-bed.

POT-HERBS, consisting of different

sorts of small aromatic herbs, and some other kinds, used in composition, and separately, in several culinary occasions.

In a general sense, Pot-herbs may be said to comprehend many of the kitchen garden plants, but are principally understood to comprise chiefly such as are in request to improve soups, broths, and some other similar culinary preparations, in which, sometimes, several different sorts of small herbs are used less or more, of particular kinds in composition, and some singly, on the same and other occasions.

They consist of the following sorts; thyme, majoram—savory—sage—parsley—mint—pennyroyal—sorrel—chervil—basil—coriander—dill—fennel—marigold—borage—burnet—tansey—tarragon—chives—leeks—onions—green-beet—white-beet—spinach—celery—endive—lettuce—love-apple—capsicum—purslane.

These being the principal sorts that come under the denomination of Pot-herbs, they are all used as such, some or other of them, less or more, compound or separately, for particular different culinary purposes as above; and some of them are most commonly used separately, as principal culinary and salad-herbs, such as spinach, green and white, to boi, as separate dishes; celery, endive and lettuce, as choice salad herbs, and sometimes to stew.

But we may just remark, that, of the above list of Pot-herbs, the most generally useful sorts in common request are the thyme, majoram, savory, parsley, sage, mint, marigold, penny-royal, leeks, celery, onion.

However, in considerable gardens, and those of large families of fashion, all the above sorts are often required on different occasions, and in which it is necessary to have a proper supply accordingly: a large portion of the principal sorts the most generally used, especially of the different sweet aromatic kinds in request for soups, broths, &c. as specified in the second list above; some of which, as leeks, celery, and onion, are always raised in considerable crops; the others in small or moderate quantity; and of those in demand only on some particular occasions, may be in still smaller supplies.

For particulars of some further descriptions of the respective uses, mode of growth, and general culture, see AROMATICS and KITCHEN GARDEN PLANTS; in which the different sorts appear under their botanic and English names, referring to their respective genera accordingly for the general description of each sort separately.

POTS. Garden Pots for plants and flowers.

In gardening, Pots are particularly necessary in the culture of numerous sorts of plants, such as in all tender exotics of the green-house and stove, all of which must be planted in Pots for the convenience of moving them in and out of these departments as occasion requires.

Pots are also exceedingly useful in raising many young seedlings and cuttings, that may require moving to occasional shade, shelter, and artificial heat; likewise for many young plants that are tender whilst young, requiring to be removed under shelter for the first two or three winters, but become hardy enough afterwards to bear the full air the year round; and Pots are likewise very convenient in which to plant many of the more curious hardy flowering plants and others, and choice flowering shrubs, &c. to remove occasionally to adorn any particular compartments.

There are about eight different sizes of Garden Pots, which are necessary in order to suit the different sorts of plants, as well as all sorts of plants in their different stages of growth; as when the plants are young and of small size, they may be first planted in small Pots; and as they by degrees increase in bulk, shift them into pots a size larger, repeating it as often as necessary. See *PLANTING in Pots and Shifting Plants*.

The several sizes of Pots are in regular gradation, and at the Pot-Houses each size has its name for the convenience of readily supplying the sizes wanted for particular uses; they being always reckoned by the cast, from two to sixty Pots to each, according to their sizes, the largest Pots being only two to a cast, and the smallest sixty; so that as being of eight different sizes or casts, they are distinguished by the following terms, twos, eights, twelves, sixteens, twenty-fours, thirty-twos, forty-eights, and sixties; so according to the above numbers there are so many Pots to each cast; the several casts from the twos, being in a gradual diminution in size, and the price of the different casts is the same; those of two, &c. being as much as those of sixty, and so of the rest; from two to three shillings is the general price per cast at the potters' in the neighbourhood of London.

In the order of garden Pots, there is a particular shallow sort of a wide, squat, pan-form make, used in some occasions, especially among the myrtle-gardeners in the neighbourhood of London, who, in raising great quantities of the plants of that species annually, in order to have always a regular succession advanced to proper growth, for the markets of

that metropolis, generally use these kinds of wide shallow pan Pots, wherein to prick or plant the requisite supply of numerous small myrtle cuttings, in summer, &c. for the annual propagation; and on which occasion, they are commonly called store-pans.

And, as in these store pans they generally prick a great number of the above small slips or cuttings, at only about an inch or two apart, to the amount of hundreds in each such pan, just to strike them, and to remain two or three months or more, till advancing a little in growth; in which interval the said pans thus stored, are convenient for removing to different situations required, such as, at first planting or afterwards, either into a hot-bed, whereby to strike the cuttings more expeditiously, or for the same advantage, in default of hot-beds, to place under a garden frame and lights, or each pan placed under a hand-glass, either with or without a hot-bed; and also for removing them to a green-house or garden frame, for protection in winter, &c. all of which, being thus continued in the store pans, two, three, or four, to five or six months, or more, according to the progress of growth they make, so as when they discover to be well struck in bottom radicles and shoot a little top, in one summer's growth, are then pricked separately in small Pots, or occasionally three, four, or five in larger, for a year, then separated as above, or sometimes in May, are bedded out in beds of natural earth, six or eight inches apart, to acquire an advanced state till September, and then potted singly, as just above observed.

The same kind of pan Pots are also useful occasionally, for several other purposes of propagation, both in which to sow seed and plant small cuttings, slips, &c. of tender exotics, and of various other sorts of curious or particular kinds of plants, both of the green-house, hot-house, and the open-ground, in order to have similar culture as above.

These kinds of pan Pots are ten or twelve, to fourteen inches wide, and about six inches deep, having holes at bottom as in the common garden Pots.

Another sort of Pots, of different make from the general kinds, are sometimes used, in which to plant some kinds of bulbous roots, for blowing in the apartments of a house; they are narrow and upright, of equal width from bottom to top, six, eight, or ten inches deep, or little more, and three, to four or five inches width; and are occasionally used for planting bulbs of the Guernsey lily and some other similar kinds, to blow in autumn and winter, in the windows or chimney-

piece of a dwelling or sitting room, or in a green-house, or hot-house, &c. as may be required; or especially the former, as they appear neat, and admit of placing close, or in a smaller space than the common Pots; and generally but one bulb planted in each: they being previously filled with light sandy earth, near to the top, then planting the bulb therein, cover it in evenly with earth, just only a small depth over the crown; and in which they strike their fibres down into the earth, and flower very agreeably in good perfection.

The several sorts of Pots are obtained at the potters in the different parts of the kingdom; great quantities are made in many of the villages in the vicinity of London, both for neighbouring supply, and to send to a distance by land and water carriage.

In choosing the Pots, see that they are burnt sufficiently hard, and so perfectly sound as to ring when struck with your knuckles, and that they have all holes at the bottom to discharge the superfluous moisture from the earth about the roots of the plants; the larger Pots having generally four holes, one in the middle of the bottom, and three around the circumference thereof, at equal distances; but the smaller Pots have commonly only one hole in the middle of the bottom.

With respect to the proper sizes of Pots requisite for the different sorts of plants, it is commonly mentioned in their respective genera, when any particular sizes are necessary.

When we occasionally speak of small Pots, it is generally to be understood either as fix-ties, forty-eights, or thirty-twos, according to the sorts or sizes of the plants.

For the method of planting in Pots, &c. shifting plants from one Pot to another, &c. see *Planting in Pots*, under the article PLANTING.

PRASIUM. Shrubby hedge-nettle.

For the green-house, this genus furnishes two species of Italian exotics, low shrubby ever-greens, of two or three feet growth, with whitish stalks, dividing into many slender branches, garnished with oblong and oval leaves; and white flowers of the lip kind, disposed in whorles; having bell-shaped bilabiated cups, monopetalous, ringent, two-lipped corolla; two long and two shorter stamina, four-parted germen, single style, and four naked seeds.

Class and order, *Didynamia Gymnospermia*.

The species are,

1. *PRASIUM majus*.

Major Shrubby Hedge Nettle.] With oval-oblong serrated leaves.

2. *PRASIUM minus*.

Minor Shrubby Hedge Nettle.] With egg-oval, doubly crenated leaves.

These two shrubby ever-greens are natives of Sicily, &c. and in this country require the culture of green-house plants; in which collection they effect an agreeable variety, as evergreens, in foliage all the year; flower in summer, and ripen seeds in autumn; by which they may be raised in a hot-bed in spring, or in a bed of natural earth in April; also by slips and cuttings in the same season.

PRIMULA. Primrose. Including *Polyanthus* and *Auricula*.

This famous genus *Primula* furnishes a grand collection of low, herbaceous, fibrous-rooted, flowery perennials; two celebrated species in particular, *common Primrose* and *Auricula*, have singular merit, as very beautiful spring flowers, and for each species furnishing thousands of varieties, are all of humble growth, with the roots crowned by a cluster of oblong broad leaves, and low slender flower-stalks, from about three or four to six or eight inches high, terminated by monopetalous, five-parted flowers, some singly, others in clusters.

Class and order, *Pentandria Monogynia*.

Characters.] **CALYX**, a many-leaved involucre, containing many small flowers, each having a monophyllous, tubulous, pentagonous cup, divided into five acute erect segments, and is permanent. **COROLLA** is monopetalous, with a long cylindric tube the length of the calyx, having the limb or upper part spreading, and divided into five roundish heart-shaped segments. **STAMINA**, five very short filaments, situated in the neck of the corolla, having acute erect antheræ. **PISTILLUM**, a round germen, slender style, and globular stigma. **PERICARPIUM**, an oblong, cylindric, unilocular capsule, ten-parted at top, containing numerous small seeds.

There are six or seven species in this genus, two of which demand universal esteem as flowery plants; namely, *Common Spring Primrose*, and *Auricula*; the former of which includes all the family of the Primroses, Cowslips, and all the numerous varieties of *Polyanthuses*; and the latter, all the vast train of the *Auricula* tribe. The *Auricula*, however, was formerly ranged as a distinct genus; but its general characters determining it a species of *Primula*, modern botanists arrange it accordingly; which, and the Primrose, and *Polyanthus*, are the principal species and varieties of this genus, that are the most generally estimable to cultivate as ornamental flowering plants; and of which shall first proceed to describe

scribe the Primrose family, which is very numerous in different varieties, consisting of the Common Primrose—Cowslip-Primrose,—Polyanthos-Primrose, or Polyanthus; arranging each under a distinct head.

Common Primrose kinds.

PRIMULA veris.

Common Spring Primrose.] Hath thick very fibry roots, crowned by clusters of large, oblong, indented, rough leaves, and numerous flower-stalks, from about three or four to five or six inches high, each terminated commonly by only one flower, of different colours and properties in the varieties.

Varieties of these are,] Common yellow-flowered Primrose of the woods—White Primrose—Paper-white Primrose—Red Primrose—Double yellow Primrose—Double white Primrose—Double red Primrose—Double-pink Primrose—Double crimson Primrose; all of which varieties having generally but one flower on each stem, but rise in such plenty from every part as to appear almost covered with flowers.

They all flower abundantly in March and beginning of April, continuing a month or six weeks.

All these varieties of *Common Spring Primrose* are hardy perennials: the single yellow sort grows wild in woods, &c. in most parts of England; all the others being seminal or seedling varieties of it, that have been principally obtained by culture in gardens. The double kinds in particular have singular beauty; the flowers being large, and perfectly full and double, and make a fine show, highly meriting culture in the best collections of spring-flowers.

These varieties in general delight mostly in shady situations, whereby all the sorts, both single and double, are proper ornaments for the borders of shrubberies, wilderness quarters, and shady walks, where they will flower abundantly, and make a fine appearance. Some plants may also be dispersed in other more open compartments for variety.

The propagation of all these varieties is effected abundantly by slipping or parting the roots. Numerous single kinds may also be raised from seed, sown in a shady border in autumn or spring, as directed for the Polyanthus; but raising seedlings is hardly worth practising, since they increase so plentifully by the roots.

Remarking, however, that the propagation by slipping or dividing the roots is the only method for increasing the double kinds; and as these sorts are the most beautiful, and multiply in tolerable plenty by off-sets, it is pro-

per to raise a good stock of them; which may be effected with great facility every year soon after their flowering is past, as they will then be increased into large bunches; therefore being furnished with some good roots, proceed to their propagation in autumn, about July, August, or September; taking them up out of the ground, and divide each bunch of plants into several slips, and directly plant them in a shady border of good rich earth, six or eight inches asunder, and each slip will become a good plant, and will flower strong the following spring.

Observe, it is proper to remove and part the roots of the double kinds, in particular, every year; but not to omit once in two years at most, in order to preserve the plants in vigour.

Cowslip kinds.

PRIMULA veris officinalis.

Officinal Primrose, or common Cowslip.] Hath very thick fibry roots, crowned by a cluster of oblong, indented, round leaves, and upright firm flower-stalks, five or six inches high, terminated each by a cluster of small yellow flowers, and other different colours and properties in the varieties.

Varieties of these are,] Common single yellow Cowslip of the meadows and pastures—Double yellow Cowslip—Scarlet Cowslip—Hose-and-hose Cowslip, one flower growing out of the bosom of another, the lowermost serving as the calyx; all of which varieties having the flower stalks crowned by many flowers, in bunches.

They flower in April and May, continuing in succession a month or six weeks.

All the varieties are hardy perennials, some of them inhabitants of the meadows and pasture grounds, particularly the common single yellow sort, in great abundance; which sort is of excellent use in medicine, and a fine cordial wine is made of the flowers. Some plants of all the varieties merit admittance in the pleasure garden, to increase the variety of the spring bloom, but principally the double kinds, placing them in the fronts of some shady and other borders, &c. they do not, however, succeed so well immediately under shade of trees, as the common Primroses.

The propagation of these sorts is principally by parting the roots, as directed above for the common Primrose; this method of propagation is, however, particularly necessary for all the double kinds; and having a few roots of each sort, they will multiply exceedingly by off-sets, and soon increase your stock.

Polyanthus

*Polyanthus Kinds.**PRIMULA veris elatior.*

Polyanthos Primrose, commonly called Polyanthus.] Hath thick fibrated roots, increasing into large bunches; crowned with a cluster of large, oblong, indented, rough leaves; amidst them upright flower-stalks six or eight inches high, terminated mostly by a cluster of several spreading flowers, of many different colours and variegations in the varieties.

Varieties.] The varieties of *Polyanthus* are innumerable in the different colours and variegations of the flowers; but the principal colours are—Purple-flowered—Red-flowered—Gold-coloured—Orange-coloured, &c. each having numerous intermediate shades and variegations, that sometimes in one bed or border of the seedlings we may discover many hundred different sorts, and the varieties may still be increased without end from seed; and the select varieties of each sowing may all be continued and increased plentifully by slipping the roots, which annually multiply into large bunches, and may be parted or slipped with the utmost facility into many separate plants.

They all flower beautifully in April and May, and often flower again in autumn, and sometimes in winter, in very mild seasons; but the spring is their principal season of flowering in the greatest perfection, and ripen seeds abundantly in June or July.

This variety, *Polyanthus Primrose*, is one of the most beautiful of our fibrous-rooted spring flowers for the open borders, remarkable for its wonderful feminal diversity, all of which are hardy perennials, that flourish in almost any common soil and situation, but delight most in a loamy or other rich moist soil, and in a somewhat shady border; in a shady situation, however, they continue considerably longer in full bloom than in a sunny exposure; for a fierce sun often greatly affects these flowers both in beauty and duration; it is therefore proper to plant a collection of the finest sorts in the shade, not immediately under trees, &c. but in some eastward shady border, sheltered by a wall, hedge, or other fence from the noon-day sun, planting them at six or eight inches distance; and here the plants will continue flowering in full beauty a month or six weeks: but a quantity of different varieties should also be dispersed in the fronts of the several borders contiguous to the principal walks, in assemblage with other flowers, in which they will effect a very agreeable variety.

The *Polyanthus* is one of the noted prize-flowers among florists; many of whom are

remarkably industrious in raising a considerable variety of different sorts, as well as use every art to blow them with every requisite perfection; for among those virtuosi, a *Polyanthus* must possess several particular properties to have admittance in their choice collections.

But there are numerous varieties of *Polyanthus*, that, although destitute of some of the properties required by florists, are nevertheless very pretty flowers for ornamenting the common borders.

The chief properties, however, of a florist's *Polyanthus* are principally the following:—

1. The stem or flower-stalk shall be upright, moderately tall, with strength in proportion, and crowned by a good regular bunch of flowers, on short pedicles, strong enough to support them nearly in an upright position.
2. The florets of each bunch should be equally large, spread open flat, with the colours exquisite, and the stripes and variegations lively and regular.
3. The eye in the centre of each floret should be large, regular, and bright, and the antheræ, by the florists called the thrum, should rise high enough to cover the mouth of the tube or hollow part in the middle of the florets, and render them what they call thrum-eyed; but when the style elevates the stigma above the antheræ, the eye of the tube generally appears hollow, showing the stigma in the middle, like the head of a pin, is hence called pin-eyed, and is, by some, rejected as an incomplete flower, although its other properties be ever so perfect.

But although the florists reject a pin-eyed *Polyanthus*, it is the flower in its most perfect state; and great numbers of them are of as beautiful forms, colours, and stripes, as the thrum-eyed varieties, and demand equal attention as furniture for decorating the common flower compartments, &c. or to exhibit a general show in a bed or border.

The method of propagation for the *Polyanthus* is by seed, and by parting the roots.

By Seed.—This is the only method of propagation to gain new varieties, and to raise a large stock of plants, as a blow of many new flowers may be annually obtained for the choice collection, and a large supply for the common borders: the season for sowing the seed is either in autumn, soon after it is ripe, or early in spring; in either season of sowing they will soon come up, but will not flower till the second spring; observing, however, that by sowing early in autumn, the plants generally come up freely the same year, are fit to plant out betimes the next spring, and become stronger plants by the spring following, capable

capable of flowering in greater perfection than the spring-sown seedlings: remarking, if you sow in autumn, let it be in July or beginning of August; and if in the spring, perform it in February, March, or beginning of April: and the sowing in both seasons may be performed either in large pots or boxes of rich earth, in order to move to different situations occasionally, or in an east border of light rich soil; but sowing in pots or boxes may be the most eligible for the autumn sowing, for the convenience of moving to a little shelter in frosty weather; in either method sow the seed on the surface moderately thick, covering it evenly with light earth, only about a quarter of an inch thick; or if sown in a border, it may either be raked in very light and evenly, or covered as above: the plants will appear in three or four weeks, observing, that if sown in boxes, &c. they should be removed to a shady border during the warm weather, and those of the autumn sowing to a warm situation in winter, allowing them also some protection from frost.

In the spring, or beginning of summer, when the plants of either sowing are one or two inches high, they should be planted out in somewhat shady borders, as formerly mentioned, about five or six inches asunder, to remain for flowering; which they will all effect the following spring, when those of good properties should be marked, and the others may be transplanted into the common flower-borders.

Observe, that although all the select varieties may be multiplied plentifully by dividing the roots as directed below; yet it is necessary to raise a quantity of seedlings every two or three years, both to obtain new varieties, and to keep up a stock of young plants to succeed the old ones, which after the third year's bloom rarely flower so strong and fair as the one or two years old seedlings.

It is proper likewise to continue increasing the more excellent sorts, by parting the roots.

By Parting the Roots.—By this method all the sorts may be propagated in great abundance every year; for the roots multiply exceedingly by off-sets into large bunches, so as to admit of slipping or parting annually in autumn; and every slip furnished with some fibres will readily grow, become a good plant, and flower the following spring; so that, in the propagation by parting the roots, any particular approved sort may be multiplied every year at pleasure.

The proper time of year for this work is any time in the beginning of autumn, after the plants have done flowering; or may be

performed in the spring, in March or April: but if performed in July or August, the slips will have good time to get strength before winter, so as to flower strong next spring.

At the proper time, therefore, take up the plants out of the ground, and divide each bunch into several slips, not too small, unless where as great an increase as possible is wanted; being careful to preserve some root to each slip: they are then to be planted in a fresh dug border, enriched with dung, setting them five or six inches asunder; give water directly, and repeat it occasionally till they have taken good root.

Auricula Kinds.

2. PRIMULA *Auricula*.

Auricula Ursti, or *Bear's-car*; but commonly called *Auricula*.] Hath a thick fibrated root, crowned by a cluster of oblong, broad, fleshy, serrated, smooth leaves, resembling the shape of a bear's-car, and amidst them upright flower-stalks from about three or four to six or eight inches high, terminated by an umbellate cluster of beautiful flowers, of many different colours and variegation in the varieties.

It is a native of the Alps, but has long been a resident of our gardens.

Varieties of this.] The varieties of this are amazingly numerous both in the diversity of the leaves and flowers, such as oblong-leaved—roundish-leaved—broad-leaved—narrow-leaved—green-leaved—white, or mealy-leaved, being covered with a fine mealy dust or farina. And of flowers there are, purple-flowered, numerous sorts of lighter or darker shades, stripes, and variegations—red-flowered, numerous varieties of lighter or darker reds, striped and variegated sorts—yellow-flowered, several varieties, as bright yellows, buff-coloured, dun-coloured—double purple-flowered, double yellow-flowered, variegated purples, and innumerable other most beautiful varieties. All the varieties, both plain-coloured and variegated sorts, have a circular eye in the middle of each flower, and of which there are, yellow-eyed—white-eyed—and the petals in many of the sorts are powdered with a most delicate farina, or mealy powder, which contributes exceedingly to the beauty of the flowers.

Of the above principal varieties there are innumerable diversities, and many new ones annually acquired, which being all first obtained from seeds; though as the seedlings vary so greatly, it is probable that not one in a hundred may prove a real good flower; but when once any excellent new varieties are gained, they may be increased annually by off-sets, to a large stock, and thereby continued for ages; and the true sorts, according as they are obtained,

tained, are all named by the florists, sometimes by that of the person who first raised them, but more frequently that of some illustrious personage, which they number and book accordingly.

They all flower in April and May, continuing a month or six weeks in beauty, and ripen plenty of seeds in June.

All the varieties are hardy, herbaceous, ever-green perennials, that prosper in any common soil of a garden not too wet in winter; for being somewhat succulent, a very humid soil in that season is apt to rot them: allowing them, however, any moderately dry soil, they will stand all weathers the year round.

Considered as flowery plants, they claim precedence of most other spring flowers, for their admirable beauty and wonderful variety; and among florists are esteemed the most beautiful of their prize and stage flowers, the fine sorts being planted in pots, in order for placing them upon elevated covered stages or stands, during their bloom, both to show the flowers to greater advantage, and to defend them from the full sun and showers of rain, which would impair their beauty, and hasten their decay: a share of the common sorts should also be disposed in the open borders in assemblage; or you may likewise plant a collection together in some bed or border, to show a general bloom; for they will prosper in any open ground, not under shade and drip of trees, &c. and are rarely much injured by the most inclement weather.

But a quantity of the principal varieties with requisite properties should always be kept in pots, in order for moving to different situations for the advantage of blowing the flowers in the greatest perfection.

The principal properties necessary to constitute a good Auricula, are,—the flower-stem should be upright, tall, and strong enough to support its cluster of flowers tolerably upright; the cluster or truss of flowers should be large and regular, somewhat of a roundish form, all the florets of the bunch being sustained on short pedicles, in order to support the whole in a proper position, to form the truss close and regular; the florets should be large, and the top spreading flat and regularly around, and the eye of each floret large, circular, and bright.

Flowers having nearly the above properties, being of fine colours, particularly the most beautiful variegated kinds, are proper sorts to plant in pots (twenty-fours or thirty-twos) for stage flowers; so that when you raise seedlings, &c. you should previously see them

blow, to discover their properties before you pot them, which may be done early in autumn, when the flowering is past, planting one plant in each pot, and place them in a shady border all summer, and in a warm situation in winter; and in spring, according as the flowers open, place them on some covered stage, as before observed.

But in the culture of the fine varieties of Auriculas, the florists generally prepare a particular compost earth; the principal one is light earth from some pasture ground, the top spit with the sward, or any other good light mould, and neats dung or good dry rotten hot-bed dung, having of the earth and dung an equal portion of each, and about half the quantity of drift or sea sand; and sometimes where rotten wood, that is become earthy, such as willow earth, old rotten tan, sawdust, &c. can be obtained, a portion is also added, mixing and forming the whole into an heap, to remain about a year, turning it over several times, and it will be of a proper temperature for use. See COMPOST.

In default, however, of the above mixtures, you may take any good light earth of a garden, blended with an equal portion of perfectly dry-rotten dung, and a little drift sand if possible.

Their Propagation and General Culture.

The method of propagating all these plants is by seed, to gain new varieties, and by slipping the roots to multiply the approved kinds.

By Seed.—By raising seedling plants we are sure to gain some new varieties; and being raised one year, they begin to flower the next, though it is probable, that out of hundreds, there may be but very few real fine flowers; but when once any new excellent sorts are so obtained, they multiply annually by off-sets to increase the stock.

The seed generally ripens in June, and should be sown in July or August, not later however than September; or it may be done in spring; but by sowing early in autumn, you gain time.

For this purpose get some wide pots or boxes filled with light rich compost; sow the seed on the surface, and cover it scarcely a straw's breadth deep, and directly place the pots or boxes where they may have only the morning sun during the hot weather, giving them moderate waterings; and if sown early in autumn, the seedlings will probably rise in tolerable plenty the same year; in October, however, remove the pots, &c. to a warm sunny situation for the winter; or may be placed in a garden-frame to have shelter from frost, and excessive wet or snow; but let them

enjoy the free air in all moderate weather; in March or April, replace them again in the shade to have only the morning sun, for the quite young seedlings of these plants are unable to bear the sun fully; therefore continue them in this situation all spring and summer, supplying them with water in dry weather: and in July following take opportunity of moist weather, and prick them out in nursery-beds, or in wide pots or boxes, filled with good compost; in either of which prick the seedlings pretty close, i. e. two or three inches asunder, giving water and occasional shade from the sun till fresh rooted, or if in pots or boxes, remove them to a shady situation: in these beds or pots, &c. they are to remain till they flower, which will be spring following, when all the good sorts should be marked, or may be directly transplanted into separate small pots (forty-eights) one plant in each; and next year they will all blow in perfection, and discover their properties more perfectly, then may be shifted into larger pots (thirty-twos); observing to manage them as hereafter directed.

The ordinary sorts will do to plant in the common borders, to form variety amongst other low spring flowers.

By Off-sets, or Dividing the Roots.—By this method all the select varieties are propagated, for the roots throw out off-sets in tolerable plenty, each of which being slipped off and planted, will next spring produce flowers exactly like those of the parent plant, and these in their turn produce off-sets for further propagation, which will produce also the same sort of flowers, &c. and thus may the choice varieties be annually increased, and continued for years.

The season for performing this work is, occasionally both in spring and autumn; if only to slip off any outside off-sets that appear, it may be done in spring, either before or at the time of flowering; though towards autumn, about July or August, when the flowering season is past, and the plants having had the spring and summer's growth to furnish strong off-sets, will be the most eligible season for any general propagation by slips: the roots may be then either taken up and divided into several slips, where a considerable increase is required; or the roots may stand, and only detach any outside off-sets, as aforesaid; and in either season or method of slipping or dividing the plants, proceed to pot the off-sets or slips of the choice sorts separately; but the common kinds may be planted in beds or borders, of light rich earth.

Having, however, slipped or divided the off-

sets of the fine varieties, then being furnished with a quantity of small pots (twenty-fours or thirty-twos) according to the size of the slips, filling them with the proper compost, plant one off-set in each pot; give some water to settle the earth, and promote their striking; and then place them under some shady fence, upon level clean ground, to have only the morning sun all summer, repeating the waterings in dry weather two or three times a week; and at the approach of winter place them under some warm wall open to the sun, to remain until spring, and begin to show their flowers, when the choice sorts should be placed on the Auricula stage, in order to protect the bloom from the weather, and preserve them as long as possible in beauty.

General Management.

In the culture of the fine Auriculas in pots, it is proper, as before hinted, to have some sort of covered stage for the principal sorts, having the front open to the morning sun only, on which to arrange the pots of plants when in bloom, to show the flowers to good advantage, and protect them from rain and too much sun: the stage should have several ranges of narrow shelves, one above and behind another, theatrically, on which to set the pots; some small stages are so constructed as to turn round any way at pleasure, more or less, to the sun; and some are formed circular, having the shelves arranged in a pyramidal manner: and some have canvas curtains, or a defence of mats, &c. to draw or let down occasionally, either to keep off driving rains, or afford shade from the sun, and shelter from cutting winds where the stage is much exposed.

On these stages the pots of plants should be placed in the spring, according as the flowers of each plant begin to open, and not before, to remain during the continuance of the beauty of the flowers; observing to supply them with water about three times a week, or every other morning, giving it only to the earth in the pots; at least let none fall on the flowers, for wet would greatly deface the bloom.

When the full blow is past, remove the pots directly into the full air in a shady border, to receive the full benefit of the free air and rains, to encourage their off-sets and the ripening of seeds. During the summer season they should remain constantly in the shade, but not under drip of trees, and must have proper waterings in dry weather.

In August the plants should be fresh potted into new compost; but more especially such plants as have thrown out some good off-sets, should have them separated and potted, as already

ready directed; though small plants that have made no progress in off-sets, may remain unremoved another year; observing, however, the beginning or middle of August is the best time for fresh potting them, still continuing them in the shade during the hot weather, and supply them with water.

At the approach of winter remove the pots under some warm situation open to the sun, to remain till spring; or may be placed under some hoop arches, or in a garden frame, and there occasionally sheltered from severe frost, great rains, and snow, to preserve them in greater vigour, but must constantly enjoy the full air in all mild weather; in default, however, of such shelters, arrange the pots close along under a warm wall, for the plants are very hardy; only observing, that when very wet or snowy weather begins, lay the pots down on one side with the plants towards the sun, to prevent their receiving too much moisture, which would rot these kind of plants: but in settled dry weather, and as the spring advances, place them upright again, that the flower-bud may take its proper upright direction.

In spring, about the beginning or middle of February, or early in March, it is proper to mould up the pots with some fresh compost; first take out some of the old mould to a convenient moderate depth without disturbing the roots, and clear the plants from any decayed leaves, then immediately fill up the pots with new earth: this will prove a very beneficial dressing both in strengthening the bloom and encouraging the growth of off-sets.

When the plants begin to show their flower-buds, occasional shelter, if sharp-frosts happen, will be of great service in preserving them from being blighted, which often prevents their blooming fair, and sometimes entirely destroys the flower; it is therefore advisable to use a slight covering of mats every frosty or very cold night about the first shooting of the buds.

And according as the flowers open fairly, remove the pots on the stage, &c. to remain to blow as already directed.

The further management of the potted plants after flowering is the same as before, and which is to be repeated every year.

The above intimations of culture of Auriculas in pots are principally advised for the more curious esteemed varieties, productive of the finest flowers of superior beauty in their respective particular properties; and as to the common kinds, no more is necessary in the culture than that of other hardy perennial flowers either in pots or borders, &c.

3. PRIMULA farinosa.

Farinous, Red Primula, commonly called Bird's-eye.] Hath a fibrous root, with a small scaly head, crowned by several long, smooth, crenated leaves, mealy underneath, and upright flower-stalks half a foot high, terminated by a cluster of small red flowers, having yellow eyes in the centre.

It grows naturally in the North, but is cultivated in many gardens as a flowering plant; it produces its flowers in the spring.

Plant it in any common border, it will flower annually, and multiply plentifully by off-sets.

PRINOS, Winterberry.

Two shrubby species compose this genus; one is deciduous, the other is an ever-green, both hardy shrubs for the shrubbery, &c. obtain eight or ten feet stature, garnished with oblong leaves, and monopetalous wheel-shaped flowers.

Class and order, *Hexandria Monogynia*.

Characters.] CALYX is monophyllous, six-parted, and permanent. COROLLA is one wheel-shaped petal cut into six oval segments. STAMINA, six awl-shaped short filaments, and oblong obtuse antheræ. PISTILLUM, an oval germen terminating in a short style, and obtuse stigma. PERICARPIUM, a roundish sex-locular berry, having six hard seeds.

The species are,

1. PRINOS verticillata (deciduous).

Whorled Virginia Winterberry.] Grows six or eight feet high, very branchy from bottom to top; large spear-shaped longitudinally-sawed leaves placed alternately, and small flowers from the sides of the branches, some singly, others two or three together, succeeded by purple berries remaining all winter.

2. PRINOS glabra (ever-green).

Smooth Canada Winterberry.] Grows eight or ten feet high, branchy quite from the bottom, oblong spear-shaped leaves serrated at the top, placed alternately, and at the axillas small flowers two or three together, succeeded by purplish berries continuing all the winter.

Both these shrubs are of America, are tolerably hardy, especially the deciduous kind, and have been long in our gardens as ornamental shrubs to increase the collection in the shrubbery, &c.

But the ever-green kind being of a more tender nature, it is also kept in pots while young, in order to be wintered in a green-house, &c.

They are propagated mostly by seed sown soon after they are ripe, or early in spring, in a bed of light earth, covering them full half an inch deep; some of which will probably come up the first spring; but if not sown till the spring, they often remain in the ground

till the spring following, unless forwarded in a hot-bed: when the plants are one or two years old, they should be planted out in nursery rows; it will also be proper to plant some of the ever-green kind in pots, to have occasional shelter the first two or three winters, as being rather somewhat tender whilst young; but when they have gathered strength, turn some of them out into the full ground, and retain some in pots as green-house plants.

PROTEA, Silver-tree.

A genus comprising, for our green-house collections, two species of African exotics, remarkably ornamental silvery-leaved ever-greens of the woody-like tribe, growing eight or ten feet high, adorned with spear-shaped, singularly beautiful leaves of a silky silvery appearance; and flowers produced in oval heads, each consisting of many small monopetalous florets in one general calyx.

Class and order, *Tetrandria Monogynia*.

Characters.] **CALYX**, a general, imbricated perianthium, containing many florets, having each a partial, monophyllous cup. **COROLLA**, a uniform general flower, consisting of many monopetalous florets, having the limb or upper part cut into four parts, smooth and spreading. **STAMINA**, four filaments inserted into the corolla, and incumbent antheræ. **PISTILLUM**, a roundish germen, setaceous style, and obtuse stigma. **PERICARPIUM**, none; one seed to each floret, lodged in its calyx, the whole together in a roundish head.

There are many species of *Protea*, but those of note in our gardens are,

1. *PROTEA argentea*.

Silvery Cape Protea, or common Silver-tree.]

Rises with an upright stem, having a purplish bark, and dividing into several erect branches, decorated with broad, lanceolate, acute, hairy-silky, white silvery, shining leaves, continuing all the year;—rarely flowering in this country.

2. *PROTEA conifera*.

Cone-bearing Cape Protea.] Rises with an upright stem, dividing upward into several branches, garnished with linear-lanceolate, acute, smooth, entire leaves, shining and silvery; of a fine appearance all the year.

Both these elegant plants are natives of Africa, about the Cape of Good Hope; retained here in all our curious green-house collections, in which they have a conspicuously fine appearance in their singular silvery leaves, forming a beautiful variety the year round.

They are propagated by seeds, procured from the places of their native growth; which, as soon as obtained, sow in pots placed in a moderate hot-bed; and when the plants are

come up, give moderate air, or place them in an airy glass case, or towards the front of a green-house; and afterwards managed as other similar exotics of that conservatory.

They are also sometimes propagated by cuttings, in spring and summer, by the same assistance of a hot-bed.

PRUNING.

Pruning is an operation of the knife, performed upon trees occasionally, in order both to give them any desired form, and to retrench or reduce irregular and redundant or superfluous growths, or whatever creates confusion and disorder.

But this operation is particularly necessary to be practised on many sorts of fruit-trees, more especially the dwarf sorts, such as all kinds of wall and espalier fruit-trees; it is also necessary to be performed occasionally upon standard trees, both dwarfs and half and full standards, to all of which proper Pruning is necessary; some sorts annually, as all kinds of wall trees, espaliers, and most other dwarf or trained fruit-trees; which is requisite in order to preserve the proper figure, and to keep them within their limited bounds, as well as to promote fruitfulness; but as to common standards, whose heads have full scope of growth every way, they require but very little Pruning, except just to retrench any occasional redundancy, ill-growing branch, and dead wood. Wall trees and espaliers, however, require a general regulation of Pruning twice every year, in summer, to retrench the evidently superfluous and ill-placed shoots of the year, and to train in a supply of the most regular ones; and in winter to give a general regulation both to the supply of young wood left in summer, and to the old branches where necessary.

For in Pruning wall trees and espaliers it is to be observed, that as these trees have their branches arranged with great regularity to the right and left, one above another parallelly, four, five, or six inches asunder, forming a regular spread, so as the branches of each tree completely cover a certain space of walling, &c. and as the whole spread of branches constantly send forth every year a great number of unnecessary and useless shoots; and that each tree being limited to a certain space, as just observed, an annual Pruning is consequently most necessary to retrench the redundancies, and all irregular and bad shoots, to give the proper bearing branches due room, as well as to enable us to confine each tree within its allotted limits, consistent with its regular form.

The first Pruning necessary for wall fruit-trees, is when we attempt to give the head its

first

first regular formation, effected by Pruning short or heading down in spring all the shoots produced the first year from budding and grafting, that is, the first shoots from the budding, &c. when a year old being generally pruned down in March, within four or five eyes of the bottom, whereby it throws all the sap into the remaining lower buds, and thus, instead of running up to one stem, it pushes forth several strong shoots from the lower part the ensuing summer, so as to fill the allotted space of walling and espalier regularly quite from the bottom; which shoots being trained straight and regular in a spreading manner, each at full length all summer; and in winter or spring following, if a supply of more principal shoots shall seem necessary to form the head more effectually, prune short also these shoots, each to four or five eyes; and each of them will throw out the like number of shoots the same year, which, according as they advance in length, train at regular distances at full length during the summer, as before observed; for the shoots of wall trees should not generally be shortened in the summer season, for this would cause them to push forth many superfluous, unnecessary lateral shoots; though sometimes, in order to fill a vacancy as soon as possible, strong young shoots being pinched or pruned early in the season, May or beginning of June, to four or five eyes, will throw out several proper shoots the same summer; repeating, however, the work of Pruning short occasionally one or two years, &c. as above, either in general or to particular shoots as it may seem necessary till a proper set of branches are by that means obtained to give the head of the tree a proper formation; afterwards Pruning short is to be omitted, except occasionally to any particular shoot to fill a vacant space: but some sorts of wall trees require almost a general shortening of their supply of shoots, such as peaches, nectarines, &c. which bear only on the young wood, have that of each year shortened, to force out a supply of shoots for future bearing: other sorts of wall trees and espaliers are not, in the general course of Pruning, to be shortened, such as pears, apples, plums, and cherries, which continue bearing in the same wood of from two or three to many years' growth. See *ESPALIERS*.

After the trees are thus furnished with a proper spread of branches trained regularly to the wall and espalier, they will every year throw out many more shoots than are wanted, or can be converted to use, by being some too numerous, others ill placed, and others of a bad growth; all of which must therefore be regulated accordingly by proper Pruning: for

as the regular figure of the tree, well furnished in every part equally from the bottom to the top of the wall or espalier with proper branches, capable of producing a reasonable quantity of good fruit, are the principal objects of Pruning, all our operations must be directed to these ends.

We must therefore be careful to ease the trees of every thing that is either superfluous, irregular, or hurtful, by Pruning twice every year, a summer and a winter Pruning. We call that superfluous which though good and well placed, yet is more than wanted or can be properly laid in, and that irregular which is so ill placed as it cannot be trained with regularity to the wall or espalier, such as all fore-right shoots, being such as grow immediately from the front or back of the branches in a fore-right direction, which though good of themselves, yet their situation renders them irregular or unfit for training; and we call that hurtful which is in itself of bad growth, such as all very rank or singularly luxuriant rude shoots; so that the superfluous or redundant growths should be thinned by Pruning out all that seem to cause confusion; and the irregular and hurtful rank shoots should be displaced, cutting every thing of all these sorts off quite close to the place from whence they proceed, leaving, however, a proper supply, more or less, of the regular or best placed side-shoots where necessary, so as to preserve every part well furnished with bearing wood, trained straight and close to the wall or espalier at equal distances; observing some sort of wall trees, &c. require a general annual supply of young wood, such as peach and all other trees which bear only on the shoots of a year old; others require only an occasional supply of wood, such as apples, pears, &c. and all other kinds that bear on the old wood of from two or three to ten or twenty years old or more; so that the same branches continuing in bearing many years, the trees require only a supply of young shoots now and then to replace any worn out and dead branches. See *Summer and Winter Pruning*.

For the mystery of Pruning consists in being well acquainted with the nature of bearing of the different sorts of trees, and forming an early judgment of the future event of shoots and branches, and many other circumstances, for which some principal rules may be given; but there are particular instances which cannot be judged of but upon the spot, and depend chiefly upon practice and observation.

The nature or mode of bearing of the different sorts of wall and espalier trees, &c. is materially to be considered in Pruning.

For

For example, peaches, nectarines, apricots, &c. all produce their fruit principally upon the young wood of a year old; that is, the shoots produced this year bear the fruit the year following, and the same of every year's shoots, so that consequently, in all these trees, a general supply of the best regular shoots of each year must be every where preserved, both in summer and winter Pruning, at regular distances quite from the very bottom to the extremity of the tree one very side, in such order as to seem coming up regularly one after another; and generally trained principally all at full length during their summer's growth; but in winter Pruning, a general shortening, less or more, according to the strength of the different shoots, is necessary in order to promote their throwing out more effectually a supply of young wood the ensuing summer, from the lateral eyes, in proper places for training in for next year's bearing; the fruit-buds being generally produced all along their sides immediately from the eyes, they rarely forming any considerable fruit-spurs, as in the apple, pear, &c. but the same shoots both produce the fruit and a supply of shoots at the same time for the succeeding year's bearing, though it should be remarked, that all these trees also bear on casual small natural spurs, sometimes arising on the two and three years' wood, one or two inches in length, generally well furnished with blossom buds in the proper season; and should generally be preserved for bearing; but always depend on the main young shoots as above for the principal bearers.

Vines also produce their fruit always upon the young wood, shoots of the same year arising from the eyes of the last year's wood only, and must therefore have a general supply of the best regular shoots of each year trained in, which in winter Pruning must be shortened to a few eyes or joints, in order to force out shoots from their lower parts only, properly situated to lay in for bearing the fruit the following year.

Figs bear also only upon the young wood of a year old, and a general supply of it is therefore necessary every year; but these shoots must at no time be shortened, unless the ends are dead, because they always bear principally towards the extreme part of the shoots, which if shortened would take the bearing or fruitful parts away: besides, these trees for the general part naturally throw out a sufficient supply of shoots every year for future bearing without the precaution of shortening.

And as to apple, pear, plum, and cherry trees, they generally bear principally on spurs

arising in the general branches, of from two or three to ten or twenty years old, the same branches and spurs continuing bearing a great number of years, so that having once procured a proper set of branches, in the manner already directed, to form a spreading head, no farther supply of wood is wanted than only some occasional shoots now and then to supply the place of any casual worn-out or dead branch as before hinted; the above-mentioned spurs or fruit-buds are short robust shoots, of from about half an inch to one or two inches long, arising naturally in these trees, first towards the once extreme parts of the branches of two or three years old; and as the branch increases in length, the number of fruit-buds increases likewise accordingly; this therefore determines, that in the general course of Pruning all these kind of trees, their branches that are trained in for bearing must not be pruned or shortened, but trained at full length; for if they were shortened, it would divest them of the very parts where fruit-buds would have first appeared, and, instead thereof, would throw out a number of strong unnecessary wood-shoots, from all the remaining eyes; therefore all the shoots or branches of these trees should be trained principally at full length, and as they advance still continue them entire; thus they will all readily form the aforementioned little spurs or fruit buds from almost every eye; when indeed there is a vacancy, and there is only one shoot, where two or three may be requisite, in which case pruning or shortening is allowable in these trees, to force out the supply required. See the different sorts under their proper *genera*, also the article DWARF-TREES.

In these trees great care is necessary to preserve all the proper fruit-buds or spurs, which are readily distinguished by their short, thick, robust growth, rarely exceeding one or two inches long.

In the general course of Pruning all sorts of wall and espalier trees, that when displacing the superfluous and ill-placed wood, &c. always take them off quite close both in the summer and winter Prunings, not leaving any spurs or stumps of them an inch or two long, as often done, which fills the tree full of disagreeable stumps, and which pushing out strongly from every eye, crowds the tree with a multitude of unnecessary and irregular shoots, and causes great confusion and obscurity, and exhausts the sap to no purpose, as well as occasions a great deal of labour to retrench them; remember therefore, that all improper and ineffectual shoots and branches, necessary to be displaced, must be taken off quite close

to the place from whence they arise; which in the summer Pruning, if attended to early, while the shoots are quite young and tender, they may readily be rubbed off quite close with the thumb; but when the shoots become older and woody, as they will not readily break, it must be done with a knife, cutting them as close as possible; and all winter Pruning must always be performed with a knife.

It should also generally be observed in Pruning in summer, that all the necessary supply of regular shoots that are left for training in, should never be shortened during this season, unless to particular shoots to fill a vacancy, or to reduce within bounds any too long extended shoots; for by a general shortening in this season, all the shoots so treated would soon push again vigorously from every eye, and run your trees into a perfect thicket of useless wood; therefore all sorts, whether they require shortening in the winter Pruning or not, should, in the summer dressing, be layed in at full length.

Two seasons of Pruning are requisite for all sorts of wall and espalier trees,—a summer and a winter Pruning.

Summer Pruning.—The summer Pruning is a most necessary operation; every one must know that in spring and summer wall and espalier-trees abound with a great number of young shoots that require thinning and other reforms to preserve the requisite regularity and beauty of the trees, and encourage the fruit; and the sooner it is performed, the better; it is therefore advisable to begin this work in May or early in June, and timely disburthen the trees of all evidently redundant or superfluous growth, and ill placed and improper or bad shoots; which may be performed with considerably more expedition and exactness than if delayed till after the trees have shot a considerable length and run into confusion and disorder by their shoots forming a thicket, when it will in a manner be impossible to see what you are about; besides the disadvantage of choking up the fruit behind such a thicket of wood and leaves: it is therefore of great importance to proceed in this operation in the month of May or early in June, or when the same year's shoots are sufficiently formed to enable you to make a proper choice; and if begun early in the season, while the young shoots are tender, or soft and herbaceous, as it were, the displacing the ineffectual and superabundant growths may be occasionally effected by detaching or rubbing them off close with the thumb and finger; but when more advanced to a woody state, the pruning-

knife, only, must be employed in that business.

However, at any rate, let the work of summer Pruning be proceeded in before the trees have so far advanced in shooting as to cause much confusion, which would cost you a great deal of pains, precaution, and perplexity, to penetrate and break through the obscurity to determine what is proper to retrench or what to leave.

In this Pruning, we observed above, that a great many more shoots arise from all the principal branches than are wanted, or can possibly be trained with regularity, or than are well placed or proper for the purpose; our business therefore now is to thin and regulate them, by pruning away the superfluous shoots, and all such as are ill-placed and of bad growth as aforesaid: as to superfluous shoots, they are to be considered as such when any tree throws out a redundancy of wood, or much more than what is wanted, or than can be trained in; of these you must now retrench the most irregular placed, weakest, and all such as are evidently not wanted for use, and where two or more shoots any where arise from the same eye, clear all away but one of the best, reserving a sufficiency of the moderately strong and most regular placed side shoots, and always a leading one at the end of every branch, where it commodiously occurs; and all of which retained proper shoots are to be regularly trained in to choose from in the winter Pruning, leaving more or less in proportion, according to what the trees are; or the mode of bearing, as before hinted; though in all those trees that bear always on the young wood, leave at least doubly or trebly more shoots at present than what may appear just necessary, especially of peaches, nectarines, apricots, vines, figs, &c. for it is highly requisite to reserve plenty of regular young wood in summer, to choose from in winter Pruning, to lay in for next year's bearers; but as to apples, pears, plums, cherries, &c. which continue bearing many years on the same branches, should leave only here and there some good well-placed shoots towards the lower parts, or in any vacancy between the main branches till winter; and if then not wanted, they are easily retrenched. Ill placed shoots being such as either grow directly from the front or back of the branches straight fore-right, (called fore-right shoots,) or any other way so ill placed as not to admit of training with regularity, so must all be cut out quite close; and bad or hurtful growths being considered as any very luxuriant shoots, distinguished from the others by their singularly rank

rank, vigorous shooting, and are like to prove injurious by drawing all the nourishment, and impoverishing the neighbouring ones that are of more moderate growth, should generally be removed, except where any may seem proper to leave to fill a vacant space, in which it may be pinched or pruned early to three, four, or five eyes, when it will furnish you with the like number of more moderate shoots to fill the vacancy.

Where however a tree is in general inclined to luxuriance, it is proper to retain as many of the regular shoots as can be commodiously trained in with any regularity, in order to divide and exhaust the too abundant sap, which causes the luxuriance; for by humouring somewhat the natural inclination of luxuriant trees by leaving plenty of branches and these mostly at full length, is the only method by which we can the most readily reduce them to a more moderate state of growth.

Pay particular attention always to the lower parts of your trees; for frequently we shall find proper shoots arising in places necessary to be trained in, either to supply a present or an apparent future vacancy, or as a reserve to replace any decayed or worn-out or other bad branch, so that if moderately strong well-placed shoots arise in such parts, they are particularly to be regarded at this time; and in winter Pruning, such of them as are not wanted may be easily cut out.

All weak trifling shoots should now also be taken out, unless any shall appear useful to fill a vacancy, or likely to be of service hereafter.

Observe in this Pruning not to disturb the natural fruit-buds or spurs, before described.

After having summer Pruned and cleared any tree from all useless shoots as above, let all the remaining proper shoots be directly, or as soon as they are long enough, trained in straight and close to the wall or espaliers, and all of them at full length during the summer season, for the reasons before given; not shortening any at this time, except, as before observed, when there is any great vacancy in some particular parts, it may be proper to cut or prune one or more contiguous shoots to three, four, or five eyes or buds, in order to promote an emission of laterals accordingly the same season, more effectually to supply the vacant spaces; but let all the rest be trained at full length till winter Pruning, when they must undergo another regulation; and shorten those of such trees as require it, as peach, nectarine, &c.

The work of training in the shoots in this season is, if against walls, both by nailing, by

means of proper shreds and nails, and occasionally by fastening in the smaller shoots, with little sticks or twigs stuck between the main branches and the wall; and for espaliers, tie them with small osiers, rushes, or bals strings.

Having thus summer dressed and trained your trees, it will be necessary to review them occasionally, in order to reform such branches or shoots as may have started from their places or taken a wrong direction, also that according as any fresh irregular shoots produced since the general dressing may be displaced; and likewise as the already trained shoots advance in length or project from the wall or espalier, they should be trained in close, still continuing them at full length during their summer's growth; for every thing should be kept close and regular all summer, whereby your trees will appear beautiful to the eye, and the fruit will show itself, and attain its due perfection.

For by thus properly summer Pruning and training wall and espalier trees early in the summer, you preserve their regularity and prosperity; and by clearing out all the unnecessary and useless growth, training the rest close and regular, the fruit will receive all requisite advantage from the sun, air, rains, &c. and it will of course attain the greater perfection both in size, beauty, and flavour.

Winter Pruning.—In the winter Pruning, a general regulation must be observed both of the mother branches, as required, and the supply of young wood laid in the preceding summer; and the proper time for this work is, in most wall-trees, any time in open weather from the fall of the leaf in November until March.

In performing this work of winter Pruning, it is proper to unnailed or loosen great part of the branches, particularly of peaches, nectarines, apricots, vines, and such other trees, as require an annual supply of young wood, and some considerable regulation in the general branches.

First look over all the principal or mother branches, and examine if any are worn out or not furnished with parts proper for bearing fruit, according to the rules before illustrated with respect to the nature of bearing of the different sorts of trees; and let such branches be cut down either to the great branch from which they proceed, or to any lower shoot or good branch they may support toward their bottom part, leaving these to supply its place; likewise examine if any branches are become too long for the allotted space either at sides or top, and let them be reformed accordingly by shortening them down to some lower shoot or

or branch properly situated to supply the place ; being careful that every branch terminates in a young shoot of some sort for a leader, especially in all parts where room to extend them, according as the limited space admits, having the leader either placed naturally at the termination of the branch ; or, where too long in any particular parts of the tree, prune the branch conformably to some lower shoot, &c. so as it may still terminate in a proper leader, and not generally cut the extended branches to naked stumpy or stubbed ends, as often practised by inexperienced pruners.

From the principal or larger branches, pass to the young wood of the year : or, however, in proceeding in this general winter Pruning both in the occasional reform among the principal or older branches, and more general regulation requisite in the young wood of the year, or shoots of the preceding summer, by observing the above intimations relative to the principal branches, the Pruning in the whole, both on the old and young wood, may be carried on regularly together at the same time, cutting out or retaining according to circumstances ; as for instance, in the older wood observing the particulars as above, and as hereafter, and in the general supply of young wood, cut out close all fore-right and other irregular shoots that may have been omitted in the summer Pruning ; likewise all very weak shoots, and those of very luxuriant growth, unless it be necessary to keep some to supply a vacant place ; then of the remaining regular shoots, you are to select a greater or smaller portion to leave either as a general supply for next year's bearing, as is requisite for peaches, nectarines, apricots, vines, and figs ; or only in others some occasional shoots, such as in full-trained apple, pear, plum, and cherry trees, &c. either sometimes to furnish some casual vacancies, or to supply the places of any defective or improper branches, or ineffectual bearers, as may casually occur, or that of decayed or dead wood.

But as peach, nectarines, apricots, vines, and figs, always bear principally on the year-old wood as before noticed, a general supply of young shoots must be left in every part from bottom to top at regular distances, and, at the same time, some proportional part of the most naked old wood, and of the two preceding years past bearers, pruned out to make proper room for this requisite young successional supply of future bearers next summer, necessary now to be retained in a general manner, both laterally, and as terminals to the general parent branches, which should

now be pruned accordingly ; and mostly all the said supply of the present retained shoots, except the fig, must be more or less shortened according to their situation and strength, to encourage their furnishing more readily a proper supply of shoots in spring and summer for the succeeding year's bearing, as before observed, leaving the strongest shoots always the longest, as is more fully explained under each of their respective *genera* ; but as the figs always bear towards the end of the shoots they must not be shortened.

And with respect to the apples, pears, plums, cherries, &c. as they continue to bear on the same branches of from two or three to many years' standing, the said bearers must be continued accordingly ; and the trees only require an occasional supply of young wood, according as any of the branches become defective, or unfit for bearing, and want removing ; which should now, in this winter Pruning, be cut out as it may seem necessary, agreeable to the foregoing intimations ; so should accordingly train in here and there in proper places some good regular young shoots towards the lower part, and where it may seem necessary, to be coming gradually forward to a bearing state, to be ready to replace worn out and other useless branches, to be cut out, as above, according as they may casually occur : and of the young wood, selecting what may appear necessary of the best well-placed shoots for the above occasions, and the superabundance, or those not wanted for that purpose, together with all irregular-placed shoots, rank luxuriant, and other ineffectual growths, should be now cut clean out, close to whence they originate, not leaving any spur or stump thereof, as every one of which, as we before observed, would push out several strong unnecessary shoots the next spring, to the prejudice both of the trees and fruit ; have particular regard to preserve the shoots at the termination of all the already trained branches entire, not however more than one shoot to terminate each branch ; preserve also carefully all the proper fruit spurs ; likewise observe, that the supply of young wood occasionally reserved, and the branches in general of these trees, should all be trained in at full length, and continued so in future, as far as the limited space will admit : and according as any extend above the wall or espalier or any where beyond their proper limits, they should be pruned down with discretion to some convenient bud, or lateral shoot, or lower branch, which train also entire.

In this Pruning, as in the summer dressing,

it is of importance to have a strict eye to the lower parts of wall-trees, &c. to see if there is any present vacancy or any that apparently will soon happen; in which cases, if any good shoot is situated contiguous, it should be trained in either at full length, or shorten it to a few eyes to force out two or more shoots if they shall seem necessary; for precaution should ever be observed in taking care to have betimes a sufficient stock of young wood coming forward to fill up any casual vacancy, and substitute a new set of branches in place of such as are either decayed or stand in need of retrenchment.

Sometimes in wall-trees and espaliers there are many large disagreeable barren spurs, consisting both of old worn-out fruit-spurs, and of clusters of stumps of shortened shoots projecting considerably from the branches, occasioned by unskilful Pruning when retrenching the superabundant and irregular shoots, which, instead of being cut out close, are stumped off to an inch or two long, and in the course of a few years, forming numerous barren stumps, as above said, and very little fruit, the trees appear like a stumped hedge; it is therefore, in this season of Pruning, advisable to reform them as well as possible by cutting all the most disagreeable stumps clean out close to the branches, leaving these at full length, especially of apples, pears, &c. as before advised; and reserve an occasional supply of young wood in different parts; and thus in two or three years you may reduce such trees to a regular figure and a proper state of bearing.

Bad Pruning ruins many a good tree, as is observable in numerous gardens, where the wall trees and espaliers appear as just above described, pruned every year, yet never produce any tolerable crop of fruit.

The reason is, the operation or art of Pruning is much more generally practised than understood; different pruners have different ideas of Pruning: many proceed upon little or no principle, and often prune all trees alike; and their idea of Pruning often consists in retrenching annually most of the young shoots, and shortening all the branches of every tree without exception, to the great injury of some sorts, and retarding their bearing: likewise many pruners, in retrenching the superfluous and irregular shoots, instead of cutting close, as formerly observed, they often stump them off to about one or two inches long; these remaining stumps shoot out again from every eye, and fill the tree with more numerous useless shoots than before,

which being also pruned down to stumps of an inch or two long, as above, practising the same every Pruning, so as in the course of a few years every branch is loaded with clusters of large rugged barren spurs, formed wholly of the stumps of shortened shoots, occupying the places where fruit buds or natural spurs might be expected: and, as before intimated, it is an equally erroneous idea, observable in many pruners, that all the retained shoots of wall an espalier trees in general must, in the annual Pruning, undergo the discipline of the knife, so shorten all without distinction or reluctance, often too with so much severity on trees that should not be shortened, as to destroy the very parts where fruit-buds would have been produced; they thinking this general shortening necessary to strengthen the branches; which, however, in many sorts, promotes a too vigorous growth, and retards their bearing; particularly in trees that produce their fruit-on natural spurs, forming themselves gradually all along the sides of the branches, often first towards the upper part, or that which was once the extreme part of the shoots, that shortening not only cuts off these first fruitful parts of the branches, but throws the sap back with so much vigour to the remaining buds, that, instead of forming fruit spurs, almost every bud pushes out luxuriant shoots, and the trees are continually crowded with unnecessary wood, causing a great annual trouble to retrench it, without the pleasure of having a quarter of a crop of fruit; besides the annually cutting out so much strong wood is very prejudicial to some sorts of fruit-trees.

Too severe injudicious Pruning in strong wood is greatly prejudicial to the health of some sorts of stone-fruit-trees, in particular, by causing them to gum and soon decay.

Plums and cherries, in particular, are often greatly damaged by a too severe discipline of the knife, these trees being very liable to gum by large amputations: it is therefore of importance to attend to these trees well in the summer Pruning, to retrench all the superfluous and irregular shoots betimes in the summer while quite young, and pinch others occasionally where wood is wanted to fill vacancies, so as to require but little Pruning out of large wood in winter.

But if our former hints in the summer and winter Pruning are attended to in retrenching the useless wood every year at the time advised, you will always preserve your trees free from all incumbrance; and every part will be regularly filled with bearing wood, and their general management will prove easy.

A gene-

A general nailing, &c. must every year be performed, according as we advance with the Pruning.

Therefore it is proper that every tree, as soon as pruned, be directly nailed to the wall, or if espaliers, tie or nail them to the treillage, observing, that in the winter Pruning, as the work of nailing, &c. will require to be performed more or less upon all the branches, we must be careful to train them with great regularity, nailing them along horizontally, as straight and close as possible; never cross any of the branches, but train them distinct and parallel four to five or six inches asunder, as formerly advised, or in proportion to the size of the leaves and fruit of the different sorts, making the opposite branches of each side arrange equally in the same position.

Thus far is principally all we have to advance respecting the general mode of Pruning wall and espalier trees; particulars for each sort being noticed more fully under their proper *genera*; but what we have here advanced under this article *Pruning*, is to convey some general hints to unexperienced pruners, although there are many expedients and resources, not to be discovered but by repeated practice and observation.

Pruning Standards.

Standard fruit trees require but very little Pruning: for as their branches have full scope above to extend themselves every way, they must not be shortened; besides, as our standard fruit-trees, consisting principally of apples, pears, plums, and cherries, which, as before said, bear fruit on natural spurs arising towards the upper parts of the branches, which, as observed in the wall-tree and espalier Pruning, determines that we must not shorten them, nor practise any other Pruning than just to reform any great irregularity, &c.

The first occasional Pruning, however, necessary for standard fruit-trees, is the first two years of their growth, in order to form their heads somewhat regular, by retrenching any irregular shoots; and when designed to have them form more regular spreading heads, it is customary to prune the first shoots, when a year old, down to four or five eyes, in order to force out lateral shoots from these lower buds the following summer, to give the head a proper formation. After this, suffer the branches to take their natural growth, except that, if, while the trees are young, any very luxuriant shoots ramble away considerably from all the others, and draw most of the nourishment, it is proper to prune them, ei-

ther by retrenching entirely very irregular ones, or shortening others more or less, to some regularity, to branch out consistent with the requisite form of the head.

But let it be remarked in general, that, except in such cases of reducing irregularities, let the heads of all kinds of standards always branch away as fast as possible, both in length and laterally, agreeable to their natural mode of growing; and they will naturally furnish themselves abundantly with bearing wood.

Observe however, that as, in standard fruit-trees of some years' growth, irregularities and disorder will occasionally happen, which should be regulated a little by Pruning the most conspicuously irregular and redundant growths; performing it always in winter.

For instance; where any considerable branches grow right across others, or in any other awkward direction, to incommode or cause confusion, or much irregularity in the head, they should be retrenched close; likewise any branch that rambles considerably from all the rest, should be reduced to order, by cutting it down to some convenient lower branch, so as to preserve some regularity. Where the head is considerably crowded with wood, let the worst of the redundancy be thinned out as regularly as possible, cutting them close to their origin; observe likewise that as sometimes very vigorous shoots arise considerably in the heart of the tree, or towards the bottom of the main branches, often growing upright, and crowd the middle of the head, they should be constantly retrenched to their very bottom; cut out also any very cankered parts, and all decayed wood; and clear off all suckers from the root and stem.

Standard trees thus disburthened from any considerable irregularities and confusion, so as all the proper branches have full scope to spread free and easy in their natural manner, will not fail to repay the trouble in the superior quality of their future fruit.—See each sort under its proper genus, also ORCHARD-TREES.

Pruning Forest Trees, &c.

With respect to Pruning of forest and ornamental trees, flowering shrubs, &c. it is very inconsiderable.

Forest trees, &c. must be suffered to run up as fast as possible, so their heads must not be shortened; all that is necessary is, to prune off lateral branches occasionally from the stem; or if, while young, any lateral shoot of the head is of a very rude rambling growth, it is proper to reduce it as you see convenient; but otherwise suffer the top and general branches

of the head to remain entire, and take their own natural growth; only prune lower stragglers occasionally; observing, however, it is very improper to trim up the stem too high, as often practised to forest trees, as scarce to leave any upper branches to form a head: never, therefore, trim the stem much higher than the full spread of the principal branches; for a full head is both ornamental and essentially necessary to the prosperity of the tree. See PLANTING.

And as to the shrub kind, they should also, for the general part, take their own growth at top; and only prune occasionally any lower stragglers, from the lower part of the stem, or any very irregular rambling shoot of the head, and all dead wood: but except in these cases, let their heads mostly shoot in their own way, according to their different modes of growth, in which they will appear always the most agreeable.

Where, however, it is required to keep shrubs low, in any particular compartment, you must regulate this as you shall see convenient, with your pruning-knife, preferably to garden-shears, which should never be used in that business to shrubs and trees in rural growth: in all of which, knife Pruning is the most eligible.

Pruning Implements.

For the purpose of general Pruning, several implements are necessary, such as Pruning-knives, saws, chisels, hand-bills, hatchets, &c.

As to Pruning-knives, two or three different sizes are requisite, in order to enable us to prune neatly; a strong one for cutting out larger branches, shoots, &c. and a small one for the more exact Pruning among the smaller branches and shoots of peach and nectarine trees, &c. these knives are generally made curving at the point; they should not be too long, broad, and clumsy, but have rather a shortish narrow blade, and but very moderately hooked at the point, for when too crooked they are apt to hang in the wood, and not cut clean; it is also proper to be furnished with a strong thick-backed knife, to use by way of a chisel occasionally, in cutting out any hard stubborn stumps, &c. placing the edge on the wood, and with your nailing hammer strike the back of it, and it will readily cut through even and smooth.

Pruning hand-saws are proper for cutting out any large branch too thick and stubborn for the knife; they should be of moderate sizes, one of which should be quite small and narrow, in order to introduce it occasionally between the forks of the branches, to cut to exactness.

As saws generally leave the cut rough, it is proper to smooth it with a knife or a pruning-chisel.

Pruning chisels are necessary to use occasionally, both to cut off any thick hard branch and large hard knotty part, or stump, and to smooth cuts in large branches, &c. after a saw; they should be flat, and from about one to two inches abroad; sometimes large strong chisels, fixed on a long pole, are used in Pruning or lopping branches from the stems of high standard forest trees, one man holding the chisel against the branch, while another, with a large mallet or beetle, strikes the end of the pole.

A hand-bill and hatchet are also necessary to use occasionally among larger kinds of the standard trees.

All these Pruning tools, in their proper different sizes, may be had at all the cutlery shops and ironmongers, also of many of the nursery and seedsmen.

PRUNUS, Plum-tree; comprising also the Cherry-tree, Apricot, Laurel, &c.

This noted genus comprehends different sorts of valuable fruit-trees, some flowering shrubs, and beautiful ever-greens; and to some it may seem irregular to see the Cherry-tree, Apricot, Laurel, &c. arranged as species of the same genus as the Plum-tree, as being formerly considered each as a distinct genus; but late discoveries in botany prove them to be all species of *Prunus*, and modern botanists range them accordingly; all the species of which are of hardy growth, garnished with simple spear-shaped and oval leaves, and pentapetalous icosandrious flowers, succeeded by drupaceous fruit.

Class and order, *Icosandria Monogynia*.

Characters.] CALYX is monophyllous, bell-shaped, five-parted, and deciduous. COROLLA, five large, roundish, spreading petals. STAMINA, twenty or more filaments inserted into the calyx, and short didymous antheræ. PISTILLUM, a roundish germen, slender style, and orbicular stigma. PERICARPUM, a roundish drupaceous fruit, inclosing a roundish, compressed, hard nut.

The principal species of this genus are—common cultivated Plum-tree, having numerous varieties: Bullace-tree—Sloe-tree, or Black thorn—Cherry-tree, having many varieties—Padus, or Bird Cherry—Apricot-tree, many varieties—and Laurel-tree: observing, that, although all of the same genus, several of the sorts differ materially from one another: we therefore think it eligible to range or class them according to their nature

or kinds, under the following heads—Plum kinds—Cherry kinds—Apricot kinds—Laurel kinds, &c. all however under the generical name *Prunus*.

Plum Kinds.

Under this head we may comprise three species, viz.—1. Cultivated Plum-tree, and its numerous varieties.—2. Bullace-tree.—3. Sloe-tree.

1. *PRUNUS domestica.*

Domestic Prunus, or common cultivated Plum-tree.] Grows fifteen to twenty feet high, or more, garnished with oval-spear-shaped leaves, and with the pedunculi for the most part singly, terminated by white flowers, succeeded by Plums, of many different shapes, sizes, colours, and properties in the varieties.

Varieties.] The varieties of the domestic *Prunus* are very numerous, especially of the fruit; all the different sorts being varieties of this species, though the trees of the different varieties often differ somewhat in their growth, some being strong shooters, others moderate, and frequently vary in the size and colour of their shoots and leaves; those bearing large fruit have generally larger leaves in proportion; and the difference in shape, size, &c. of the fruit is also very considerable in different varieties, some being round, others oval, and some being not much larger than Cherries, others as large as eggs; and some are yellow, others black, blue, red, and some green, &c. all of which varieties ripen perfectly in our gardens and orchards.

Principal varieties of the fruit are,

White Primordium, or Jean Hative Plum.—A smallish, oblong, yellow Plum, powdered with a white bloom, esteemed chiefly for its early perfection; ripe the middle or end of July.

Morocco, or early black Damask Plum.—A middle-sized, round, blackish-purple fruit, powdered with blue, is well flavoured, and discharges the stone; ripe end of July.

Little Damask Plum.—A small, round, black, well-flavoured Plum; ripe end of July or beginning of August.

Great Damask Violet Plum.—A moderately large, roundish-oval, dark-blue Plum, covered with a violet bloom, is of a rich juicy flavour, and quits the stone; ripe in August.

Précocé de Tours.—A roundish, dark-purple, fine, early Plum.

Queen Claude Plum, sometimes called Green Gage.—A middle-sized, round, yellowish-green Plum, having a firm, deep-green pulp, of a fine rich flavour, and quits the stone; ripe in September.

Little Queen Claude Plum.—A small, round,

whitish-yellow Plum, powdered with white, and parts from the stone; ripe end of August and beginning of September.

Green Gage Plum.—A middle-sized, roundish, green Plum, sometimes purplish on the sunny side, having a yellowish-green firm pulp, of a most delicious rich flavour, but does not discharge the stone freely; is one of our most valuable Plums, and the tree a great bearer; ripe the end of August and beginning of September.

Varieties.] There are several varieties of greenish Plums, that go by the name of Green Gages, that are of inferior quality.

Blue Gage Plum.—A middle sized, roundish, bluish Plum, of a rich flavour; ripe beginning or middle of September.

Orleans Plum.—A middle-sized, round, pale-red Plum, often of a whitish-green colour on the side away from the sun; is of but a middling flavour, and quits the stone clean. The tree is of spreading growth, a remarkably great bearer, and very profitable for common use, and for those who supply the markets; ripe end of August and beginning of September.

Drap d'Or, or Cloth of Gold Plum.—A middle-sized, roundish, bright-yellow Plum, spotted with red, of an excellent vinous flavour, and adheres to the stone; ripe beginning or middle of September.

Black Perdrigon Plum.—A middle-sized, oval, dark-coloured Plum, powdered with a violet bloom; is of a fine rich flavour; ripe middle or end of August.

Blue Perdrigon Plum.—A large, roundish, bluish-coloured Plum, replete with a delicious juice; ripe end of August.

White Perdrigon Plum.—A middle-sized, roundish-oblong, whitish-yellow fruit, covered with a white bloom; is firm, juicy, rich, and quits the stone; ripe end of August and beginning of September.

Roche Courbon, or Red Diaper Plum.—A middle-sized, round, fine-red Plum, powdered with a violet bloom, is high flavoured, and adheres to the stone; ripe end of August.

Red Imperial Plum.—A large, oblong-oval, flattish, pale-red Plum, covered with a whitish bloom; is of but a middling relish, and parts from the stone; ripe middle of September.

White Bonum Magnum, Mogul or Egg Plum.—A remarkably large, oblong-egg-shaped, whitish-yellow Plum, powdered with a white bloom, having a fine pulp that cleaves to the stone; more esteemed for culinary use, than eating raw; the tree shoots strong, with

very

very large leaves; is a great bearer, and the fruit is the largest of the Plum kind; ripe beginning or middle of September.

Red Bonum Magnum, sometimes called the *Great Imperial Plum*.—A very large, oval-oblong, deep-red Plum; not of a rich flavour, but is excellent for preserving and culinary purposes; ripe beginning or middle of September.

Fotheringham Plum.—A large, oblong, fine-red Plum, having a fine rich pulp that quits the stone; ripe end of August and beginning of September.

Myrabalan Plum.—A middle-sized, black-purple, very fine plum; ripe in August and September.

Brignole Plum.—A largish, oval, yellowish Plum, tinged with red next the sun, having a firm, dry, rich pulp, is in much estimation for sweetmeats; ripe in September.

Le Royal Plum.—A large, roundish, light-red, finely-powdered Plum, having a juicy sugary pulp, that cleaves to the stone; ripe end of August and September.

Cheston Plum.—A middle-sized, oval, blackish-blue Plum, powdered with a violet bloom; ripe towards the middle of September.

Wentworth Plum.—A large, oval, yellowish Plum, of an acid relish, and separates from the stone; is a good culinary fruit; ripe in September.

Mirabelle Plum.—A small, round, greenish-yellow Plum, having a rich pulp, that discharges the stone, and the tree a great bearer; ripe end of August.

Apricot Plum.—A large, round, yellowish Plum, having a firm, dry, sweet pulp, that separates from the stone; ripe beginning or middle of September.

St. Catharine Plum.—A large, oblong-oval, yellowish-amber-coloured Plum, powdered with a white bloom, having a rich juicy agreeable pulp, adhering close to the stone; ripe end of September.

Imperatrice Plum.—A smallish-middle-sized, roundish, dark-bluish-purple, finely-powdered Plum, of an agreeable flavour, the pulp adhering to the stone; ripe in the beginning of October.

Little Green Damask Plum.—A small, round, greenish Plum, powdered with a whitish bloom, having a green very agreeable pulp, adhering to the stone; ripe middle or end of September.

Pear Plum.—A moderate-sized, oval, whitish-yellow Plum, of an inferior flavour, esteemed principally for preserving; ripe late in September.

Muscat Plum.—A smallish, oblong, flat,

dark-red Plum, of but an indifferent relish; ripe in September.

Damascene Plum or Damson.—A small, roundish, dark-blue Plum, of a tolerably agreeable acid relish, both for eating and culinary purposes, and the tree a great bearer; ripe in September.

St. Julian Plum.—A small, round, dark-violet-coloured fruit, covered with a mealy-powder; has but little relish; ripe end of September.

Cherry Plum.—A very small, round, cherry-shaped, red Plum, valued chiefly as a curiosity; and the tree is often planted among flowering shrubs, for the sake of its beautiful bloom in spring; and its cherry-like fruit exhibit a pretty variety in summer; though by its flowering very early, the bloom is often cut off, and seldom succeeded by much fruit.

Thus far is principally all the most noted varieties of this fruit cultivated in the English gardens, and in the nurseries for sale; though there are numerous other varieties, particularly of the common sort, growing in the orchards and hedges of farmers, &c. in different parts of the country; all the sorts being varieties of one species, first obtained from seed; and the approved sorts of them have been multiplied and continued by budding and grafting. See their *Propagation*.

But besides the above varieties of the fruit, there are also the following for ornamental plantations.

Double-blossomed Plum-tree—Gold-striped-leaved—Silver striped-leaved—and the stoneless Plum.

The two following species, *Bullace-tree* and *Sloe-bush*, grow wild in hedges, but are sometimes cultivated both for variety and use.

2. PRUNUS infinita.

Wild Plum, or Bullace tree.] Grows twelve or fifteen feet high, the branches somewhat spinous; oval leaves, hairy underneath, and the pedunculi by pairs, terminated by white flowers, succeeded by small, round Plum-like fruit, of different colours in the different varieties.

Varieties are,] Common black-fruited—White-fruited—Red-fruited; all of which ripen late in autumn. They are very acid, though of a tolerably agreeable flavour, and by many esteemed very wholesome, if eaten when quite ripe. They grow wild in the hedges in many parts of England, &c. in great abundance, so are not often cultivated; a few plants however merit culture for variety, also some in the shrubbery and wilderness compartments, where they will effect an

an agreeable diversity in autumn when in fruit.

3. PRUNUS spinosa.

Thorny Prunus, Black-thorn, or Sloe-tree.

Grows ten or twelve feet high, very branchy and bushy quite from the bottom, armed with strong sharp spines, small, spear-shaped, smooth leaves; pedunculi growing singly, terminated by flowers, succeeded by small, round, black, berry-like fruit, the smallest of the Plum kind; ripe late in autumn. It grows wild every where in hedges and woods, and is very proper to plant for field hedges, being of very quick close growth. See HEDGES.

The above three species are all that are proper to arrange under this head, considered as of the Plum kind, in respect to the growth of the trees, and nature of the fruit; though the first species only, and its varieties, are proper for general culture.

The trees of all the sorts are of the deciduous tribe, of hardy growth, and prosper in any common soil and exposure; they all flower or blossom profusely in the spring, April, and beginning of May, and make a fine appearance; all the flowers of every sort consist each of five small petals, and twenty or more stamina, the flowers and fruit being produced on short spurs arising from the sides and ends of the branches; and the fruit ripens in autumn, gradually in different sorts from the middle of July until October; exhibiting a most delightful variety in the different colours, shapes, and sizes, of the cultivated Plum kinds in particular, as well as afford a most useful supply for family use, both as excellent table fruit, and for various culinary purposes, and for preserving, &c.

With respect to the merit of the different species, &c. the first sort, *Cultivated Plum-tree* and varieties, every one knows its value as a fruit tree, and no good garden should be without a collection of the best sorts; and as to the ornamental varieties, double-blossom kind and striped-leaved sorts, as also the *Cherry Plum*, they are proper for decorating the shrubbery; but the second and third species, *Bullace-tree* and *Sloe-bush*, they are only sometimes admitted in gardens, orchards, shrubbery, &c. for variety, particularly the former, the fruit of which cause an agreeable diversity whilst growing, and afford variety at table, when all the more rich stone-fruits are gone: as to the *Sloe-tree*, however, its principal merit is to plant for forming field hedges, as before observed; it grows thick and thorny from the very bottom, and makes a strong close hedge.

The common *Plum-tree* and its varieties may be trained both as dwarfs for walls and espa-

liers, &c. and standards and half standards.

Those, however, trained against walls and espaliers, generally produce the largest and fairest fruit; so should always train some of the best sorts in both these ways, and may have any of the varieties as standards in the garden or orchard.

Propagation of all the above Species and Varieties.

First, the common Plum tree.—As to the method of raising Plum trees, all the varieties were first obtained by seed, *i. e.* from the stones of the fruit; and the approved kinds, so acquired, were afterwards multiplied by grafting and budding; for they do not continue the same sorts from seed, as from the seed of one tree there may rise many different sorts, and probably not one like the mother-tree, or very few that produce fruit worth eating; but being in possession of any approved sorts, they may be multiplied at pleasure, by ingrafting shoots or buds of them into any kind of Plum-stocks.

The general propagation therefore of Plum-trees is, by grafting and budding, and may also be increased occasionally by layers; but the two former are the most eligible methods of propagation.

By Grafting and Budding.—This is performed upon stocks of any sorts of the Plum-kind raised from the stones, sown in autumn in beds of good earth, about two inches deep; and when the plants are a year old, they being planted out in nursery rows two feet and a half asunder, and having from one to two or three years' growth, will be in a fit order to graft or bud with the desired sorts; which is performed in the usual way, either low in the stock for dwarfs, and at several feet height for standards (See GRAFTING and INOCULATION): observing, that when the first shoots from the graft or bud are one year old, those of the trees designed as dwarfs for walls, &c. should be headed down within five or six inches of the bottom, more particularly of the budded trees, in order to force out laterals from the lower eyes, so as to furnish a proper set of branches, proceeding regularly from the bottom of the tree, to cover every part of the wall and espalier. But as to standards, their first shoots may either be suffered to run and branch in their own way, or headed to a few eyes, if it shall seem necessary, to force out lower laterals to give the head a more regular spreading formation; afterwards, let them all take their own growth.

When the trees thus raised by grafting or budding are from one to two or three years old, they are of a proper size for final transplanting

planting into the garden, &c. though trees of six or eight years old may be safely transplanted; remarking however, the younger they are planted where they are to remain, the sooner and more firmly they will establish themselves, and form for bearing.

By Layers.—This is only practised occasionally; performed any time from November till March, chusing the last summer's shoots, and lay them by slit-laying; in one year they will be rooted; they must then be separated, and planted in nursery-rows, and trained either for dwarfs or standards, as may be required.

The double-blossom Plum, the two striped varieties, and stoneless kind, are all propagated by budding or grafting upon any kinds of Plum-stocks, either for dwarfs, or half or full standards.

And the Bullace-tree, and Sloe-bush or Black-thorn, are propagated by sowing the berries or stones an inch deep in a bed of common earth in autumn; and the Sloe-tree also abundantly by suckers from the root.

Observe however, that to continue the different varieties of the Bullace tree distinct, they must be propagated by budding, grafting, or laying.

Planting them in the Garden, &c. and general Culture.

The season for planting all the sorts of Plum-trees is any time in open weather, from the fall of the leaf in November until March.

The trees of all the varieties will succeed in any common soil of a garden or orchard, and in any open exposure; allot however some of the best sorts for walls and espaliers, observing those for walls should generally have an east or west aspect, or even a south wall for some of the choicest sorts; and some may also be planted against a north wall, to furnish some late fruit: and those for espaliers may be planted around any of the open quarters, as may also the standards.

First, of planting and managing the trees designed for walls and espaliers.

Plant the wall and espalier trees fifteen or eighteen feet distance; though if the walls, &c. are rather low, eighteen or twenty feet distance will be requisite, in order that in default of a proper height of walling, there may be more scope to train the branches horizontally.

Observe, if the trees thus planted are quite young, being only of one year's shoot from the grafting or budding, they should in March be headed down, as before observed, to four or five eyes, to force out lower horizontals in the ensuing summer, which, according as

they advance in length, train in horizontally at full length all summer, unless you would forward a farther supply of lower branches as fast as possible; in which case, you may pinch the young shoots in May down to a few eyes; each will throw out several laterals the same year, which train also horizontally at full length during the summer's growth; and in winter pruning, cut out only any foreright and back shoots, and train in all the regular ones at full length; for the branches of these trees must not be shortened, only occasionally to procure wood to fill vacancies, because the branches always form fruit-spurs first towards their extreme parts, which would be destroyed by shortening; so that after having shortened the first and second year's shoots occasionally, as above, and thereby procured a proper set of lower horizontals, to give the head its first form; let the whole then be trained in entire about four, five, or six inches asunder; and, according as the trees shoot, every summer train in a necessary supply of the regular shoots to fill the wall, &c. at the same time retrench superfluities, and irregular and very rank luxuriant growths, and train the supply of regular wood still at full length at the above distances; and thus the trees will soon cover a large space, and the same branches, not shortened, will continue bearing many years. See PRUNING.

For all the sorts of Plums bear principally upon spurs, half an inch or an inch long, arising from the sides of the branches, of from one or two to many years old, when trained always at full length; but if shortened, they would throw out a multiplicity of useless wood, and hardly any fruit-spurs; therefore shorten none, except some occasional shoots to fill any casual vacancy, and always train the general branches at full length, both in the summer and winter pruning.

Observe all the sorts of wall and espalier Plum-trees should be pruned twice every year, a summer and a winter pruning, in order to retrench superfluities of each year, and all foreright and other irregular shoots, and bad wood, and to train in a necessary portion of young wood where wanted to fill vacancies or to supply the place of decayed, worn-out, and other bad branches, that may casually occur; observing the general directions for summer and winter pruning, under the article PRUNING.

Standard Plum-trees may be trained both as full standards and half-standards, budding or grafting the former six feet high, and the latter only three or four; or both kinds may be

be worked low in the stock, and the first shoot trained to those heights for a stem; then let them branch away and form a head.

These standards may be planted both in the garden and orchard, at from about twenty to thirty feet distance; which having had their head previously shortened in the nursery when one year old from budding, &c. if thought necessary, in order to force out lower branches to give the head a spreading form, they should now be planted with their heads entire, all but retrenching any irregularity, and should afterwards be permitted to take their natural mode of growth, except just reforming occasionally any cross-placed or very crowded branches, and all dead wood.

Cherry kinds.

PRUNUS Cerasus, or Cherry-tree.

The Cherry was formerly placed as a distinct genus (*Cerasus*); but its *characters* proving the same as the Plum, and as both sorts readily take by budding or grafting upon one another, it is now retained as a species of *Prunus*. There is but one species of the cultivated Cherry, but which, like the Plum, sports exceedingly in variety; there are, however, several species of the Cherry kind, as Common Cherry-tree—Wild Cherry-tree—Bird Cherry, &c. the first of which and its varieties is the principal species for general culture for the fruit; likewise some of the Wild Cherry; all the others are for the shrubbery and other ornamental plantations.

The species are,

I. PRUNUS Cerasus.

(*Cerasus*)—or *Common Cherry-tree*.] Grows twenty feet high, or more, garnished with oval-lanceolate, smooth leaves, almost sessile, umbellate clusters of flowers, succeeded by large roundish red fruit of different sizes and properties in the varieties.

Varieties of the fruit.] The above species comprehends many varieties of the fruit, the most material of which are the following.

Common Red Kentish Cherry.—The tree forms a spreading head, with numerous slender branches, bearing round bright-red Cherries, of a sharp acid relish, unless permitted to hang till dead ripe, when they become of a dark-red colour, and of a high flavour; is a remarkably great bearer, and proper to cultivate where large quantities of the fruit are required for sale, is also profitable for private use, and if full ripe, is an excellent Cherry; ripe in July.

This variety is supposed to be the original kind, and that most of the other sorts were first raised from it.

Little May Cherry.—The tree a moderate

shooter, having slender shoots and small leaves, and small, round, red fruit, valued chiefly for its early perfection; ripe, end of May or beginning of June.

Common May-Duke Cherry.—The tree large, spreading, and a great bearer, having large, round, dark-red, very fine eating Cherries; ripe sometimes in the end of May, but mostly in June.

Arch-Duke Cherry.—The tree large, branching strong and erectly, having larger, round, dark-red fruit; ripe, end of June and in July.

White-Heart Cherry.—The tree is of very large spreading growth, producing heart-shaped, whitish fruit, tinged with red next the sun; ripe in June and July.

Red-Heart Cherry.—A larger, heart-shaped, red-coloured, excellent Cherry; ripe, June and July.

Black-Heart Cherry.—A large, heart-shaped, very dark-red, rich-flavoured Cherry; ripe, end of June and in July.

Amber-Heart Cherry.—A middling-sized, heart shaped, amber-coloured fruit; ripe, middle or end of July.

Ox-Heart Cherry.—A very large, heart-shaped, red Cherry; ripe, middle or end of July.

Bleeding-Heart Cherry.—A large, longish, heart-shaped, deep-red, beautiful Cherry, but the tree no great bearer; ripe, middle or end of July.

Hertfordshire late Heart Cherry.—A middle-sized, heart-shaped, firm, good Cherry; ripe, end of July and beginning of August.

Carnation-coloured Cherry.—A very large, roundish, white and red, beautiful, firm Cherry; ripe, end of July, and in August.

Lukewarm Cherry.—A middle-sized, roundish, dark-coloured, very good Cherry; ripe, end of July.

Morello Cherry.—The tree a moderate shooter, but spreading, with numerous slender branches, and a great bearer, producing large, round, dark-red fruit, having a tender juicy pulp, of a sharp acid taste; but if properly ripened in a sunny exposure, is of a rich agreeable relish. The trees being generally planted against a north wall, never ripen the fruit perfectly till late in the season; but some should also be planted on a south wall, to have the full sun, where the fruit will ripen three weeks sooner, and attain a much richer flavour, and prove an excellent Cherry for the table; ripe in August and September.

Black Coroun, or Courone Cherry.—The tree of middling growth, and a great bearer, producing middle-sized, round, black, very

juicy, excellent Cherries, of an agreeable bitterish flavour; ripe, end of July and in August.

Bigaron Heart Cherry.—A largish fine Cherry; ripe, July and August.

Crown Heart Cherry.—Large, roundish-heart-shaped Cherry; ripe in August.

Tradescant's Cherry.—A largish fine Cherry; ripe in August.

Turkey Heart Cherry.—A large, roundish-heart-formed Cherry; ripe, July and August.

Holman's Duke Cherry.—A large, round, good Cherry; ripe, June and July.

Yellow Spanish Cherry.—A large, yellowish, firm fruit; ripe in July and August.

White Swiss Cherry.—A large, whitish, juicy Cherry; ripe, July and August.

These are all the principal varieties of Cherries proper for general culture, and trees of all the sorts are sold at the public nurseries by the above names, annexed to each variety, all of which are deciduous, and of hardy growth, will succeed in any common soil and situation, and bear well both in dwarfs for walls and espaliers, and in standards of all sorts. See their *Culture*.

Varieties of the trees.] Cultivated principally for ornament and variety in shrubbery plantations.

Double-blossomed Cherry.—The tree is of a moderate growth, and produces large, very double, pure-white flowers, of great beauty, placed on long slender foot-stalks; each flower being as double as any rose, rising in great abundance all over the tree, and make a fine ornamental appearance in the shrubbery and other compartments of the pleasure-ground; flowering in May, but rarely any fruit, except sometimes from some semi-double flowers.

Red-blossomed Cherry.—Having pale-red flowers.

Weeping or Pendulous Cherry.—A tree of very moderate growth, with slender, pendulous or drooping branches, hanging downward like the weeping-willow, producing small fruit.

Dwarf Cherry tree.—A tree of low slender growth.

2. PRUNUS avium.

Great Wild Cherry-tree.] Grows forty or fifty feet high, having oval-spear-shaped leaves, downy underneath, and umbellate sessile clusters of white flowers, succeeded by small round fruit, of different properties in the varieties, and all of a peculiar bitterish flavour.

Varieties are,] Common, small, black wild Cherry—Red wild Cherry—Larger fruited wild Cherry; ripe, end of July and in August.

The trees of the first two varieties of this species are of a large lofty growth; and grow wild in England, &c. in woods and hedges, but are proper to cultivate both as fruit, forest, and ornamental trees, and are often planted in gardens, avenues, lawns, and parks, as they make a fine appearance in spring when in blossom, and bear great crops of fruit, which succeeds the varieties of the cultivated Cherry, and though small, is of an agreeable flavour, and considered as timber-trees, they are greatly esteemed by the cabinet-makers, turners, and some other trades, the timber being of a fine reddish colour.

The following are the Bird Cherry kinds, cultivated chiefly for ornament, the fruit being not good to eat; but being greatly coveted by the birds, have the appellation of Bird Cherry.

3. PRUNUS Padus.

(Padus)—or *common Bird Cherry.*] Grows fifteen or twenty feet high, of a shrub-like growth, and with a spreading head, large, oblong, rough, serrated leaves, having two glands at the back of their base, and long loose clusters of white flowers, succeeded by small, round, black fruit in August.

Variety.] *Cornish cluster Bird Cherry*, having generally a taller upright stem, a more compact regular head, broader leaves, distinguished however with two glands at the back of the base, like the other; and with shorter, more compact clusters of flowers, succeeded by larger red fruit.

The common sort grows wild in hedges in the northern parts of England.

4. PRUNUS virginiana.

Virginian Bird Cherry.] Grows thirty feet high, dividing into a very branchy head, having a dark-purple bark, oval, slightly serrated, shining-green leaves, having two glands at the fore part of the base, and long clusters of white flowers, succeeded by small, round, berry-like, black fruit.

5. PRUNUS canadensis.

Canada Dwarf Bird Cherry.] Grows but four or five feet high, branching horizontally near the ground, and has smooth branches, broad, spear-shaped, rough, downy leaves, without glands, and long clusters of white flowers, succeeded by small, round, berry-like, black fruit; ripe in autumn.

6. PRUNUS Mahaleb.

(Mahaleb)—or *Perfumed Cherry.*] Grows ten or fifteen feet high, having smooth whitish branches, small, oval, shining-green leaves, and corymbose clusters of white flowers, succeeded by small fruit.

7. PRUNUS caroliniana.

Carolina ever-green Bird Cherry.] Grows four

four or five feet high, branching from the ground, garnished with ever-green, oblong, spear-shaped, serrated leaves, without glands; and clusters of flowers, in a racemus, succeeded by small fruit.

All the above seven species of the Cherry kind, arranged under this head, flower commonly in April and May, so abundantly as in a manner to cover the branches; each flower having five small petals, and twenty or more stamina, as observed of the plums, succeeded by fruit all of the Cherry kind, ripening in different sorts from May until September; remarking however, that the fruit of two species only are esculent, *i. e.* *Common Cherry-tree* and its varieties, and the *Great Wild Cherry*; those of the other species being of a disagreeable relish.

All the varieties, however, of the common Cherry-tree and great Wild Cherry merit culture for their fruit; and as Cherries in general are valuable as a most refreshing fruit in the heat of summer, and for their attaining the earliest perfection of mature ripeness, of any of our tree fruits, every good garden should be furnished with a collection of the trees of different sorts, but principally of the common Cherry and varieties.

But the double-blossom kind, &c. and all the sorts of Bird Cherry and the Perfumed Cherry, are employed principally in shrubberies for ornament and variety.

The common Cherry, in all its varieties, is cultivated both in gardens for walls, espaliers, and standards, and in orchards, both in assemblage with other standard fruit-trees; and in many places whole orchards of them, in full standards, are planted, in order to supply the markets with the fruit. In gardens, however, it is proper to have a portion both as dwarfs for walls and espaliers, and half and full standards; and if some of the best kinds are planted against walls of different aspects, they will furnish a succession of ripe Cherries from May, or beginning of June, until September, besides the supply from the espaliers and standards; for the trees will bear in all exposures; but it is highly proper to have some of the earliest and other more valuable kinds against a south or south-east wall; those in the south exposures will ripen soonest, and will be succeeded regularly by the others in the east, west, and north aspects; a north wall however is very commonly allotted for the Morello Cherry in particular; but as this is a most excellent Cherry when well ripened, it is eligible to allow a share of the trees a south aspect, where they will ripen sooner

and in greater perfection; and those planted against a north wall will succeed them, and continue until September. However, where there is scope of ground, and different situations, it is advisable to plant several different sorts accordingly, both some superior sorts for walls, of early, middle, and late kinds; and always a more considerable portion of standard trees in proper collection of the best varieties, planted in gardens and orchards, to furnish the principal production of fruit, both in private gardens, &c. for the general domestic supply, and in larger plantations in places where the fruit is designed for the markets; whereby, in the different orders of training and planting the several varieties, a constant supply of ripe Cherries may be obtained for three or four months.

Considerable orchards of these trees are planted in some parts, particularly in Kent, for the supply of the London markets, consisting principally of the Kentish and Duke Cherries, black and white hearts, &c. and the black Coroun, as being the most certain, best, plentiful bearers; but where there is proper scope of ground, it would be of beneficial advantage to plant a good collection in standards, of all the principal varieties, both for private and public supply; regulating the quantity of trees accordingly; as cherries are mostly a profitable production, being in general estimation, both as a desirable table fruit, and for many other family occasions, during their season.

The Great Wild Cherry-tree is always trained for full standards, and planted in any open situation in orchards, parks, avenues, and hedge-rows of fields, &c. in which latter it is abundant in many places, and is particularly so in some of the counties round London, for their great production of fruit, to supply the markets of that metropolis in August, after the consumption of the other larger kinds.

The mode of bearing of all the varieties of these trees is both on the year-old wood, and that of many years, principally upon short spurs arising from the sides of the branches, if not shortened; but if shortened, they throw out wood-shoots, and but few fruit-buds; therefore the branches of these trees must not generally be stopped, but suffered always to remain at full length, where room for their extension.

All the sorts of these trees will prosper in any common soil, capable of producing good crops of esculent herbs and roots, grass and corn, &c.

Method of Propagation and General Culture.

The method of propagation for all the varieties of the Common Cherry-tree is by grafting and budding them upon stocks of any of the cherry kind, raised from the stones of the fruit,

of any or all sorts promiscuously; but for having larger-growing trees, both for standards, walls, and espaliers, the most general stocks used on that occasion are the Wild Black and Red Cherry, raised from the stones of the fruit: they will, however, grow upon any sort of Cherry-stock; and they will likewise take upon Plums, though plum-stocks are not advised for general use; they will also grow upon laurel-stocks; which, however, is only sometimes practised for curiosity, suffering a small part of the stock to grow up to show the singularity of the two sorts growing upon the same root. All the varieties will likewise grow upon the Bird-Cherry; but this should only be practised when required to dwarf any trees as much as possible; which being grafted on the common or Canada Bird-Cherry, are proper to train for small dwarf trees, either to plant occasionally in pots, or some in the open borders, and in pots for forcing, or to plant in the borders of a forcing-frame. (See FORCING FRAMES.) However, for general use, always use stocks either of any of the common cherry varieties; or, to have larger trees, as before intimated, may use principally the Wild Cherry-stocks, as being the freest shooters and of longest duration; though, in default of these, may use any sort of common Cherry-stocks.—And as to the method of raising the stocks in general, it is from the stones of the fruit, sown in autumn in beds of light earth, covering them near two inches deep; they will come up in the spring; and in autumn or spring following, if the plants are strong, transplant them in nursery-rows two feet and half asunder, to remain for grafting, &c. which, when about the size of a large goose-quill to that of a person's little finger, or but little more, they will be fit to work for dwarf trees; but for standards, they must have at least four years' growth, because they must be grafted at five or six feet height.

Or to have trees of more moderate growth either for walls, small standards, or dwarfs, the Morello and small May Cherry stocks are proper; but to obtain these stocks more certainly of their peculiar moderate growth, it would be proper to raise them from layers, as the seedling stocks are apt to vary to others of strong growth; or also for smaller trees, may occasionally use the Bird Cherry stock, as before observed.

The grafting and budding of all the sorts is performed in the usual way, though grafting is most to be recommended for general practice, as they are not so liable to gum in the grafted part as in that of the budded trees; though both methods are occasionally used successfully, and may be practised accordingly, as the stocks oc-

cur in proper growth, &c. and whip-grafting is the most eligible in the general part, in that method of propagation; and the budding being only one general method, is here performed accordingly in the common way; performing the grafting in the spring, February and March, and the budding in summer, June or July; observing to graft or bud the dwarfs near the ground, and the half and full standards from three to six feet high: the grafted trees will shoot the same year, and the budded ones not till the spring following.

Observe, that when the first shoots from the graft or bud are a year old, those of the dwarf trees for walls, &c. must be shortened down in March or beginning of April, to five, six, or eight inches long, according to their strength, to procure lateral shoots to form the head; but as to the standards, they may be shortened or left entire as the case requires. If you would have them form a spreading head, the first shoots may also be shortened to force out lower branches; after this, let the branches both of the dwarfs and standards remain mostly at their full length; and whilst the trees continue in the nursery, train those designed for walls, &c. to stakes, in a proper position, and occasionally pinch or prune young shoots of the year early in summer, down to a few eyes or buds, where it may seem expedient, in order to procure a production of laterals therefrom, the same season, to train in for a farther supply of young wood, to increase the expansion of branches as soon as possible, all which still continue entire.

When the trees are from one or two to five or six years old, they are proper for final transplantation into the garden and orchard; though if planted when their heads are not more than two or three years old, they will succeed much better than larger trees.

The season for planting them may be any time in open weather, from the end of October, or beginning of November, till March.

Plant the wall and espalier trees eighteen or twenty feet distance; and if the walls are tolerably high, may plant a half or a full standard in the spaces between the dwarfs, that whilst these cover the bottom and middle, the standards may cover the upper part of the wall.

The management of these trees, thus planted against walls and espaliers, is principally as follows.—First, observe, that if they were planted when only one year old from the grafting, &c. with the first shoot from the graft or bud entire, they should be pruned short in March or beginning of April, as observed in their nursery culture, to furnish lateral branches; but if they were headed in the

the nursery, and horizontals thereby obtained, they must not be shortened now nor hereafter, except occasionally in particular shoots to fill a vacancy; for as the fruit-spurs first rise towards the upper end of the branches, a general shortening would not only cut away the first fruitful parts, but force out a great deal of useless wood; let therefore the necessary branches, arising every year after the first heading down, be trained horizontally at full length, five or six inches asunder; and if wood is wanted, pinch some adjacent young shoot in May or early in June, or shorten it in the spring following, and it will push forth two or three laterals; being careful to retrench all fore-right and other irregular-placed shoots, and continue training the regular branches still at full length, at equal distances, till they have filled the allotted space of walling or espalier; thus, by arranging the branches entire, they will soon spread considerably, and emit numerous fruit-spurs all along their sides, and in two or three years bear abundance of fruit.

Observe the bearing wood does not want renewing annually; but the same branches continue bearing several years, and only want renewing with young wood occasionally, as any branch becomes barren or an ill bearer, except in the Morello Cherry in particular, which generally bears the most abundantly in the year-old young wood: a general successional supply of each year's shoots must therefore be retained for successional bearers, as hereafter explained.

The trees in general, however, of all the sorts must be pruned twice every year; a summer pruning early in the season, to retrench all evidently superfluous shoots soon after they are produced, likewise all fore-right and other ill-placed shoots, and rank wood, as soon as possible; and to pinch shoots where wood is wanted, so as there may be as little pruning as possible upon the older wood, which is apt to gum by much cutting; retaining, however, a general moderate supply of the regular-placed shoots, to chuse from in the winter pruning, training the whole at full length: and in winter pruning, examining now the general branches, old and young, both in the former-trained bearers, and the retained shoots of the preceding summer, still retaining all the fruitful and regular placed former trained branches; and if, among these, any particular irregularity, disorderly or improper growth occurs, the whole should now be reformed by proper occasional pruning accordingly, in the order required, either by reducing with your knife, more or less, any disorderly growth, to requisite regularity, or by cutting others clean out,

as it shall seem necessary, by your observations in the process of pruning; and in old trees or others, as it may happen, it is proper to retrench any casual worn-out, or declined naked branches, destitute of bearing wood, fructiferous buds, or fruitful spurs, and to cut out all decayed wood; observing, in your proceeding, to retain a plentiful succession of last summer's young wood, in proper places, where necessary, and to supply the place of any unserviceable old wood, now retrenched; and at the same time cut out all superfluous, or over-abundant, and other unnecessary shoots, reserved last summer, not now wanted, leaving only some well-placed ones, in any vacant spaces, as above intimated, or some in particular parts, to train in between the main branches, to be advancing for bearers, ready to supply any casual deficiency; and generally a terminal shoot to the general branches in all parts where the allotted space admits of extending them in proper regularity: then according as each tree is thus pruned and regulated, let the general branches and shoots be trained in regularly, and nailed to the wall, &c. about three to four or five inches asunder, all at their full length, to the extent of their limited space. — See PRUNING, under the heads, *Summer* and *Winter Pruning*.

Observe, in both seasons of pruning, in cutting out the useless wood, always to cut every thing quite close. See PRUNING.

Likewise be particularly careful to preserve the fruit-spurs, only retrenching such as become very rugged, unsightly, and barren, not furnished with blossom-buds.

Observe, in the above general pruning of wall and espalier Cherries, that, as the Morello in particular, and the small early May Cherry, bear both on the young wood of last summer, the fruit blossom buds issuing immediately from the eyes of the shoots very abundantly, and upon small natural fruit-spurs arising on the two and three years' wood and continuing on the older branches; but generally bear the most plentifully on the young wood; and therefore it is necessary both in the summer and winter pruning to retain a general supply of the young shoots of each year, trained in plentifully in all parts of the tree in summer, of the most regular placed, as many as can be conveniently admitted with some proper regularity: and in winter-pruning, making a general selection of the best well placed in said shoots of last summer, to train in for successional bearers the ensuing season, cutting out the superabundant, with part of the naked former bearers occasionally, to make room for the young supply, leaving a terminal one to each mother branch, agreeable to the foregoing

going intimations: and thus train in the general branches, and shoots horizontally, about three or four inches asunder, all at their natural length.

Standard Cherries should be planted twenty-one feet distance at least; though, if for a whole orchard, twenty-four feet, or eight yards distant every way, will be requisite. Observe that the first shoots having been previously shortened in the nursery, if thought necessary to promote lower branches to form the head, plant them now with their heads entire, except just reducing any irregular growth, and suffer them to branch every way, and shoot in length as fast as they are able, not shortening any, and all the branches will soon form numerous fruit-spurs.

Very little pruning is required for Standard Cherries, and the less the better, as too much use of the knife, in larger wood particularly, causes them to gum and canker; therefore, all that is necessary is, occasionally to retrench any very irregular-growing branch, and all decayed wood.

The Double-blossomed Cherry is also propagated by grafting or budding, like the other varieties, upon any kind of Cherry-stocks, and may be trained both as dwarfs and half and full standards, to effect the greater variety in the plantations.

The Wild Cherry-tree is easily raised from seed, i. e. the stones of the fruit; though any variety producing larger and fine fruit may be continued by grafting, &c. and will bear sooner. — To raise them, however, from the stones, procure a quantity in autumn, when the fruit is dead ripe, and sow them in beds of light earth an inch and a half deep; they will come up in the spring, and after having one or two years' growth, plant them out in nursery-rows, with their tops entire; here train them up for standards, with stems six feet high; then let them branch out above every way, to form heads.

They may be planted out as standards in gardens, orchards, or any open grounds for the fruit, and in ornamental plantations of forest trees.

All the sorts of *Bird Cherry* are also propagated plentifully by the seed or stones of the fruit, sown in the autumn in light earth, near an inch deep; the plants will rise in the spring, and in a year after should be planted out in nursery-rows, one or two feet asunder, to remain a few years till fit for the shrubbery, &c. and may also be propagated by grafting.

These sorts may also be propagated by layers, which will readily strike root, and be fit

for transplanting in one year. They will also grow by cuttings planted in autumn.

The *Perfumed Cherry* is often also propagated by grafting upon any sort of Cherry-stocks, raised as before directed in the propagation of the common Cherry-tree, and may also be tried by layers.

Of forcing Cherries for earliest Fruit.

Cherries forced by artificial heat, in forcing houses, are obtained at the earliest season, April and beginning of May.

For this purpose, the earliest Dukes and May Cherry are the proper sorts, but principally the former; trained both in standards, of four, five, or six feet stems, to elevate the heads near the top glasses of the forcing-house; the heads being generally pruned to a small compass for that purpose; and in dwarf standards, with short stems and low heads: and both of which, for this occasion, should be such as are previously trained in the full ground, till the heads are of three, four, or five years' growth, or till they have commenced bearers in some tolerable degree; and then the forcing-houses, for this occasion, having internal borders of good earth, either in the back part for the taller trees, and in the front for lower; or sometimes, where no internal bark-pit, for bark-bed heat, the forcing being effected wholly by fire, the whole bottom space is entirely formed into a compartment of earth of proper depth; and the trees are planted therein, in rows from the back to the front, in some regular gradation according to their height; sometimes with dwarfs planted between the taller standards, and towards the front; and occasionally dwarf trees in pots are introduced, both in a cherry-house, as above, and in general forcing houses, for different sorts of trees, that are occasionally forced, such as peaches, nectarines, &c.

Cherry forcing-frames, having the whole bottom space entirely of earth, in which to plant the trees, have fire flues ranged internally along the back wall and front, &c. and some having an internal bark-pit, in the middle space for bark-bed heat, as before noticed, a raised border is formed behind for the trees, and low ones next the front glasses, for smaller trees; having also flues as above; though, when having a bark-bed, the forcing is sometimes effected principally by the heat thereof, or assisted occasionally, in severe weather, by a gentle fire heat in the flues: but are also very commonly without a bark-pit, and worked entirely by fire moderately.

When the trees are planted in the full earth of the forcing-house, they should be permitted

permitted to have taken good root therein, before they are forced; if of one year's growth the better; and during which interval, should be exposed to the full air, by having all the glasses off, till near the time to begin the forcing, that the trees may be of proper strength.

The season to begin the forcing is January, or beginning of February, previously having all the glasses put on close a week or two before; then, if the forcing is by fire-heat, should make moderate fires every evening and morning, to support a constant regular, mild, internal heat; giving air in fine days, especially when the trees begin to push; and giving also occasional waterings to the borders; or where the forcing is principally by bark-bed heat, the bed should be made in proper time accordingly, that it may acquire a requisite degree of heat, by the time it is intended to commence the forcing, about the middle or latter end of January, or beginning of February.

By the above means of artificial heat in forcing-houses, the trees come into blossom very early, but generally sooner by fire heat; will be mostly in full blossom in February; and the fruit will be well set, and advancing in free growth in March, and attain full perfection of gradual ripeness in April and early in May. See FORCING-FRAMES, HOT-WALLS, BARK-BED and BARK-PIT.

Apricot, Kinds.

PRUNUS Armeniaca, Apricot-tree.

Under this head is ranged only one species, the *Armeniaca* or Apricot, a choice fruit tree, comprehending many valuable varieties of the fruit: it was formerly ranged as a distinct genus (*Armeniaca*), but is now a species of *PRUNUS*.

Class, order, and characters, the same as the Plum-tree (*Prunus domestica*).

The species is,

PRUNUS Armeniaca.

(*Armeniaca*)—or *Apricot-tree*.] Grows fifteen or twenty feet high, with a large spreading head, having reddish shoots, large, nearly heart-shaped leaves, and close-sitting, pale-red flowers, rising all along the sides of the young branches; succeeded by large roundish fruit, of a yellow and reddish colour in different varieties.

The most noted varieties of this fruit in the English gardens are,

Early White Masculine Apricot.—A small round whitish yellow fruit, ripe towards the middle or latter end of July.

Early Red Masculine Apricot.—A small round fruit, reddish next the sun, and of a juicy agreeable flavour; ripe, middle or latter end of July, and beginning of August.

Orange Apricot.—A large roundish fruit of

a deep-yellow colour, tinged with red next the sun, having a firm but rather dry pulp, is however a handsome fruit; ripe, beginning or middle of August.

Algiers Apricot.—An oval, somewhat compressed, pale-yellow fruit, is tolerably juicy and well flavoured; ripe, early part of August.

Roman Apricot.—A large, roundish, yellow fruit, firm, juicy, and well-flavoured; ripe, beginning or middle of August.

Turkey Apricot.—A very large, oval, compressed, deep-yellow fruit, having a firm, well-flavoured pulp; ripe, beginning or middle of August.

Temple Apricot.—A middle-sized, roundish, compressed, deep-yellow, firm, good fruit; ripe, middle of August.

Breda Apricot.—A large, roundish, deep-yellow fruit, having an orange-coloured pulp, is an excellent Apricot, and the tree a good bearer both against walls and in espaliers and standards; ripe, middle or end of August.

Brussels Apricot.—A moderate-sized roundish-oval fruit, spotted with red next the sun, the other side yellow, having a deep-orange-coloured, firm, high-flavoured pulp; and the tree bears well against a wall and in standards; ripe, middle and end of August.

Royal Persian Apricot.—A large, roundish, fine-flavoured fruit, yellow and reddish; ripe in August.

Transparent Apricot.—A middle-sized, roundish, clear fruit, with a firm, rich pulp; ripe in August.

Dunmore Breda Apricot.—A large, round, most excellent rich fruit; ripe, August and September.

All the varieties of these trees blossom early in the spring, about the end of February and in March, arising principally from the sides of the young shoots of the former year, immediately from the eyes or buds; also sometimes upon spurs from the two years old wood; and the flowers are succeeded by young fruit in April, increasing gradually in magnitude till July and August, when they attain perfection; observing they should be gathered before they become wholly soft ripe, otherwise they will eat mealy and with no flavour; but being gathered according as they discover mature growth, while the fruit remains moderately firm, they will then eat brisk and agreeably flavoured.

As these trees blossom and set their fruit early in spring, often whilst sharp frosts and cutting blasts prevail, frequently destroying most of the bloom and newly-set fruit, so that they sometimes have but very thin crops, for this reason they require a sheltered, warm, sunny situation in this country. In favourable seasons,

seasons, however, they sometimes produce five times more fruit than they can nourish or bring to due perfection; in which case the fruit is always thinned when about the size of ordinary cherries, or little smaller or larger; and those thinned off are excellent for tarts.

But the trees of most of the sorts require to be trained against a warm wall, in order both to protect their early blossom and young fruit from the injuries of the weather, and to promote the more early and perfect ripening of the Apricots; they will succeed in an east or west aspect. It is, however, proper to allow the early, and most of the principal large kinds, a south wall; and having them in different aspects, effects a variation in the times of ripening.

Some sorts will also bear tolerably in espaliers and standards, particularly the Breda and Brussels Apricot.

Apricots are valuable summer fruit for several different purposes. Green and young for tarts; for which purpose, being gathered before the stone becomes hard, they make the most excellent tarts or pies of any fruit so early in the season. When ripe they are very fine table fruit, provided they are gathered before they become soft and mealy. And being preserved in sugar are an excellent sweetmeat.

Method of Propagation and general Culture.

These trees are propagated by budding upon any kind of Plum-stocks.

The stocks for this purpose are raised from the stones of the fruit, sown in the autumn in beds of light earth two inches deep; they will come up next spring; and in autumn or spring following, the plants will be fit to plant out in nursery-rows; and in a year or two they will be fit to bud for dwarfs for walls, &c. but for half standards and standards they must have three, four, or five years' growth, and trained up with stems from three or four to six feet high; though sometimes the budding for standards is performed low in the stock, and the first shoot trained up for a stem.

The budding is performed in August, being careful to procure shoots from which to take the buds from trees of the best sorts, as proved by the fruit they bear; performing the work of budding them in the usual way (see INOCULATION). The buds will not shoot till following spring, at which time, before they begin to push, head down the stock a little above the insertion of the bud; soon after which, the buds will shoot and advance rapidly, and by autumn form a large shoot of a yard or more long; and the trees are then proper for planting out for good, especially the dwarfs intended for wall trees; or some may remain a year or two longer in the nur-

ery, and trained in a proper expansion for planting against walls; and others for standards; observing, that whether they remain in the nursery, or are transplanted into the garden, the above first shoot from the bud must, in March following, be headed down to four or five eyes, to procure lower horizontals, as observed of the Plums and Cherries.

When, however, those intended for wall-trees are of one year's growth, with their first shoots or head entire, they are of a very proper size for planting out finally where they are to remain. They may be planted any time in open weather from October until the beginning of March, chusing a south wall for the early and some other kinds, to come in forward; but as those exposed to the full south sun are apt to become soon mealy, it may be proper to plant a principal supply against east and west walls.

They do not require any particular soil or compost, but will succeed in any common soil of a garden; previously, if for a full plantation, trenching the border two spades deep.

Plant them in a range close along the wall, at eighteen feet distance, with their heads entire for the present, which fasten either to the wall or to stout stakes, one to each tree, to preserve them steady until spring, when they must have their first pruning, &c.

Their management, after being planted in the garden, is as follows; in the first place observing that if the trees are only one year old, with their first head from the bud entire, they must be headed down in the spring, as aforesaid, to four or five eyes, to force out branches below; after this give the trees water in dry weather, and they will readily push out shoots from all the remaining eyes, which in summer nail up regularly to the wall at their full length; and if any fore-right or back shoots come out, rub them off, being careful to continue the regular shoots to the wall all summer and the following winter; and in spring shorten each shoot to about eight, ten, or twelve inches, according to their strength, leaving the lowermost ones, on each side, rather the longest; this pruning short being still necessary in order to procure a farther supply of lower branches, that every part of the wall may be occupied quite from the bottom; having particular attention to preserve nearly an equal number of branches arranging on each side of the tree, and nail them close to the wall horizontally, four, five, or six inches asunder. The summer following, each horizontal will push out three or four, or more, new shoots, of which, if any rise fore-right and behind the branches, rub them off early in the season, and nail in all the regular side shoots, at full length,

length, all summer, except it is necessary to pinch any particular shoot early in the summer to fill a vacancy as soon as possible. In the winter pruning examine if there be any superfluities or irregular growths left in summer; cut them out close, and let all the regular-placed necessary shoots be shortened, though they should not now be pruned so short as in the two first years, only cutting each shoot according to its strength, from about eight or ten, to fifteen or eighteen inches long; for we may now suppose the head of the tree to be tolerably well formed; should therefore prune so as to obtain a farther supply of wood, and a production of fruit; remarking, that as these trees bear principally upon the wood of a year old, it is eligible to train in a general supply of young shoots, of each year, in every part; the same shoots producing, at the same time, both a crop of fruit and a supply of wood for next year's bearing; still remembering that the annual supply of wood must always be shortened in the winter pruning; for if left entire, they would produce only some shoots near the top, and leave the bottom naked, so as, in a few years, the whole tree would become very thin of bearing wood below, and bear only a little towards the extreme parts of the branches; this therefore determines that, in winter pruning, the shoots should always be more or less shortened according to the strength of the tree, situation and strength of the respective shoots, in order to obtain a necessary succession of young wood annually in proper situations, so as to continue all parts of the tree from the bottom to the extremity, every way regularly filled therewith for bearing; observe, likewise, that as these trees bear also upon short spurs, arising upon the two-years-old branches, it is proper to preserve them wherever they appear, only retrenching such as project considerably fore-right; leaving all those of one or two inches long, keeping in mind however that the young shoots, of one year's growth, are the principal bearers: those produced one year bear fruit the next, and a general supply must be every year retained, and not shortened in summer, which would force out laterals from every eye, and spoil the shoots for next year's bearing; but in winter pruning, a general shortening, more or less, is necessary, and the whole tree then regularly nailed to the wall.

Observe, they must be pruned twice every year, a summer and a winter pruning.

The summer pruning consists in reforming the irregularity of the numerous shoots annually produced in this season, beginning in May or early in June, and rub or cut off

close all fore-right and back shoots, and all evident superfluities and very rude growths; retaining, however, in every part, a full supply of the regular side-shoots, as succession-wood for the next year's bearing, training them in at full length, as before directed, to remain till the winter pruning; for it is of importance to leave doubly more, at least, than a sufficiency of the well-placed shoots at this season, to have plenty in every part to choose from in the general winter pruning. See PRUNING.

And the winter pruning comprehends a general reform among all the branches and shoots, such as the retrenching all worn-out and old naked branches ill furnished with bearing wood, as they from time to time occur, to make room for those furnished with proper young shoots of the preceding summer; at the same time selecting and retaining, in every part, the best of the said shoots for next summer's bearing, cutting out close all the superfluous or unnecessary and ill-placed shoots, and cut out also or reduce part of the former year's bearers and unfruitful old branches in every part of the tree, to make due room to train the necessary supply of young wood at proper distances; being careful, in retrenching the old wood occasionally, to prune it down either to a young shoot, or to some convenient branch it supports, which is furnished with one or more such shoots, so as every branch may also terminate in a young shoot for its leader, cutting off all the small shoots arising from the sides of the main ones, and let the general supply of young wood in every part be now shortened moderately, according to their strength, for the reasons before given. The smaller shoots cut to about eight or ten inches, the middling ones to twelve or fifteen, and the strong shoots to eighteen inches or two feet long, pruning them generally to a wood-bud, in order to obtain a shoot at the end for a leader, which will draw nourishment to the fruit. Cut out also all dead wood and cankered parts, and decayed spurs and stumps; then, as soon as one tree is pruned, let it be directly nailed, which should now be performed with great regularity, training all the branches, &c. horizontally, as straight and close to the wall as possible, at equal distances. See PRUNING.

Observe, when any of these trees are of a strong vigorous growth, they should be treated according to their nature; in such case, therefore, it is advisable to leave the shoots thicker or more abundant than in moderate shooting trees, and shorten them less in proportion, that by dividing the sap among many, and a greater extent of branches, it checks the

luxuriancy which would take place in a smaller number.

For the more we prune the strong young wood in a luxuriant tree, or the shoots much shortened, the more vigorous will the tree shoot, and produce but very little fruit.

But the natural inclination of very vigorous trees should in some measure be indulged, by training as many branches as can be conveniently laid in, and shortening them but moderately, some very luxuriant ones hardly at all; which being practised two or three years, it will reduce them to a moderate growth and good state of bearing, when they may be treated in the common way.

But as the management of this tree, and the Peach and Nectarine, are nearly similar, in respect to pruning, &c. as they all bear on the young wood, we refer to that article, where more particulars of pruning and training these kind of trees are exhibited, which, for the general part may be applied to the Apricot-tree. See *AMYGDALUS Persica*.

Old Apricot wall-trees should be well attended to in pruning, whereby to continue them in a good fruitful state, by encouraging young wood in proper abundance; for by this care, the trees will not only more certainly produce abundant crops, but the fruit of old trees generally ripen earlier, with a peculiar richer, vinous flavour; therefore observing, that as these old trees are apt to run up naked below in the main branches, should be careful, when young wood advances in these parts, and all vacant spaces, to preserve it accordingly, pruned and trained in regularly, both as successional bearers, and to furnish future supplies of new shoots for the same occasion, so as to continue all parts of the tree, from bottom upward, regularly furnished with bearing wood.

Standard Apricots are sometimes planted, and in some favourable seasons bear plentifully, particularly the *Breda* and *Brussels Apricot*, either in half or full standards; the half standards will be more out of the power of the winds and cold air.

They should be planted in a sheltered warm situation in the full sun, that they may have the greater chance of setting a good crop of fruit, and of ripening more effectually with a rich flavour; and their culture in the order of growth is nearly the same as that of other standard fruit-trees; they require but little pruning, or only to reduce or retrench any very irregular growth, or out-growing ram- bler, or occasionally to regulate confused crowding branches, and to cut out casual decayed wood; all which is performed generally

in winter; but, except in the above occasions permit the general branches to advance mostly in their natural growth; and in favourable seasons, in spring, the trees will produce abundant crops, in good perfection.

Protecting the blossom and young fruit.—As Apricot-trees against walls blossom very early, both blossom and young fruit are very liable to injury from frost and cutting blasts; it is therefore advisable to afford occasional protection, in unfavourable seasons, to some of the forwardest and most valuable kinds, either with mats, suspended over the trees, or twigs of evergreens stuck between the branches, beginning the covering as soon as the blossom begins to expand, and continue it till the fruit are fairly set; the mats to be used on nights and bad weather, but the evergreens to remain constantly till all danger is past, observing the same methods as directed for the peach and nectarines. See *AMYGDALUS Persica*.

Thinning the fruit.—In some favourable seasons these trees set many more fruit than can attain perfection; and as they sometimes are placed very close, or often in clusters, and sitting close to the branches without any yielding footstalks as in cherries, &c. they, in their advancing growth, would both impoverish and thrust one another off; and therefore, these fruit, and peaches and nectarines, are principally the only sorts as require any material thinning; and which in wall-trees, particularly when in superabundance, should not be omitted, and the thinning is also proper occasionally in standards in some degree; generally beginning to thin them when about the size of large cherries or but little bigger, which should be done with great regularity, leaving the largest, fairest, and best situated, to grow to maturity, mostly all singly, or at least never more than two at the same eye, but most commonly single in the large kinds; as directed in thinning peaches.

Those thinned off make most excellent tarts, and should always be saved for that purpose, and for which occasion they may be thinned by degrees, both in wall-trees and standards; not, however, in the former in particular, to leave the superabundant fruit to grow large in any considerable degree, nor in great quantity, to rob the continuing crop of its proper nourishment; and for this said use, they should always be gathered before they stone or harden in the heart or middle.

Of forcing Apricots for earliest Production.

By forcing we obtain Apricots in the most early season, May, June, and July, sometimes two months before their natural production, effected by having trees of proper sorts in forcing.

forcing-houses, or hot-walls, worked by fire, or bark-bed, or sometimes both.

The trees for this purpose are commonly dwarfs, trained principally in the order of wall or espalier trees, or sometimes in small low standards: all generally trained trees in the full ground, till advanced to some tolerable degree of bearing in a moderate production; and being then planted, some in the borders of the forcing-house and hot-wall, are trained in the manner of wall-trees, generally to a light open treillis; and some also, in a forcing house, in small dwarf standards, placed forward; or occasionally some of similar growth, planted in pots, are introduced in the same situation; and in all of which, the trees being substantially well fresh-rooted in their places, are forced at the proper season by means either of fire-heat, or bark-bed, or sometimes both occasionally in forcing-houses, but in hot-walls mostly by fire-heat.

All forcing-houses and hot-walls have flues for fire-heat, and sometimes the former have a pit for a bark-bed; but where none, the whole bottom space is of good earth, as observed of the Cherry forcing-house, and the trees planted therein, generally in assemblage with peaches, nectarines, plums, &c. as the same degree of heat is applicable to the whole in the requisite temperature for forcing.

The season to begin the forcing is principally in January, or early in February: when, or rather some little time before, the glasses are shut close; and at the proper time, the fires are made in the furnace moderately every evening and morning, to heat the flues in a proper degree, to dispense a moderate regular heat, to warm the internal air to a requisite temperature, which forwards the trees accordingly to early blossoming and fruiting; they having admission of fresh air moderately in fine days, more freely when a warm sun; and sometimes watered both in the earth, and occasionally over the branches after the blossom is past, and the fruit fairly set; which hereby, in the whole, advances in forward growth, and attains early perfection, six weeks or two months, or more, before its natural season. See FORCING-FRAMES, &c.

Laurel Kinds.

PRUNUS Lauro-cerasus, or Laurel-tree.

Under this head are ranged two beautiful evergreen trees for ornamental plantations, viz. Common Laurel, and Portugal Laurel.

The species are,

1. *PRUNUS Lauro-cerasus*.

Cherry-bay, or the *Common Laurel-tree*.] Grows twenty feet high or more; very branchy almost from the bottom, making

strong green shoots; large, oblong, stiff, shining, evergreen leaves, having two glands at the back, and long clusters of small white flowers, succeeded by large roundish-oval black berries; flowering in April, and the fruit ripens in September, or beginning of October, but is not good to eat.

Varieties.] Gold-striped leaved—Silver-striped leaved.

This species and varieties are some of the most beautiful evergreens in nature; are of a fine free growth; the leaves singularly large and elegant, remaining all the year.

It is a native of the East, about the Black Sea; but is very hardy, and thrives here in any situation.

2. *PRUNUS lusitanica*.

Portugal Laurel.] Grows twelve or fifteen feet high, forming a very branchy full head, having the young branches of a reddish colour; oblong-oval, thick, dark-green, eglandulous, evergreen leaves, and loose bunches of small white flowers, succeeded by roundish black berries; flowering in June, and the fruit ripens in autumn: not eatable.

Both these species are noble evergreens; are commonly considered as shrubs, but are of the tree kind; the Common Laurel, in particular, becomes a large tree in its native soil, and the southern parts of Europe, where there are whole woods of it; both the species, however, thrive here, which, in many places are arrived to some considerable size, and are great ornaments to our shrubberies and other plantations, appearing elegantly green and beautiful the year round.

They are hardy, and rarely injured by inclement weather, except in very severe winters, which sometimes kills the young shoots and outer leaves.

They prosper in any common soil, and in any exposure; the Common Laurel, in particular, will grow almost any where, even under shady trees, or against fences.

Both the species are most excellent furniture for all ornamental plantations, in assemblage with the evergreen tribe in particular; and some disposed towards the fronts of deciduous plantations have also a most beautiful effect. Clumps and plantations of the Common Laurel in lawns, parks, or any out grounds, are also very beautiful; and as it prospers in almost any situation, and being a fast grower, may be employed to conceal any disagreeable fence or other unsightly object; in all which ways they will appear most beautiful, at all seasons, with their noble, large, evergreen foliage.

Hedges are sometimes formed of this tree

for ornament; but where this is practised, the hedge should not be trimmed with garden-shears, which would mangle and spoil the beauty of their large leaves; therefore all necessary cutting should be performed with a knife, in order to preserve the leaves entire, and thus the hedge will make a very fine appearance.

The common Laurel is also sometimes trained with a single clean stem, to form tall standards; and in which order of growth, are proper both to introduce in decorating plantations, in assemblage with other ornamental tree kinds, and in forest-tree plantations, either in assemblage with others of the ever-green tribe, or some separately in distinct compartments.

It has been hinted by some that the leaves and fruit of these trees are of a noxious quality: but so far from being poisonous, the leaves of the common Laurel are often used in the kitchen to put into custards, &c. which gives them a most agreeable bitterish flavour; and the berries are often put into brandy; though strong distillations thereof, improperly administered, have proved hurtful.

The season for planting these trees may be any time in open weather, from the latter end of September or beginning of October, till March, or beginning or middle of April, though October and beginning of November is the most successful season, or also in any of the spring months, in open mild weather.

Method of Propagation.

The propagation of these beautiful trees is very easy, by seed and cuttings: but as cuttings are the most expeditious mode of propagation, they are most commonly raised by that method.

By Seed.—In autumn, when the seeds or berries are ripe, sow them in beds of light earth, near an inch deep, and allow them some protection in severe frosts in winter, either by hooping and matting the bed, or covering it with any dry long litter; but let them remain uncovered all mild weather; with this care the plants will come up in the spring, giving occasional waterings in dry weather; and in the autumn or spring following, when the season is settled, plant them out in nursery-rows to remain two or three years, or till wanted for any plantation.

By Cuttings.—This is a sure and very expeditious method of raising these evergreens; the young shoots strike freely, and soon commence proper plants. In August or September, in moist weather, procure a quantity of cuttings of the same year's shoots, cutting them off from about eight or ten, to twelve or fifteen

inches long, with about an inch of the old wood to the bottom of each cutting if possible, though this is not indispensably necessary: having procured the cuttings, strip off the leaves from the lower part, and then plant them in a shady border, in rows twelve inches asunder, planting each cutting half or two thirds into the ground; give water in dry weather, and probably those planted in August will be rooted the same year; they, however, will be all well rooted next summer, and shoot at top, perhaps a foot long, by the following autumn, at which time, or in the spring after, they may be transplanted or bedded out in wide nursery-rows, to acquire strength for final transplantation.

In both the above methods of propagating these trees, they may be trained either bushy, of a shrub-like growth, or trimmed up to a single stem for standards.

PSIDIUM, Guava-tree.

Two exotic trees of the Indies are the principal species of this genus, and are retained here in stoves for variety, garnished with oval and oblong leaves, and pentapetalous flowers.

Class and order, *Icosandria Monogynia*.

Characters.] CALYX is monophyllous, campanulate, and five-parted at top. COROLLA, five oval, concave, patent petals. STAMINA, twenty or more short filaments and small antheræ. PISTILLUM, a roundish germen under the calyx, long style and simple stigma. PERICARPIUM, a large, oval, baccaceous fruit, having numerous small seeds.

The species are,

1. PSIDIUM *pyriferum*.

Pear-fruited Psidium.] Rises with a woody thick trunk, branching twenty feet high, having quadrangular branches and a smooth bark, narrow, oval, obtuse, opposite leaves, and the pedunculi having one flower, succeeded by an oblong pear-shaped fruit.

2. PSIDIUM *pomiferum*.

Apple-fruited Psidium.] Grows twenty feet high; narrow, oblong, pointed leaves, and the pedunculi terminated by three flowers, succeeded by apple-shaped fruit.

These plants must be kept in pots, and always placed in the stove.

They are propagated by seed obtained from the West Indies, sown in pots and plunged in a bark-bed; and when the plants are come up three or four inches high, plant them in separate pots, and manage as other exotics of the stove.

PSORALEA.

This genus furnishes some shrubby exotics for the green-house, and sometimes retained in stove collections, garnished with pinnated and

and trifoliate leaves, and papilionaceous flowers.

Class and order, *Diadelphia Decandria*.

Characters.] CALYX is monophyllous and five-parted, having the lower segments twice the length of the others. COROLLA is papilionaceous and pentapetalous. STAMINA, ten diadelphous filaments and roundish antheræ. PISTILLUM, a linear germen, subulate, long, ascending style, and obtuse stigma. PERICARPIUM, a compressed pod, having one kidney-shaped seed.

The most noted species are,

1. *PSORALEA pinnata*.

Pinnated African Psoralea.] Rises with a woody soft stem, branching five or six feet high, pinnated leaves of three or four pair of narrow lobes, terminated by an odd one, and at the axillas close-fitting blue flowers with white keels. It is a native of Ethiopia.

2. *PSORALEA bituminosa*.

Bituminous Italian Psoralea.] Rises with a shrubby stalk, branching sparingly, about two or three feet high, trifoliate or three-lobed leaves of a bituminous scent; and blue flowers in close heads. Grows in Italy and in France.

3. *PSORALEA aculeata*.

Prickly African Psoralea.] Rises with a shrubby branching stem three or four feet high, trifoliate leaves, having wedge-shaped lobes, terminating in a recurved sharp point, and the branches terminated by roundish heads of blue flowers. Grows in Ethiopia.

4. *PSORALEA cytisoides*.

Cytisus-like, Cape Psoralea.] Grows with a shrubby stem and branches, pinnated, three and five-lobed leaves, and axillary clusters of flowers.

These plants flower here every summer; the first sort greatest part of that season, and the others in July and August; all of which are succeeded by seeds in autumn.

Keep them in pots in order for removing into the green-house in winter.

They are propagated by seeds, sown in a hot-bed in the spring; and when the plants are two or three inches high, prick them in separate small pots, and gradually hardened to the open air, so as to bear it fully by the end of May or beginning of June.

They may also be propagated by cuttings any time in summer, planted in pots and plunged in a little heat, or covered close with hand-glasses, shaded from the sun, and watered.

PTELEA, Shrub Trefoil.

The plants are of the shrub kind, consisting of two species only, one for the shrub-

bery, the other for the stove, garnished with trifoliate and simple leaves, and tetrapetalous flowers in bunches.

Class and order, *Tetrandria Monogynia*.

Characters.] CALYX is small and cut into four parts. COROLLA, four oval-lanceolate spreading petals. STAMINA, four awl-shaped filaments, having roundish antheræ. PISTILLUM, a roundish compressed germen, short style, crowned by two obtuse stigmas. PERICARPIUM, a roundish bilocular membrane, having two seeds.

The species are,

1. *PTELEA trifoliata*.

Trifoliate Ptelea, or Carolina Shrub Trefoil.]

Hath a shrubby upright stem, dividing into a branchy head eight or ten feet high, covered with a smooth purplish bark, trifoliate leaves formed of oval-spear-shaped folioles, and the branches terminated by large bunches of greenish-white flowers, succeeded by roundish, bordered capsules.

2. *PTELEA viscosa*.

Viscous Indian Ptelea.] Rises with several strong shrubby stems, branching erectly twelve or fifteen feet high, having a light-brown bark; spear-shaped, stiff, simple leaves; and the branches terminated by clusters of greenish flowers.

The first species is a hardy deciduous shrub, and a proper plant for the shrubbery and other ornamental plantations, to increase the variety.

The second sort being of the temperature of stove exotics, must be kept mostly in the hot-house, except about two or three months in the heat of summer, when they may be set in the open air.

The first sort is propagated by seed, layers, and cuttings.

By Seed.—In March, or beginning of April, sow the seed in a bed of light mould, half an inch deep; or to bring them as forward as possible, may sow them in pots, and plunge them in a moderate hot-bed, just to bring up the plants an inch or two high: give occasional waterings all summer, and protection from severe frost in winter; and in spring following plant them out in nursery-rows, to acquire strength for final transplantation.

By Layers.—Perform this in autumn; chuse the young shoots, give them a small slit underneath, then lay them in the earth, and they will be rooted in a year's time.

By Cuttings.—In the spring cut off a quantity of young shoots, plant them thick in pots, which plunge in any hot-bed, or in a bark-bed, just to strike them: they will readily

readily root, and be fit to transplant the following autumn.

The second species is propagated commonly by seeds: sow them in pots, and plunge them in a hot-bed; when the plants are two or three inches high, prick them in separate pots, plunging them also in the hot-bed, or in the bark-bed of the stove.

PULMONARIA, Lung-wort.

The plants are hardy, herbaceous, fibrous-rooted perennials, medical and flowery plants, rising with annual stalks, from about ten or twelve inches to a foot and half long, having oval and heart and spear-shaped leaves, and terminated by bunches of pentapetalous flowers.

Class and order, *Pentandria Monogynia*.

Characters.] **CALYX** is monophyllous, five-corned, quinque-dentate, and permanent. **COROLLA** is monopetalous, funnel-shaped, with a cylindric tube, and the limb half cut into five obtuse, erect, patent segments. **STAMINA**, five short filaments, having erect connivent antheræ. **PISTILLUM**, a four-parted germen, one filiform style, and obtuse stigma. **PERICARPIUM**, none; four roundish seeds lodged in the persistent calyx.

There are about six species: some are cultivated for medicine, others to increase the variety of the herbaceous collection.

The most material species are,

1. **PULMONARIA officinalis**.

Common Officinal Spotted Lung-wort.] Hath the root crowned with oval-heart-shaped, rough, white-spotted leaves, and upright stalks near a foot high, terminated by bunches of red, purple, and blue flowers.

It is cultivated both for medicine and for variety in the garden:—is good for disorders of the lungs, coughs, and consumptions.

2. **PULMONARIA angustifolia**.

Narrow-leaved Lung-wort.] Hath narrow, spear-shaped, hairy, radical leaves; upright stalks about a foot high, terminated by bunches of flowers, becoming of a fine blue colour.

3. **PULMONARIA virginica**.

Virginian Lung-wort.] Rises with upright stalks about a foot and half high; spear-shaped, obtuse, smooth leaves; and the stalks terminated by clusters of blue flowers.

Varieties.] With red flowers, — purple-flowered, — white-flowered.

All these species flower in April and May, and the seeds ripen in June and July.

They are all perennial in root, which is of the fibrous kind; but they are annual in stalk, rising in the spring, and after having flowered and perfected seed, they decay: they are

very hardy plants, and will grow almost any where, but delight most in somewhat shady situations.

They are propagated by seeds and by parting the roots.

By seeds.—Sow them in the spring in any bed or border of common earth, and rake them in; they will soon come up, and in July or August put out the plants either where they are to remain, or in nursery beds till October, then transplanted finally.

By parting the roots.—Autumn, about August or September, is the proper time; but the sooner after they have done flowering, the better; do not divide them too small, and plant the slips directly, and they will flower strong the following spring.

PUNICA, Pomegranate tree.

Two species, of the tree and shrub kind, are the principal species retained in our gardens, one a moderately hardy fruit tree, the other a somewhat tender shrub, both of them cultivated chiefly for variety; are adorned with spear-shaped and linear leaves, and pentapetalous fine red flowers.

Class and order, *Icosandria Monogynia*.

Characters.] **CALYX** is monophyllous, bell-shaped, quinque-dentate at top, coloured, and permanent. **COROLLA**, five roundish, erect, spreading petals, inserted into the calyx. **STAMINA**, twenty or more short filaments having oblong antheræ. **PISTILLUM**, a germen under the receptacle, single style, and a capitated stigma. **PERICARPIUM**, a large, roundish, apple-shaped fruit, having nine cells filled with roundish succulent seeds.

One of the species, *Common Pomegranate-tree*, produces a very large eatable fruit called a Pomegranate, though they seldom attain true perfection in this country.

The species are,

1. **PUNICA granata**.

Common Pomegranate-tree.] Rises with a tree stem, branching numerously all the way from the bottom, growing eighteen or twenty feet high; spear-shaped, narrow, opposite leaves; and the branches terminated by large most beautiful red flowers, succeeded by large roundish fruit, as big as an orange, having a hard rind filled with soft pulp and numerous seeds.

Varieties.] Large double-flowered, remarkably beautiful, — striped-flowered.

These trees are deciduous, grow naturally in Italy, Spain, and Portugal, where they ripen fruit abundantly; in this country, however, they require a warm situation; and if trained against a south wall, they will sometimes

times produce full-sized fruit, though it rarely ripens with any tolerable flavour; but as both the flowers and fruit make a fine appearance, a few of the trees merit culture in every good garden.

They all flower abundantly in July, August, and September, and the fruit ripens in autumn.

2. *PUNICA nana*.

Dwarf American Pomegranate.] Rises with a shrubby stem, branching four or five feet high, narrow short leaves, and small red flowers, succeeded by small fruit; begins flowering in July, and continues till October.

The first of these species is a moderately hardy tree, and may be planted for ornament in shrubberies and other plantations for the beauty of their flowers; but it is advisable to plant some also against a warm wall and train them like other wall-trees; they will generally flower more abundantly, and have a chance to ripen fruit; it should be observed, as they produce their flowers always on the young shoots of the year, arising principally from those of the year before, it is therefore proper to train in plenty of the strongest best placed shoots of each year, which in winter should be shortened to promote their furnishing a greater supply of young wood in summer for flowering; and let them be trained to the wall at equal distances, and managed nearly as directed for peaches and nectarines, &c.

The double-flowered variety produces much larger and more beautiful flowers than the others; it is therefore in greatest estimation to cultivate for ornament.

The second sort being rather tender, it is proper to plant it mostly in pots, in order to have shelter of a green-house in winter.

Both the species and varieties are propagated abundantly by layers; autumn is the proper season: chusing the young branches, give a little slit underneath at a bud, and lay them in the usual way, giving occasional waterings in summer; and by next autumn they will be well rooted, and fit to transplant in nursery rows for two or three years, to get strength, and then planted where they are to remain.

Those of the common sort and varieties may be trained as standards, either as half or full standards, or as dwarfs.

But those designed for walls must be managed accordingly, as directed for peaches, &c. as aforesaid.

PYRUS, Pear-tree, comprehending also the Apple-tree and Quince-tree.

The Pear, Apple, and Quince, were long considered as so many distinct genera: but the botanists having discovered their characters to

be alike, have ranged them all as species of the same genus; and as such we will also consider them, and arrange them accordingly: they are all of the tree kind, adorned with oblong and oval leaves and pentapetalous icofandrous flowers.

Class and order, *Icofandria Pentagynia*.

Characters.] **CALYX** is monophyllous; concave, divided into five spreading segments and permanent. **COROLLA**, five large concave petals inserted into the calyx. **STAMINA**, twenty, or more, short awl-shaped filaments, having simple antheræ. **PISTILLUM**, a germen situated under the calyx, supporting five styles, having simple stigmas. **PERICARPIUM**, a roundish umbilicated fruit with five membranaceous cells, each having one oblong smooth seed or kernel.

Agreeable to the above characters, the *Malus*, Apple-tree, and *Cydonia*, the Quince-tree, formerly considered as distinct genera, are, according to the Linnæan sexual botany, retained as species only of *Pyrus*: they are certainly all of the same family; for, besides their agreement in characters, all the three sorts will readily take by grafting and budding upon one another; however, as the Pear, Apple, and Quince, have always been considered as different sorts of fruit, each sort being of a peculiar shape and property, and each comprehending many varieties, we will arrange each species and its varieties under a separate head, viz. Pear Kinds,—Apple Kinds,—and Quince Kinds, all under the generic name *Pyrus*.

Pear Kinds.

1. *PYRUS communis*.

Common Pear-tree.] Rises with an upright large trunk branching thirty or forty feet high, in some widely around, others more erectly, often forming a conical head; oval-lanceolate, serrated leaves, and corymbose clusters of white flowers from the sides of the smaller and extreme branches, succeeded by large fruit extended at the base; of different properties in the numerous varieties.

The botanic description is—*Pyrus* with oval serrated leaves, and flowers in a pedunculate corymbus.

Varieties.] There is only one species of this tree; but it comprehends almost endless varieties, all of which being of the above description, and bear their flowers and fruit upon spurs arising from the sides and extreme parts of the branches, when of from three or four to many years old, the same branches and spurs continuing fruitful a great number of years; the different varieties furnishing fruit for use from the beginning or middle of July until May or June

June next year; which, according to their times of ripening, may be divided into three classes; Summer Pears, Autumn Pears, and Winter Pears; the Summer Pears ripening in different sorts from July until the middle or end of September, and are generally fit to eat from the tree, or at least, do not keep above a week or two before they rot. And the Autumn Pears attain perfection of full growth in September and October; some of which ripen maturely on the tree for immediate eating, in that season, others, being gathered, require to lie some time in the fruitery, and some will keep two months: but all the Winter Pears, although they attain to their full growth on the tree by the end of October, yet in the general part they do not acquire perfection for eating till they are gathered and have lain some time in the fruitery to mellow, some one, two, or three months, others longer; so that, in the different varieties, they attain maturity for eating from the end of November till April and May; those of each class having different properties, some being melting, others breaking, some mealy; and some are hard and austere and can be used only for kitchen uses; but our list consists mostly of eating Pears, with a few of the choicest hard Pears for baking and stewing, &c. though any of the large eating Pears may also be used occasionally for culinary purposes, before they are quite ripe.

As many of the fine sorts were first obtained from France they are still continued in most catalogues by the French names; observing that as the varieties of the fruit are very numerous, we shall only give a list of the most valuable, arranged in three classes, — Summer Pears, — Autumn Pears, — Winter Pears.

Summer Pears.

Summer Pears are such as ripen for immediate eating off the trees, from the beginning or middle of July until the middle of September, and continue but a short time in perfection: some of the earliest sorts keep good only a few days before they become mealy and rotten; and very few of the sorts will last much above a fortnight; but by having different varieties, the succession may be continued two months or ten weeks, till succeeded by the autumnal sorts, which will continue for eating from the end of September till Christmas.

Little Musk Pear.] A small, roundish, yellow Pear of a musky flavour, valuable for its early perfection: ripe, beginning or middle of July.

Green Chiffel Pear.] A smallish, nearly oblong, light-green Pear, melting very juicy and agreeably flavoured: ripe, middle or end of July and beginning of August.

Red Muscadelle, or Fairest Supreme.] A middle-sized, beautiful, red-striped and yellow Pear, somewhat firm, breaking juicy and rich flavoured; ripe, the end of July and beginning of August.

Jargonelle Pear, commonly so called, but is properly Cuisse Madame, (Lady's-thigh).] A largish, long, pyramidal, russety-green Pear, tinged with brown next the sun, having a fine, breaking, juicy pulp, of a most delicious rich flavour; is the best summer Pear in the world, and the tree a good bearer, both in standards, espaliers, and against walls: ripe towards the middle of August.

Cuisse Madame Pear, commonly so called, frequently called Windsor Pear, but is properly the Jargonelle.] A fine, large, oblong, smooth, yellowish-green Pear, sometimes reddened next the sun, having a firm pulp tolerably juicy and agreeably relished, though not high flavoured, and is apt to become mealy when full ripe; but being a large handsome fruit, and the tree a remarkable good bearer, it highly merits culture, as one of the principal summer Pears, and is particularly profitable for the supply of the markets, and for which the trees are abundant in the gardens and orchards several miles round London, and in many other places: ripe towards the middle of August.

Windsor Pear.] A large oblongish Pear, somewhat similar to the last mentioned, but generally more swelling upwards, of a greenish-yellow colour, having a softish pulp, but soon becomes mealy: ripe, middle or end of August.

This sort and the former bear a great resemblance to each other; but this is rather shorter and more swelling towards the crown.

Great Blanquette Pear.] A large, roundish, yellowish-green, smooth Pear, having a soft juicy flesh of a rich flavour: ripe, beginning or middle of August.

Little Blanquette Pear.] A small, roundish, smooth, yellowish-green Pear: ripe, middle or end of August.

Early Russet Pear.] A middle-sized, oblong, reddish Pear, melting and replete with sugary juice: ripe about the middle of August.

Musk Robine, or Queen's Pear.] A small, roundish, top-shaped, yellowish-coloured Pear, tender, sweet, and musky: ripe, middle or end of August.

Red Orange Pear.] A middle-sized globular Pear, reddened on the sunny side, the other green; melting and richly flavoured: ripe, end of August.

Perfumed Pear.] A middling, roundish, deep-red Pear, spotted with brown, having a melting perfumed flesh: ripe, end of August.

Orange

Orange Musk Pear.] A large, round, yellow Pear, very good if eaten from the tree, as soon as a little ripe: it ripens at the end of August.

August Muscat, or Royal Pear.] A largish, globular, whitish-yellow Pear, breaking, sugary and perfumed, and one of the finest Pears of the season: ripe, end of August.

Onion Pear.] A middle-sized, globular, brown-skinned Pear: ripe, end of August.

Salviati Pear.] A largish, globular, flattened Pear, reddish and yellow to the sun, and whitish on the other side, tender and agreeably flavoured: ripe, beginning of September.

Red Admirable Pear.] A large globular Pear, crimson-coloured on the sunny side: ripe, in September.

Summer Bon Chretien, or Good Christian.] A fine, large, oblong Pear, beautifully reddened next the sun, and whitish on the other side, breaking and highly flavoured: ripe, beginning of September.

Rose Water Pear.] A middle-sized, globular, brownish-red, rough Pear, breaking and finely flavoured: ripe, middle of September.

Summer Bergamot Pear.] A largest, round-flatted, greenish-yellow Pear, melting and sugary: ripe, middle of September.

Varieties.] There are two or three varieties of this sort that differ in size, but are all of the Bergamot shape.

Orange Bergamot Pear.] A largish, round, flattened, yellow Pear, reddish next the sun, breaking and replete with perfumed juice: ripe towards the end of September.

Other Summer Pears are known by the following names: Primitive Pear,—Catharine Pear,—St. James's Pear,—Crawford Pear,—Citron des Carmes,—Pear Piper,—Brute Pear,—Muskdrone,—Lammas Pear,—Lemon Pear,—Green Musk Pear,—Long-stalked Blanquette,—Lord Chincy's green Pear,—Prince Pear.

All the kinds of Summer Pears ripen on the trees fit for eating, but should be gathered before they are too ripe.

Autumnal Pears.

Autumn Pears are such that attain their full growth on the trees from about the middle and end of September till the end of October, and which after being gathered gradually mellow and improve in flavour, and will keep some a month, others six weeks, and some two months or longer, being in eating in the different varieties, some in September, others principally in October, November, and December.

Autumn Bergamot Pear.] A middle-sized, roundish, flattened, yellowish-green Pear, faintly reddening next the sun, melting, and of a richly

perfumed flavour: ripe, the end of September or beginning of October, continuing good until the end of November.

Swifts Bergamot Pear.] A middle-sized, roundish, greenish Pear, finely striped with red, melting and tolerably well flavoured: ripe, end of September, continuing in eating till November.

Great Russelet Pear.] A large oblong brown and reddish Pear, sometimes spotted, having a tender rich pulp: ripe, middle or end of September.

Brown Beurre, or Beurre de Roy Pear.] A fine, large, oblong, russety, brown and greenish Pear, very melting, juicy and sugary, and is one of the finest Pears of the autumn: ripe, beginning of October, and keeps good till December.

White Beurre Pear.] A large, roundish, top-shaped, whitish-yellow Pear, melting, very juicy and good: ripe, beginning of October, and keeps till November.

Red Beurre Pear.] A large, oblong, reddish Pear, melting and very fine: ripe, beginning of October.

Green Sugar Pear.] A middle-sized, top-shaped, smooth, green Pear, full of a rich sugary juice: ripe, end of October, and keeps good all November.

Messire Jean, commonly called Monsieur John Pear.] A largish, nearly round, swelling, brown Pear, with a rough skin, having a breaking delicious pulp: ripe, end of October, continuing in perfection all November and part of December.

Crasanne Pear.] A large, somewhat globular, flattened, greenish-yellow, russety Pear, hollowed at the top, is remarkably tender and sweet, and may be ranked as the finest Pear of the season: ripe, end of October, keeping good till December.

Swan's-egg Pear.] A moderately large, egg-shaped, dusky-green Pear, brownish next the sun, is very juicy and agreeably flavoured: ripe, the middle and latter end of October, continuing in tolerable perfection till near Christmas.

Verte Langue, Long Green Pear, or Autumn Mouth water.] A large, long, very green Pear, is melting and juicy: ripe, in October, and continues till December.

Marquis's Pear.] A fine large, swelling, flat-topped, greenish-yellow Pear, faintly spotted with red, having a tender good pulp: is in eating in November and December.

Grey Good-wife Pear.] A middle-sized, roundish, brownish-red Pear, moderately tender and well-flavoured: is in eating from the end of October till December.

Rouffeline Pear, or Long-stalked, late Autumnal Muscat.] A large, oblong, long-stalked Pear, reddish on the sunny side, is tender and of a musky flavour: in eating in the end of October and part of November.

Muscat Fleury Pear.] A smallish, globular, brownish-red, long-stalked Pear, tender and high flavoured: in eating from October till December.

Twice-flowering Pear-tree.] It often produces blossom twice a year, the first in the spring, and the second in Autumn, so is preserved in many gardens as a curiosity.

Other varieties of autumnal Pears are—Befideri Pear—Dean's Pear—Vicar's Pear—Vine Pear—Autumn Rose Pear—French Bergamot—Beurre Bergamot—Hamden's Bergamot—Brocas's Bergamot—Gansel's Bergamot, a fine late Pear—Poire Pendar, or Knives Pear—Chat Brule, or Burnt-cat Pear—Auchin Pear—Swiss Bergamot—Longueville Pear—Scotch Bergamot—Pound Pear, very large.

All the autumn Pears should have their full growth on the tree, but not hang till quite ripe, which is the middle or end of September and in October, being their season of full growth.

Winter Pears.

Winter Pears arrive to full growth about the middle and end of October, and some late sorts the beginning of November, but do not attain maturity for eating until they have lain some considerable time in the house, some a month or six weeks, others two or three months or more, before they ripen, as observed below in their description, so that they succeed one another in perfection generally from about November and December until May.

By the Winter Pears being so long acquiring perfection after gathered from the tree, many persons have thought them fit only for culinary uses; but most of the following list are very fine eating Pears, after having lain the proper time to mellow.

St. Germain Pear.] A large, long, yellowish-green, extraordinary fine Pear, of the melting sugary kind: in eating from December until February.

Bessy Chaumontelle Pear.] A large oblong Pear, having one side purplish, the other of a whitish-green colour, is melting, of a very rich delicious flavour: in eating from December until March or April.

Martin Sec, or Dry Martin Pear.] A large, oblong, russety-reddish Pear, is breaking, somewhat dry, but of a fine perfumed flavour: in eating, end of November, December and January.

Colmar Pear.] A large, swelling, flat-top-

ped, greenish-yellow Pear, spotted with yellow; is tender and exceedingly fine flavoured: in eating from December till January or February.

Spanish Bon Chretien.] A large pyramidal purple and yellow Pear, having many dark spots on the purple side; is a fine Winter Pear, ready for eating the end of December, continues good near two months.

Virgoleuse Pear.] A large, oblong, greenish-yellow Pear, sometimes brownish next the sun, is an excellent fruit: in eating from the beginning or middle of December until the end of January.

Dauphine Pear.] A middle-sized, roundish, top-shaped, smooth, yellowish-green Pear, having a melting, sugary, musky pulp: in eating the end of November, continuing in perfection all December and most part of January.

Winter Verte Longue Pear.] A longish, green-coloured, smooth, spotted, exceeding good Pear; in eating the end of December and January, &c.

Winter Beurre Pear.] A middling-sized, oblong, yellowish, red-spotted, very fine Pear; ready for eating in December and January.

Epine d'Hyver, or Winter Thorn Pear.] A large, long, pyramidal whitish-green Pear; is melting, and in fine eating from December till February.

Martin Sire, or Lord Martin Pear.] A large, roundish, irregularly-swelling, smooth Pear, red on one side, the other yellow; is breaking and of a perfumed flavour: in eating in December and January.

Winter Bergamot Pear.] A middle-sized, roundish, greenish-yellow Pear: in eating from the end of November until the spring.

Holland Bergamot.] A large, round, greenish Pear, having a tender rich pulp; in eating from January till April.

Winter Bon Chretien.] A very large, long pyramidal, yellowish-green Pear, having often an uneven surface; is breaking, very juicy, remarkably sweet and rich flavoured, and often proves the best Winter Pear in the collection: in eating from February till April or May.

German Muscat Pear.] A middle-sized, oblong, russety-red Pear, having a melting rich pulp: in eating from February till May or longer.

Easter Bergamot Pear.] A large, roundish, flat-topped, greenish Pear, having many rough spots, is of the breaking kind; and is in eating from February till April or May.

Winter Russet Pear.] A middle-sized, longish Pear, red on one side, the other of a greenish-yellow, is melting and agreeably

bly relished: in eating in January, March, &c.

St. Martial Pear.] A longish, oblong, smooth Pear, one side purple, the other yellow; having a buttery rich flesh: in eating from February till May or June.

Cadillac Pear.] A very large, roundish, red and yellow Pear, having a hard, tartish pulp, but is excellent for baking and other culinary purposes: in use from November or December till May.

Union Pear, or Uvedale's St. Germain.] A large, long, deep-green Pear, reddish on one side, having a hard, sour pulp, but is excellent for baking, &c. in perfection from November or December till May or longer.

Great Black Pear of Worcester, or Parkinson's Warden.] A remarkably large, oblong, dusky brown, rough Pear, having a hard austere pulp, but is very fine for culinary uses, from November till March or April.

Double Flowered Pear.] The tree produces double flowers succeeded by a large, short, yellowish and red Pear, rather hard and austere; but is remarkably fine for baking, &c.

Other different varieties of Winter Pears are known by the following names—*Good Lewis*, a large longish Pear—*Ambrette*, a large roundish Pear—*Thick-stalked Pear*, a very large roundish fruit—*Amadot*, a middle-sized oblong Pear—*St. Austin*, a middling-sized oblong Pear—*Russet of Anjou*, a large roundish Pear—*Seven-elbowed Portugal Pear*, large and good.—*Echassieri*, or *Winter Green Sugar Pear*, a large, oblongish, fine fruit.—*Bessi di Cassoy*—*Iron-coloured Pear*, a middle-sized oblong fruit—*Golden Winter Pear*, a large globular fruit—*Villain of Anjou*, a large roundish Pear—*Wonder of Winter*, very large—*Chauceau du Roi Bergamot*, a very fine Pear—*Carlisle Pear*—*Tarling Pear*, a middling, largish, very fine eating fruit—*Carmelite*, a middling roundish Pear for kitchen uses—*Winter Citron Pear*, for baking—*Blood Pear*, for baking, &c.—*English Warden*, a large Pear for baking and other culinary uses.

There are many other varieties of Pears of less account, both of Summer, Autumn, and Winter kinds, that are unnecessary to insert here; and indeed it would be almost impossible to discriminate the various sorts of Pears, found in the orchards and gardens in country villages, and about farm houses, in different parts of England, &c.

But as the varieties described in the above three lists having known merit, and are cultivated in most of the nurseries for sale, by the names here prefixed to each kind, consisting of near sixty different sorts, besides the others briefly mentioned, are more than sufficient to

furnish the most extensive garden with a copious variety of eating Pears almost the year round:—and for culinary occasions, besides the sorts particularly mentioned for that purpose, may use almost any of the large hard Pears, especially of the autumn and winter kinds.

All the varieties of this tree are hardy, and will succeed in any common soil of a garden or orchard, both as dwarfs for walls and espaliers, &c. and in standards of all sorts; and in all of which modes of training they will bear plentifully.

And as Pears are very desirable principal table fruit, obtained in perfection several months in the year for eating, in the early, middle, and late kinds, and many sorts valuably useful in culinary occasions, such as for baking, stewing, &c. and also for making the liquor called perry, every proprietor of gardens, orchards, and other districts, should allot a chosen collection of the most approved different varieties, more or less, according to his extent of ground; generally a larger supply in standards for the principal production; and choose principally some of the prime sorts for walls and espaliers, in which to improve the goodness of the fruit; and in each order of training, have rather a smaller portion of the summer Pears, of the best sorts, doubly more of the best autumn kinds; and a principal supply of the most capital winter Pears, all of which may be plentifully raised by grafting and budding upon seedling Pear and Quince-stocks, as hereafter directed; and most of the sorts are to be had at the different nurseries; and may be planted in autumn or spring, or any time in open mild weather, from the latter end of October or beginning of November, till March.

In intending to plant a collection of Pear-trees, no time should be lost, when it is considered that these trees, suppose at planting, have two, three, or four years' old heads, seldom begin bearing till of five or six years growth, and often in some sorts, seven, eight, or ten, before the branches form their first fruitful growth, in any general production; especially in some strong shooters, worked on free or Pear-stocks, which are generally longer before they commence bearers, than those grafted or budded upon Quince-stocks, by reason of the latter being moderate growers, and the trees worked thereon shoot moderately to wood accordingly, and sooner become prolific in natural fruit-buds for bearing; and are very often trained in dwarfs for wall and espalier trees, and sometimes in small standards.

But for general standard Pears it is most eligible to allot a principal supply of the common full standard trees, grafted or budded on

free shooting Pear-stocks, having clean six feet stems, elevating the head at that height from the ground, and planted abundantly in gardens and orchards, &c. twenty to thirty or forty feet distance; both of summer, autumn, and winter Pears, as before intimated.

Likewise, in wall and espalier trees, worked both on Pear-stocks for larger expansion, and on Quince-stocks for moderate growth, as may be required, it is of importance to allot a good wall and espalier for some of the choicer kinds, both Summer, Autumnal, and Winter Pears, in order both to forward the growth of the fruit and to improve its size, beauty, and flavour: a south, east, and westerly wall are the proper exposures; and it is eligible to plant some in each of those aspects, to vary the times of ripening, though most of the Summer Pears will succeed very well in almost any aspect, and if some are planted also against a north wall they will ripen later and continue the succession of any approved sorts longer in eating; but it is particularly necessary to allow all the fine sorts of Winter Pears an east or west wall, or a well exposed espalier, otherwise they will not perfect their fruit kindly in unfavourable seasons; in espaliers, however, that are well trained, all the sorts of Pears attain great perfection, and the espaliers may be arranged round the quarters of the kitchen garden, or in any other free situation where the soil is of similar quality. See ESPALIERS.

Remarking, that these trees, both against walls and espaliers, should generally be allowed a great deal of room to spread, especially the larger sorts, grafted or budded on free stocks, for by having full scope they will extend their branches horizontally, more than twenty feet on each side of the stem, and the whole will sometimes form a spread of forty or fifty feet, with height in proportion.

The above extensive expansion, however, occurs principally in trees as are grafted or budded on free stocks, i.e. such as are raised from the kernels of any sort of Pears, which being strong free shooters, the trees worked thereon shoot strong and extensive accordingly, but when worked upon Quince-stocks, which are of the same family, but very moderate growers, it dwarfs the trees considerably in proportion, as they shoot moderately in much smaller extent of growth, and sooner form themselves into a prolific state, for production of fruit; and are more generally adopted for wall and espalier trees, than for common standards, but some reject them as stocks for any general culture, on a supposition that the trees are not so durable as those on Pear stocks.

Standard Pear trees, in some sorts, also assume a very extensive spreading growth in the branches, and some grow in a more upright direction; I have observed an old standard Pear that was advanced to a surprising magnitude, both in the trunk and principal branches, and of a stupendous height, and the branches of such extensive expansion horizontally; that the lower ones extended so widely over some low cottages, they were obliged to be supported on strong upright props; and the tree produced many bushels of Pears annually.

However, in all the methods of training these trees, it is highly requisite to allow them sufficient room to spread to their full extent, and their branches suffered to extend themselves always at full length; for Pear-trees should never be shortened, except in the first or second year, &c. to obtain a supply of lateral branches to form a more regular spreading head, as hereafter elucidated, because as they always bear their blossom and fruit upon short spurs arising from the sides of the branches, first, however, towards the extreme parts, then by degrees all along the sides almost from every eye, that shortening would cut away the first fruitful parts, and thus by stopping their progress of shooting in length it would force out strong shoots from all the lateral eyes, and prevent their forming spurs or fruit-buds at those parts; but being trained at full length, they shoot moderately, and in two or three years naturally form short spurs of from about half an inch to an inch or two long, the same branch and spurs continuing fruitful a great number of years.

But it must be observed, that Pear-trees are generally several years before they attain any tolerable bearing state, for the branches seldom begin to form fruit-spurs till they are from about two or three, to four or five years' old; at that age, however, they sometimes begin to bear, but never any general crop till they are eight or ten years' old.

Method of Propagation, and general Culture in the Nursery.

Pear-trees are propagated by grafting and budding upon any kinds of Pear-stocks; also occasionally upon Quince-stocks, and sometimes upon white-thorn stocks, but Pear-stocks are greatly preferable to all others for general use, whereby to have large trees, and the Quinces for moderate growers.

The numerous varieties of Pears having been first accidentally obtained from seed, and as seedlings of these varieties rarely produce the same sorts again, the approved kinds are continued and increased only by grafting or budding upon stocks raised from the kernels of any kind of Pears,

Pears, as above said; or occasionally upon Quince-stocks, especially for dwarfs of any sort, as the Quince being a moderate shooter, as before observed, they moderate the growth of the trees grafted or budded thereon, so as to be more easily kept within a smaller compass; and bear two or three years sooner, more prolifically according to size, and for the same reason, white thorn stocks have been used, but these, being of a different fraternity, are not so generally successful, and are almost totally disused in the nurseries, so that Pear-stocks are proper for general use, for principal large trees, both for walls, espaliers, and standards, and Quince-stocks for smaller growths; observing therefore to raise proper supplies of stocks of these two kinds, less or more of each, as required; effected by sowing the kernels of the fruit of any sorts of Pears and Quinces, the latter also by suckers, layers, and cuttings: procuring the kernels of the perfectly ripe fruit of summer and autumnal Pears, the same of the Quinces, and sow them in the latter end of autumn, October, November, or December, &c. or early in the spring months, in beds of light earth, covering them near an inch deep; they will come up in the spring, and in autumn, winter, or spring following, plant out a parcel of the strongest in nursery-rows to remain for grafting and budding, which after having from one to two or three years' growth here, or when about half an inch to an inch thick, or a little more or less, they will be of proper size to receive the grafts and buds.

The grafting and budding them is to be performed in the usual method, performing the grafting in the spring, and the budding in summer (See GRAFTING and INOCULATION): being particularly careful to procure the grafts and buds from such trees as produce the finest fruit of the respective sorts you intend propagating.

Being, however, provided with the grafts and buds, proceed to graft them, &c. accordingly for dwarfs and standards; observing, that those designed as dwarfs for walls, espaliers, or standard-dwarfs, be grafted or budded near the bottom; and for half and full standards, the stocks may either be previously trained up from three or four to seven or eight feet high to form a stem, then grafted near the top, or may be grafted low in the stock, like the dwarfs, and train the first main shoot for a stem the above height; all the grafted trees both dwarfs and standards will shoot the same year, but the budded ones not till the spring after; and when their heads are two years old from the grafting and budding, they may, if thought proper, be

planted out for good, or remain longer in the nursery, as may be convenient.

Observe, however, that the dwarfs designed for walls, espaliers, &c. whether they remain longer in the nursery, or are transplanted at a year old into the garden, should have the first shoots from the graft or bud when a year old, headed down in March to five or six eyes to force out a proper supply of four, six, or more lateral branches near the ground, to furnish the wall and espalier with bearers quite from the bottom, and these will readily produce others to cover the upper part.

But standards, supposing them to be grafted on high stocks, may either be headed near the top of the stock, or permitted to run up, as the case may require, that if shortened it will force out laterals near the head of the stem, and form a more spreading full head; and if suffered to run up with the first shoots entire, they will form higher, and generally more upright heads in the end; such standards, however, that are grafted or budded as low in the stock as for dwarfs, must have the first shoot trained upright at full length, six or seven feet high for a stem, if for full standards, then may either top it at six feet height, to force out laterals near that part to form a spreading head as aforesaid, or suffer it to run and branch in its own way to form a more erect and higher head.

All the headed trees, however, both dwarfs and standards, being cut down in the spring, will soon branch out from all the eyes immediately below; being careful during the summer to trim off all shoots from the stem, and suffer all the top shoots to remain entire, and they will form handsome beginning young heads by the end of summer: and in autumn, winter, or spring following, they may have their final transplantation into the garden, &c. provided it was not done before heading down.

But if obliged to retain them longer in the nursery, let the whole have any requisite pruning to reform irregular growths, and the different trees trained accordingly, agreeable to the form they are designed to assume, whether dwarfs for walls and espaliers, dwarf-standards, or half or full standards, suffering the whole to branch away at full length, not shortening any after the above general heading down, when a year old, except it should seem occasionally necessary, either to reduce any casual irregularity, or to procure a more sufficient supply of lower branches, after which, however, no further general shortening should be practised to these sort of trees, for after having obtained a proper set of regular branches near the head of the stem, they will readily furnish more in their turn to increase the head upwards.

Their

Their Transplantation into the Garden, &c.

When the trees, however, are from one or two to four or five years old, from the graft or bud, they are of a proper growth for planting out finally; but if larger trees are required, those of six or eight years old may be safely transplanted; younger trees, however, always succeed well, even if only two or three years old.

The season for planting them may be any time in open weather from the end of October till March; but if in autumn, or early in winter, it will be an advantage.

They will succeed in any common soil of a garden, or any good fertile orchard-ground, or field, that is not copiously wet, or very stiff or stubborn, but moderately light and pliable, one good spade deep, at least, if more the better; preparing the ground by proper trenching one or two spades deep, as the depth of good soil admits, either wholly if for a full plantation, or only along the place for each row of trees, otherwise the place for each tree; or only, at present, dig a hole for each tree at eligible distances.

First, of Planting the Dwarfs, and their general Culture.

The distance to plant Dwarf-Pears for walls and espaliers is for those on free stocks not less than twenty feet, but if twenty-five, or more, the better, especially if lowish walls, &c. that in default of height, there may be full scope to extend their branches considerably in a horizontal direction, as they will effectually fill that space, or even much more if allowed it them; but the above distance appearing very considerable at first, and the trees standing so wide having a straggling appearance for several years before they approach one another to effect any uniformity, they are rarely planted at that distance, some scarcely half so much, but seldom more than twenty feet; however, it is of importance to grant these trees sufficient room; and the higher the walls the better, which is of particular advantage to Pears, evident by those growing against the ends of high buildings, as they extend themselves very considerably every way, as before observed, and their branches requiring to be trained constantly at full length, in which they will emit fruit-tips all the way along their sides; therefore they may be planted at least twenty to twenty-five feet distance, and in each interval of twenty-five feet, may plant a cherry, or any other moderate-shooting fruit-tree, to fill the vacancy, and bear a few years, till the Pears advance in growth; and according as these approach one another, cut the others away by degrees, so as at last the Pears may occupy the whole space. Having, however, fixed on the di-

stance, and the holes dug, and the trees ready, let them be planted in the usual way, and all with their heads entire, at least for the present. See PLANTING.

However, for trees as are dwarfed by grafting or budding upon Quince-stocks, fifteen to eighteen feet is their proper distance for planting, either for walls or espaliers, and which sorts are very proper for gardens of but moderate or small extent, or any others.

The trees being thus planted, their general management, with regard to training and pruning, is nearly as follows.

Observe, in the first place, that if the young wall and espalier trees thus planted are only one year old from the graft or bud, having their first shoots of a year-old entire, these should in the spring be headed down to five or six inches, as directed in their nursery culture, to force out lower horizontals; but if they were previously headed in the nursery, as we advised, and having thereby thrown out laterals to form a regular set of horizontals, consisting of six or more regular branches near the bottom, they should not now be shortened, but trained to the wall or espalier at full length horizontally, preserving an equal number on each side five or six inches asunder, they will readily emit a further supply of horizontals to cover the wall, &c. regularly upward, and at the same time, as being not shortened, they will gradually form themselves for bearing, as every shortening of the branches of these trees retards their bearing a year at least; if, however, there is a want of branches, some of the middlemost may be pruned short, and trained to the wall or espalier. According as the trees shoot in summer, train in a farther supply of all the regular shoots in every part where they occur, at full length, unless it shall seem necessary to prune some strong shoots to obtain a greater supply of horizontals the same year in order to furnish the head as soon as possible: at this time, however, displace all fore-right and other irregular growths of the year, continuing the supply of regular shoots close to the wall, as they advance in length during their summer's growth. And in the winter pruning, examine the supply of shoots retained in summer, selecting all those that are well placed and properly situated for training in, to increase the number of horizontals regularly on each side, which leave wholly entire, and at the same time retrench any superfluities and ill-placed shoots omitted in summer; then let the whole supply of regular horizontals in every part be trained in straight and close to the wall and espalier, horizontally and equally on both sides of the tree, every branch at full length,

length, four, five, or six inches asunder, as aforesaid. See WALL and ESPALIER TREES, PRUNING, &c.

Another method sometimes practised in training these trees for walls and espaliers is, that after their first heading down, and having thrown out several laterals, select three of the strongest and most regular placed of them, one on each side and one in the middle, nail the two side ones horizontally at full length, and the middle one upright; next year the tree having produced a further supply of shoots, add two or four of them as side-horizontals, arranging them on each side of the stem as the two former, training the middle shoot still in an upright direction; observing, however, if it should not furnish horizontals low enough, it may be shortened so as to make it throw out shoots at any requisite height, continuing the middle one always upward for a stem, and the side ones horizontally for bearers.

By either of the above methods of training these trees, continue every year increasing the number of horizontals, till the allotted space of walling and espalier is regularly covered with bearers at equal distances, still continuing them all at full length in all future training, as far as the scope of walling, &c. will permit; and they will all naturally form fruit-spurs at every eye, almost their whole length, and the same branches continue in a fruitful state a great number of years.

In the general training of these trees, let it always be remembered, that the branches trained in for bearers must never be shortened, because, as we before observed, their fruit-spurs being generally produced first towards the once extreme parts, then gradually along the sides of the branches, of from two or three to many years growth, so that there is no need of shortening to procure a new supply of bearing wood annually as in peaches, nectarines, and such other trees as bear fruit upon the young wood only; but in Pears the same branches not only continue for years in a bearing state, but become every year more and more fruitful even to a great age, if not retarded and spoiled whilst in training by shortening, as is very often the case; for shortening these sort of trees, both stops their progress of growth and bearing, by reducing the length of the branches considerably, and cutting away the first fruitful parts, as they generally begin bearing first at or near the parts which was once the extremity of the shoots; and by reducing their length it forces out numerous, strong, useless shoots from the eyes below, at the places where fruit-buds would have been otherwise formed, and instead thereof crowd the tree with a great re-

dundancy of unnecessary wood, and but little fruit; but by training the bearers from the first at full length, and continued so far as the allotted space will possibly allow, they not only sooner fill the space of walling, &c. but emit fruit-buds from almost every eye, and bear abundantly.

When the trees have once thus filled the wall or espalier with the branches, they need but very little farther supply for many years, and that only occasionally, according as any worn-out or decayed branch occurs, and wants renewing with young wood. See PRUNING.

But two prunings every year are requisite to preserve their regularity and bearing state,—a summer and a winter pruning.

The summer pruning should be begun in May, or early in June, and rub off all the superfluous and unnecessary shoots of the year, and all fore-right and other ill-placed shoots, retrenching them quite close, being careful to leave the terminating shoot of every horizontal or bearer entire; and reserve here and there a well-placed shoot towards the lower parts in particular, and where there are any apparent vacancies, or at least, it is generally proper to retain some shoots as above to train up between the mother branches, till winter pruning, and if then not wanted, can be easily retrenched, training them in for the present at full length.

The winter pruning may be performed any time from the fall of the leaf until March; in this pruning examine the branches in general, see if they are any where too much crowded, or are trained irregularly; and if any such occur, let them be regulated as they may require; at the same time examine if there are any vacancies; and in which case train some contiguous shoots reserved in the summer dressing, to supply the deficiencies; all other shoots trained in last summer, not now wanted to supply any vacant space, must be cut clean out close to the branches, being careful still to preserve the terminating shoot of every branch entire, in all parts, as far as the allotted space admits, likewise all the fruit-spurs in every part, and fasten in all the branches regularly at full length.

But in winter-pruning old trees however, decayed and worn-out branches will sometimes occur; be careful therefore to cut out all decayed wood wheresoever it appears, training young, if possible, in its stead; likewise, where any branch, either through excessive age or any other defect, is become barren or worn out, let it either be retrenched to some eligible lower young branch or shoot, or may previously have young bearers in training a year or two or more from the bottom

tom between the main horizontals, which is eligible enough in old trees, when there is any apparent vacancy happening either by decayed wood or worn-out branches, and according as the young ones assume a bearing state, retrench the bad wood, and train the young supply in its place; in this case look always well to the bottom of your trees, and if any good shoots offer where there is an appearance of a vacancy like to happen, train them up between the main branches to be advancing to a bearing state, to be ready when wanted.

Where any of the choicer sorts of these trees have, through great age or some other natural cause, or by bad culture, become infirm, their branches in general either in a declining worn-out or barren state, or extended long and naked, not furnished with bearing wood, we should endeavour to renew them with young bearers, by heading the branches wholly down near the bottom in winter or spring, they will break out in the old wood, and in the following summer furnish a large supply of strong young shoots, which train agreeable to the rules before laid down, and they will soon form a new tree, as it were, and bear plenty of good fruit.

After each winter-pruning of these trees against walls and espaliers, they will require a general nailing, &c. let this always be done with great regularity, training all the branches horizontally as straight as possible their whole length, at equal distances. See WALL TREES, ESPALIERS, &c.

As to dwarf standards of these trees, see their mode of training, &c. under the article DWARF TREES.

The culture of the borders wherein these wall and espalier Pears are growing, is common digging once every year at least, and with the addition of manure occasionally in common with the other parts of the garden; though if some good rotten dung is applied every other year, and the ground well dug or trenched every winter, it will greatly promote the size and perfection of the fruit.

Planting them for Standards and general Culture.

Standards of any sorts of Pears bear plentifully in any open situation, though the fruit may not always be so large and fine as those of wall and espalier trees; summer and autumn Pears however ripen in great perfection on standards; as will also most of the common winter Pears. Observe, in planting them, that trees of from two or three to four or five years old, having tolerable heads, are of a proper age and size for planting, and are preferable to older trees for any general plantation. See

PLANTING. And that having been trained as directed in their nursery culture, and formed heads, consisting of several branches, let them be planted with all their heads entire, except retrenching any very irregular-placed branch, but retain all the others, and suffer them to remain at full length, and plant them in the usual manner of tree-planting. See PLANTING.

In their future growth suffer them to branch away as fast as they are able, according to nature, and they will soon form large branchy heads, suffering all their branches to remain entire, and extend themselves in length, and they will all emit numerous fruit-spurs, and bear plenty of fruit.

The general culture of full-grown standard Pears, in respect to pruning, is very trifling, and that only required occasionally, probably once only in several years; such as the retrenching any very irregular growing branch, such in particular as grow cross-ways, and greatly incommode the neighbouring branches; also to thin such branches that are very much crowded, and confuse the head considerably; cutting out all decayed wood and eradicate suckers from the root and stem. See PRUNING, article *Pruning Standards*.

Where these standard trees are situated in a garden, in which the ground is necessarily digged or trenched annually for the reception of the under-crops, and occasionally enriched with dung, they generally produce finer fruit than in orchards, or other districts where the ground is not in similar culture; though it may also be observed, that where the trees are situated in good ground, both in gardens, grass orchards, or other compartments, they bear plentiful crops of very good fruit.

Gathering and preserving the Fruit.

The maturity of Pears, after arriving to full growth, is generally known by their changing from a green to a yellow or reddish colour, &c. and by their frequent falling from the tree, and when with a gentle twist or turn up, easily quit their hold; but those tokens are more particularly observable in summer and autumn Pears; for winter Pears being not maturely ripe when gathered, often require a good pull before they quit the branches.

Summer Pears ripen in succession in different sorts, from about the beginning or middle of July till the middle of September; many of the earliest ripen all at once, as it were, and continue good but a few days, either on the tree or when gathered, nor will any of the sorts keep good long; and none of these sorts should hang on the tree till soft ripe, otherwise most of them will be mealy and insipid; let these

these sorts therefore be gathered as soon as they are arrived to full growth; and just begin to colour and discover maturity, but before they become soft and mellow; observing that, for family use, they may be gathered from the tree according as they attain perfection; but let the general crop of each sort be always taken down before they ripen fully, and lay them in any dry room; none of the kinds will keep long, some only a few days, and scarcely any of them above a fortnight, though from different varieties ripening at different times, the succession is continued for eight or ten weeks.

Autumn Pears ripen in different varieties, from about the middle of September till the end of October; some of the forwardest ripen eatable on the tree, others requiring to lie some time after being gathered before they acquire perfection. Let the different sorts of this class of Pears be gathered according as they arrive to maturity: those designed to keep some time should be gathered just when they have attained full growth; their maturity or full growth on the trees is known by their frequent dropping, and by their readily quitting the tree on being handled: gather them in dry weather, and lay them in a dry close room, or in baskets, each sort separate; they will thus gradually mellow, acquire rich juices, and delicious flavour.

Winter Pears attain their full growth on the trees about the end of October or beginning of November; but the eatable kinds do not acquire maturity for eating on the tree, nor for some considerable time after they are gathered, some probably in a month, others two or three, and some more, and some sorts not till spring following, and often continue in perfection till summer, as is noticed in the description of the different sorts of winter Pears; but the baking kinds may be used any time from October or November during their continuance.

All the winter Pears however should be indulged with as full growth on the tree as the weather will permit, even until the end of October or first week in November of the later kinds, if the season continues mild; be cautious, however, to get them gathered before attacked by much frost.

In gathering all sorts of Pears for keeping, always chuse dry weather, and when the fruit is also quite dry.

The method of gathering these fruit is to pull one and one by hand, by a gentle twist, or turn upward; and if they readily separate, it is a sign of full growth, more particularly the summer and autumn Pears; being parti-

cularly careful in gathering not to bruise them; and let each sort be kept separate.

According as they are gathered, carry them directly into the fruitery rooms, where those intended for long keeping, such as the late autumnal and all the winter Pears, should be previously laid up in heaps, and covered with cloths, in order to promote a perspiration, and discharge the watery moisture; which prepares them for keeping, as well as improves their flavour: this fermentation or sweating will be effected in a week or fortnight, when they should all be wiped dry with a woollen cloth; then let a quantity be deposited upon the shelves of the fruitery, to remain for first eating, and let all the others be also disposed in some similar manner, each sort separate; it will then be proper to cover the whole thickly with clean dry straw, to exclude the moist air, &c. whereby they will keep longer and more effectually in good perfection: others of the prime sorts for longer keeping may be packed up in baskets, &c. thickly lined within with straw, then some thick paper; and having filled the basket with the Pears, cover them down also with paper, then a good thickness of straw over all, fastening the whole as close down as may be, tying a label, with the name of the fruit and time of ripening, to each basket, and then place them in a close warm room; they will thus succeed those on the shelves for use, and keep good a long time; and if some are also put into large earthen jars, plugged and roined down perfectly close to exclude the external air, they will keep a long time sound, especially the latest sorts, which will keep till May or June.

They should be occasionally looked over, to remove all such as assume any tendency to decay, before they spread the putrefaction to the adjacent fruit; this should be properly attended to at intervals, to those on the shelves or any where in the open fruitery in particular, as they are more liable to putrefaction, and can be easily examined; but those packed up in close baskets, &c. are not so easily observed, nor will they require it so often; it is however proper, after some considerable time, to look them over.

Of forcing Pear-trees for early Production.

Pears in wall-trees are sometimes forced by artificial heat in forcing frames, in some of the prime early summer kinds, to obtain a portion of these desirable fruit as early in the season as possible, such as Jargonelles in June, their natural season is not till August.

This is effected by means of hot-walls and forcing frames; previously having some trees of the choicest early summer Pears, such as

the Jargonelle aforesaid, trained in wall-trees against a south wall, till advanced to some tolerable state of bearing; and being then inclosed with glass frames, in the manner of forcing-frames or hot-walls, and having internally either flues for fire heat, erected forward and extending long ways, or otherwise a pit arranged in that direction, in the interval space between the trees and the glass work, for a bark or dung hot-bed; and that by one or other of these methods a proper degree of artificial heat is produced internally within this glass-case frame, to force an early growth in the trees inclosed therein, and forward them to early flowering and fruiting; in which managing them in the common way, as other trees in forcing frames, whereby they will generally advance very agreeably in their early production, as sometimes to have some ripe early in June, or some time in that month.

For this purpose the Jargonelle is one of the principal sorts, as being the superior of all our summer Pears, of a handsome growth, middling large size, with a fine juicy, rich pulp, of a delicious flavour; however, any other principal early sort may also be admitted for the same occasion.

Apple Kinds.

PYRUS Malus.

The Apple-tree (*Malus*) being now considered as a species of *Pyrus*, as formerly observed, we have arranged it accordingly under this head, together with all its varieties, which are exceedingly numerous in the difference of the fruit: some for eating, others for baking, boiling, cider, &c. and may be said to be the most valuable fruit in the world for its various economical uses, and long continuance in perfection, which, in the different sorts, is the year round.

Class, order, and characters, are the same as the *Pyrus Communis*.

Of the Apple kind there may be reckoned four principal distinct species, viz. 1. Common apple-tree, comprising numerous varieties of the fruit—2. Berried apple or Siberian crab—3. Chinese apple-tree—4. Sweet-scented Virginia crab: of which the trees of the last three sorts are cultivated principally for variety, and only the common apple in its different varieties, as proper for general culture as valuable fruit-trees.

The species are,

1. *PYRUS Malus.*

Malus, or Common Apple-tree.] Grows twenty or thirty feet high, having oval, serrated leaves, and sessile umbels of whitish-red flowers, succeeded by large, roundish, and oblong fruit, concave at the base.

Varieties.] The varieties of this species are amazingly great, in respect to the differences of the fruit; and the botanists contend that the wilding, or crab-apple of the woods and hedges, is the original kind, and from the seed of which the cultivated Apple was first obtained; whose varieties, no doubt, are multiplied to some hundreds, in different places, having been all first accidentally obtained from the seed or kernels of the fruit of various sorts at different times in the course of a great number of years, and the approved sorts continued and increased by grafting upon crabs or any kinds of apple-stocks; but although the number of different varieties is very considerable, there are not above forty or fifty sorts retained in the nurserymen's catalogues as principal fruit, which however is doubly sufficient to furnish a successional supply of Apples all the year. The different varieties arrive to full growth in successive order, from July till the end of October; the summer kinds, that ripen before the middle of September, are many of them ripe for eating immediately from the tree, and do not keep long: but most of the autumn and winter kinds, that ripen from the middle or end of September till the end of October, improve in perfection after being gathered, as they lie in the fruitery; and many of the winter kinds in particular keep good many months, even until the arrival of Apples next summer.

The most noted varieties are generally known by the following names, &c.

Genneting, or June-eating Apple.] A small Apple, oblong and roundish in different varieties, of a most agreeable flavour, valuable for its early perfection, being in eating sometimes in June, against a wall, but on standards principally in July, and beginning of August.

Margaret Apple.] A middle-sized, oblong Apple, one side tinged with red, the other pale-green, and is highly flavoured; ripe for eating in July and August.

Common Codlin.] A largish, oblongish, irregular, greenish-yellow Apple, tinged with red, valuable for its early growth, being fit for many culinary purposes, from June till August and September, and is also a tolerable good eating Apple when arrived to maturity; ripens fully in August, becoming of a bright-yellow and red colour.

Kentish Codlin.] A large, longish, irregular Apple, excellent for culinary uses, in August and September.

Summer Pearmain.] A middle-sized, oblong, fine, red-striped Apple, good for eating and culinary uses: ripe in August and September.

Scarlet Summer Apple.] An oblong, deep-red,

red, beautiful Apple, for eating and kitchen purposes, in August and September.

Summer Calville.] A large, fine summer Apple: ripe end of August and September.

Quince Apple.] A small, roundish, quince-shaped, russet and yellow Apple; ripe for eating in September.

Summer Rambourg.] A large, handsome, variegated red and yellow Apple: ripe in August and September.

Loan's Pearmain.] A middle-sized beautiful Apple, having one side finely reddened, the other variegated also with red: ripe in September and October.

Royal Pearmain.] A large, oblong, beautifully reddened Apple, for eating and culinary uses: ripe in September and October.

Red Autumn Calville.] A moderately-large, oblong, fine-red Apple, of a vinous aromatic flavour: ripe in autumn.

White Autumn Calville.] A large, oblong, fine eating Apple: ripe in autumn.

Golden Russet.] A roundish, middle-sized, russet-yellow, good eating Apple, with a firm acid pulp: ripe in autumn.

Golden Rennette.] A middle-sized, roundish, beautiful, red and yellow Apple, having a firm fine-flavoured pulp, excellent both for eating and baking, &c. ripe in October, and continues till spring, if packed up close.

Golden Pippin.] A small, roundish, and oblong, beautiful yellow Apple, firm, and admirably fine flavoured: ripe in October, and may be kept till the spring.

Court-pendu, or Hanging Body.] A large, oblong, handsome Apple, red next the sun, the other side pale, and generally hangs downward: in eating in autumn and part of winter.

Grey Leadington Apple.] A longish, moderately large, greyish-green, very fine Apple, being a most excellent table fruit: ripe in autumn and part of winter.

Aromatic Pippin.] A middle-sized, roundish Apple, one side russet-coloured, the other side yellowish; is of an agreeable aromatic flavour: ripe for eating in October, keeping good a long time.

Violet Apple.] A largish, oblong Apple, one side reddened, the other variegated, having a firm sweet pulp, flavoured like violets: ripe in October, &c.

White Rennette.] A large, roundish, whitish-green Apple, having a firm sugary pulp, good both for eating, and for baking and boiling: ripe, end of October, continuing good till January.

Rennette Grise.] A roundish, middle-sized Apple, grey-coloured on one side, the other

tinged with yellow; in eating, from October till Christmas, or longer.

Winter Pearmain.] A moderate-sized, oblongish Apple, red on one side, the other variegated red and yellow; is tolerable for eating, but very good for boiling: ripe, end of October, continuing good all winter.

Kentish Pippin.] A large, oblongish, whitish-green Apple, good for eating, but particularly adapted for the kitchen uses, from October till spring.

Nonpareil Apple.] A middle-sized, roundish, somewhat flattened, dusky russet-green Apple, having a firm pulp, replete with a sharp agreeable juice; a most excellent winter fruit for the dessert; in eating from November or December until May.

Large Nonpareil.] A large, round, light, russet and yellowish Apple; is a fine handsome fruit, but does not continue in perfection so long as the common Nonpareil; in eating from November or December till March.

Holland Pippin.] A large, roundish-oblong, greenish Apple, having the eye pretty much sunk; is a very fine fruit, both for eating, and in great estimation for culinary purposes, from October until March or April.

Monstrous Rennette.] A remarkably large, oblong Apple, one side red, the other green, valued chiefly for baking or boiling, in November and December, &c.

None-Such Apple.] A roundish beautiful Apple, being finely tinged with red on one side; is highly flavoured, and excellent both for eating and culinary uses: ripe about autumn, and continues till the end of December.

Royal Russet.] A fine, large, roundish-oblong, deep-russet-coloured, rough Apple, having a soft, yellowish pulp, of a mild flavour, and is admirable for all culinary uses in particular; is in perfection from October or November until April.

Embroidered Apple.] A moderately-large, beautiful Apple, adorned with broad red stripes; is a middling fruit, both for eating and kitchen purposes, and is in perfection in winter.

Wheeler's Russet.] A middle-sized, roundish-flattened, russet-coloured, and yellowish Apple, having a firm, brisk, agreeably relished pulp, both for eating and culinary uses, and is in perfection all winter and spring.

Pile's Russet.] A smaller, middle-sized, oblong-oval Apple, russet-coloured on one side, green on the other, having a very firm flesh, of a sharp acid relish; is by some esteemed for eating, but is in high repute for baking, con-

tinuing in perfection all winter, until April or May.

Stone Pippin.] A pretty large, whitish, very hard Apple, having a sour unpleasant pulp eaten raw, but is in good estimation for baking; is in perfection all winter, spring, and great part of summer.

Barnard's Baking Apple.] A very large, fine, baking Apple, in perfection in winter, and keeps good till summer.

Kitchen Rennette.] A large, handsome, whitish Apple, in high repute for all culinary uses: in perfection all winter.

The above varieties being the most approved sorts, they are cultivated in most of the nursery-gardens for sale.

The following are less material varieties of eating and culinary Apples mentioned in some fruit catalogues,—Summer Russet, a roundish, russet-coloured Apple—Summer Pippin, a roundish yellow Apple—L'Api, a small bright-red Apple—Transparent Apple, having a pellucid pulp—Virgin Apple, long and beautifully red—Anise Apple, longish, and flavoured like aniseed—Gilliflower Apple, middle-sized, and delicately reddened—Salmon Apple, longish, red, and yellow fruit—Margil Apple, middle-sized, ridged, and red-striped—Kirton Pippin, roundish, whitish-green, and often cracked—Lemon Pippin, small, roundish, yellow fruit—Aclemy Russet, a roundish, russet-coloured Apple—Gray's Pippin, large, roundish, grey, and green Apple—Winter Greening, a very large green Apple—Black Pippin, a large dark-green Apple—Partridge Apple, a large kitchen Apple—Lord Hlay's Pippin, a middling roundish Apple—Spencer's Pippin, a middling, round, brownish and yellowish-green Apple—Winter Pippin, a roundish firm Apple—Costard Apple, large, irregular, and red striped—Winter Rambourg, a large, round, red Apple—Cat's-head Apple, very large, for culinary uses. Of the above, the first five or six sorts are forward Apples, and all the others are autumn and winter fruit, and most of which may be used occasionally for eating and kitchen uses.

And of Cider Apples, the following are the principal sorts—Redstreak Apple—Royal Wilding—Everlasting Hanger—Gennet Moyle—Whitfour Apple—John Apple—Woodcock Apple—Herefordshire Underleaf—which, with many others, are well known in the cider counties, as Devonshire, Herefordshire, &c.

To the above lists may also be added the following varieties, being all off-spring of *Pyrus Malus*.

Fig Apple.] Having been formerly supposed

that the trees produced fruit without any previous visible flower, like the Fig-tree, it obtained the name *Fig Apple*; but the fact is, the tree certainly produces flowers, that are visible, which, however, are almost apetalous, or without petals, so are not conspicuous like those of the other varieties, but are, nevertheless, furnished with the generative organs, succeeded by proper fruit.

Paradise Apple.] A low weak-shooting tree, of a shrub-like growth, produces small fruit of no value, so is retained in some gardens for variety, and is sometimes used as stocks on which to graft other Apples, to render them of a very dwarfish growth, both sometimes for espaliers and walls, or principally in small dwarf-standards, to plant in borders, and for small gardens, and for planting in pots for curiosity.

Dutch Paradise Apple.] Grows a little stronger than the former, and is often used for stocks to graft upon to form dwarf-trees; as in the last-mentioned.

Wilding, or Crab Apple.] The tree grows more than twenty feet high, producing small, roundish, and oblong yellow fruit, intolerably sour, harsh, and disagreeable to the taste, so are used only principally for making verjuice. The trees of this variety grow wild in England, &c. in woods and hedge-rows, and are rarely cultivated in gardens, except for stocks on which to graft the cultivated Apples; for which purpose they have great merit, as trees grafted on Crab-stocks are generally very hardy and durable; sometimes, however, a few plants are introduced in the shrubbery plantations for variety, and are employed by the farmers for making field hedges, as being of quick growth, soon run up, and form a hedge expeditiously. See HEDGES.

Thus far terminates our list of the varieties of this great species, *Pyrus Malus*.

There are, however, besides the above, many other varieties of less value; but those of the above list are the generally known approved sorts; all the varieties, good and bad, are the off-spring of this one species (*Pyrus Malus*), the trees of all the sorts having oval sawed leaves, and sessile umbels of flowers, appearing in April and May, upon short spurs on the sides and ends of the branches, succeeded by fruit soon after, growing to perfection, in different sorts, from July until the end of October, as before observed; those, however, that ripen before the middle of September, keep but a short time, some of the forwardest probably not above a fortnight, others a month, or but little more; but the winter kinds continue in succession several months, especially if

if housed in dry, close apartments, and thickly covered with clean straw to exclude the free air, damps, and frost: and if a quantity of the latest are packed up close in baskets or boxes lined with straw, to exclude the air, they will continue sound and good till next summer.

The following species being also of the Apple kind, are retained in our gardens, some both for the production of their singularly small eatable fruit, esteemed a great curiosity; and for variety, and others principally for the latter occasion.

2. *PYRUS baccata*.

Berried-fruited Apple, commonly called Siberian Crab.] A small shrub-like tree, branching out low, growing about ten or twelve, to fifteen feet high, in the different varieties; garnished with oblong, equally-ferrated leaves, and crowded peduncles, with pale red flowers, succeeded by small berry-like Apples, of different varieties.

Varieties of this are,] Common small berry-shaped, yellowish and red fruit—Larger Apple-fruited, of different sizes, bigger or smaller in the different varieties of the trees—Small red berry-fruited; all of which varieties, though denominated crabs, are agreeable eating in autumn, and proper to serve to table in a dessert, both for variety, curiosity, and to eat.

(Americana) — American Berry fruited Crab.] A dwarfish tree, garnished with oblong, sawed leaves, and producing numerous small berry-like, red Apples; eatable when full ripe; sometimes served in the dessert for variety, and are estimable to use for preserves, &c.

3. *PYRUS coronaria*.

Sweet-scented Virginia Crab.] Grows ten or twelve to fifteen feet high, garnished with narrow, angulated, ferrated, smooth leaves; and pedunculated umbels of whitish, sweet-scented flowers; succeeded by many small round Crab Apples, remarkably sour and austere.

Variety.] Evergreen Virginia Crab.

4. *PYRUS spectabilis*.

Large-flowered Chinese Apple-tree.] Grows twenty or thirty feet high, garnished with oval-oblong, ferrated leaves, and sessile umbels of large, semi-double, red flowers, singularly beautiful; succeeded by small Apple fruit, of but little value.

The above three last species of the Apple tribe are proper to cultivate, some both as secondary fruit-trees, for their production of fruit for occasional eating, particularly the Siberian Crabs, and to plant for variety in

shrubberies, borders, &c. and all the others are principally for variety in any pleasurable compartments; allotting the Chinese Apple tree a conspicuous situation, for its large beautiful flowers; though all the sorts deserve a principal situation, as they will effect a very agreeable variety in their growth, flowering, and fruiting.

However, as fruit trees, it is eligible to admit some of the different varieties of the Siberian and American Crab, disposed either in the borders of the kitchen or pleasure garden, or both, for the sake of variety, in the agreeable singularity of their curiously small apples; the trees also appear very ornamental in blossom, which is generally succeeded by a plentiful production of fruit, exhibiting an entertaining variety in the autumn season; and they may be trained both as espaliers, wall-trees, and small standards, and managed the same as directed for other apple trees.

All the above three species, and their respective varieties, are propagated by grafting, layers, and cuttings; and by all of which methods, the several varieties continued distinct in their respective peculiarities.

General Observations on the common Apple-tree.

The trees of all the varieties of the common Apple bear well in any mode of training, such as in espaliers, against walls, and all kind of standards; they however are rarely indulged with walls, as all the sorts of Apples attain full perfection without that aid, the walls being commonly reserved for such tender fruits as stand more in need of their assistance; in espaliers, however, it is eligible to have a collection of the choicer sorts, as in this mode of training the fruit generally attain greater perfection as to size, beauty, and flavour, than in standards; but all the varieties likewise acquire good perfection on standards of all sorts, though probably in a less degree in some particular sorts; and it is from common high standards that the general supply of Apples is obtained for common use, and for the supply of markets, making cider, &c.

In espaliers, the trees may either be arranged by themselves, or in assemblage with Pears, &c. alternately, to effect the greater variety, being generally arranged around the outer boundaries of the quarters of the kitchen-garden, in the borders verging the main walks; but some may also be arranged in any other department, either for the sake of variety or convenience. See ESPALIERS.

And in common standards they may be both disposed in ranges thinly in the garden, and formed into orchards, according to the supply

supply required; and in some places they are cultivated in hedge-rows of fields; and in the cider counties they plant them out both in hedge-rows, and in large fields, in wide ranges, to admit of having crops of corn, &c. between; but in common orchards they are planted about thirty or forty feet distance, and the ground is generally laid down in grass. See ORCHARDS.

Dwarf standard. Apples are sometimes raised, a few for variety or curiosity, or to plant in small compartments, or in borders, and for small gardens, as before intimated; and if properly trained, will bear in very great perfection, in quantity according to their size of growth. See DWARF TREES.

The mode of bearing of all the varieties of Apples is principally upon short spurs, issuing from the sides of the branches of from two or three to many years old, as observed of Pears and plums, &c. formed first towards the extremity of the two or three years' wood, then by degrees along the sides of the branches, provided the branches are always trained at full length, as advised for other trees that bear chiefly upon spurs, as shortening promotes luxuriance, and forces out numerous strong wood shoots in the place where fruit spurs would have been formed; but being trained always entire, they assume a moderate growth, and gradually emit natural spurs in every part; and as the same branches and spurs remain fruitful many years, determines, that in the general course of training and pruning these trees, we should not shorten their branches, except occasionally in the first and second year after grafting, if thought necessary, to force out lower laterals to give the head its first proper form; afterwards, permit the branches to extend generally at full length, both in espaliers, &c. and all manner of standards; and thus they will all soon form a bearing state.

Apple-trees often begin bearing at two or three years old, and at six or eight will bear in tolerable plenty according to their size.

Method of Propagation, &c.

All the varieties were first accidentally obtained by raising them from the kernels of the fruit; but we cannot depend upon seedlings to continue the same sort of fruit.

Grafting therefore is the mode of propagation to increase and continue the different varieties the same; performing it upon Crab, or any kind of Apple-stocks, raised from the kernels, both for dwarfs and standards; also upon Codlin and Paradise Apple-stocks raised from cuttings and layers, when designed to have espaliers and other dwarf trees, or for small standards, as low as possible, to be con-

finied within a moderate space, or for small gardens; some sorts of Apples may also be raised by layers and cuttings, particularly the common Codlin, which may likewise be raised from suckers, from the root and stem of such trees that are wholly of the Codlin kind quite from the root; and as this tree is of very moderate growth, it is commonly trained in small standards of two or three, to four or five feet stems, branching out above in full, but not in large heads; however, the best general method of propagating all the other kinds of Apples is by grafting upon the proper stocks, as aforesaid.

The method of raising the different sorts of stocks for the above purpose is,—the Crab and Apple-stocks are raised from the kernels of the fruit; but the Codlin and Paradise-stocks must be raised by cuttings and layers, to continue them with certainty of the same kind and moderate growth; however, as to the Crab and Apple-stocks, they may be raised from the kernels of any of the sorts, procuring the kernels in autumn or winter, either from rotted fruits, &c. or from such as have been pressed for verjuice and cider, clearing them from the grossest of the pulp; then sow them in beds of light earth, moderately thick, either all over the bed, or in drills, covering them about an inch deep; they will come up in the spring, when, if the season proves dry, water them occasionally, which will greatly forward the seedlings and strengthen their growth; and in autumn, winter, or spring following, the largest may be planted out in nursery rows, previously shortening their tap-roots, and planting them in lines two feet and a half asunder, to remain for grafting; and after having from one to two or three years' growth here, they will be fit for grafting, particularly for dwarfs, or even for full and half standards, if intended to form the stem from the graft, which is an eligible method for these trees; but if the stock is to form the stem, they will require three or four years' growth, to rise to a proper height, seven feet for full, and four or five for half standards.

The work of grafting all the sorts is the same as for other fruit trees, and should be performed in March, either by whip-grafting, cleft-grafting, &c. according to the size of the stock. See GRAFTING.

Having, however, provided proper grafts of the different sorts of Apples you intend to propagate, then let those stocks designed for dwarfs of all sorts be grafted within six inches of the ground; and standards may also be grafted low, and one shoot from the graft trained up for a stem, or may be grafted on tall

tall stocks, inserting the grafts at five or six feet high: or for low and half standards, may be grafted at two or three, to four or five feet; or lower for dwarf standards: but always graft the most abundant in full standards, for the principal general bearers: the grafts of all the sorts will shoot the same year; and by the autumn following, the trees having formed little heads, consisting of two, three, or four shoots, may then be transplanted finally into the garden and orchard, or may be retained a year or two, or longer, in the nursery, as occasion may require; observing, however, to train them for the purposes intended, such as dwarfs for espaliers, &c. &c. and uprights for standards, heading the dwarfs down in March following, within six inches of the graft, to force out more laterals below to form a fuller head, proceeding immediately near the bottom, so as to fill the espalier, &c. equally with branches, quite from within six or eight inches of the ground, regularly upward. But as to standards, those grafted low must consequently be trained with one shoot upright, at full length, for a stem, five or six feet high at least, for full standards, before it is topped; though if grafted on tall stocks of height sufficient for a stem, the shoots from the graft may either be headed to five or six eyes, if you would have them form a more spreading head, or may remain entire, and aspire more in height, and assume a more upright growth: in all the modes of training, be careful to keep the stems clear from all lateral shoots, displacing all such as soon as they appear, and encourage only a proper set of branches at top to form the head.

When these trees, however, have heads from one to two or three years old from the graft, they are of a proper age for final transplantation; though trees of four or five years old will also succeed very well, and even trees of six or eight years' growth may also be safely transplanted if required; but younger trees generally grow better and make more progress in the end.

The public nursery-gardens are generally well furnished with all the varieties of these trees for sale, either quite young from the graft, or trained trees of several years' growth, at very moderate prices.

In the choice of the different kinds for planting, should be careful to have a collection of the principal varieties, both in espaliers and standards, in quantity in proportion to the extent of ground in the garden, orchard, &c. as the trees of the best sorts are as easily raised and cultivated as the most indifferent; allotting generally a smaller portion of the summer

kinds, such as ripen in August, to about the middle of September, for immediate use off the trees, as they will not keep long; a larger supply of the autumn sorts, and most of all of the principal winter keeping Apples: observing, in the summer kinds, it is advisable to allot a principal supply of the common Codlin in small standards, as being generally both a great bearer, and the fruit the most useful of the summer apples for culinary purposes, from its young green growth in June or July, till its full maturity in August and September, when it becomes also a good eating apple: and as the tree is a moderate grower, it admits of being planted in small standards closer or more abundant in a small extent of ground than most of the principal Apple kinds.

The season for planting all the sorts of Apples is any time in mild weather, from the end of October till March; but if planted in autumn, or early in winter, they will fix themselves more firmly before attacked by the drought of the following summer.

They will succeed in any common soil of a garden and orchard, and in any free situation, except in low very moist land, in which they are apt to canker, and soon go off: in a pliable mellow loam they are generally very successful: be, however, in no great anxiety about the soil; any good or common middling soil of a garden, orchard, or field, not too wet, will do very well, being properly prepared, by good trenching, where the ranges of trees are to stand.

First of planting them in Espaliers.

Espalier Apple-trees should be ranged at not less than eighteen or twenty feet distance; but if twenty feet, it will be more eligible, especially for trees grafted on crab or Apple-stocks, which being free shooters, their branches will readily fill that space. However, as to trees grafted on codlin and paradise-stocks, fifteen or eighteen feet may be a sufficient distance; though the latter, in particular, is sometimes planted only twelve or fifteen feet asunder, as being a very moderate shooter: it is, however, advisable to allow every sort full room enough, according to their growth, to have proper space to extend their branches always at full length; observing, as the trees having been headed down in the nursery, and thereby produced laterals forming tolerable heads of several regular branches, they should now be planted with all their said heads entire, only retrenching any very irregular growth, that do not range consistent with the intended form, and prune any broken roots; then having opened a capacious hole for each tree at the above distances, proceed

to plant them in the usual manner as explained in the article *Planting*, being careful to place them with their branches ranging the way of the espalier: then, or at least, as soon as the earth of the holes and roots together are properly settled, let all the branches be trained in horizontally to the right and left, an equal number on each side, all at full length, five or six inches asunder; or if the tree is young, having only two or three shoots, these should be pruned down half way in the spring, to obtain a further supply of laterals; and according as they shoot in summer, still continue them along entire; at the same time train in a farther supply of new shoots, to increase the number of horizontals or bearers; and thus continue increasing their number, every year, till the espalier is regularly filled from the bottom to top; preserving all the branches at full length, as far as the allotted space will admit, for the reasons before explained, both here and under the article Pear; for these and the Pear-tree require almost exactly the same management.

With respect to their general culture, in espalier trees, planted and trained as above; observing, that as the same branches or bearers continue fruitful many years, they must be continued accordingly, as long as they remain of proper growth; and observing in this order of training, they must constantly have a summer and a winter pruning annually: in the summer-pruning cut out all the superfluous and ill-placed shoots of the year, and train regular ones towards the lower parts in vacant spaces, if any; at least, retain a supply of some best, well-placed shoots in different parts to remain till winter, some of which may be then wanted to fill some unforeseen vacancy; clearing out all others at this time (summer-pruning) as close as possible. And in winter-pruning examine the branches in general, if any worn-out or decayed parts appear, now is the time to retrench them, retaining young in their place; and if any vacancy occur, retain some contiguous young shoot to fill it: and as observed of the pears, &c. leave generally a terminal shoot, less or more, to each main branch: all others of the young shoots of last summer, not now wanted, cut clean out, close to the branches, still continuing all the branches, and any occasional supply of shoots, at full length, as far as their limited bounds will allow; then train the whole regularly, tying or nailing them in as straight and close to the railing as possible, four, five, or six inches asunder.

Likewise in wall-trees, any of the principal choice varieties of eating apples may be

trained, both to forward and improve the growth, beauty, and flavour of the fruit; such as gennetings—margaret apple—golden-pippins—golden-reinets—pear-mains, &c. or any other approved eating kinds, a tree or two of a sort, where there is plenty of walling to spare; and in which they may be planted and trained as directed for the espalier apples; and they will bear a plentiful production of good fruit accordingly for earlier eating; especially if some are against a south or south-west or east wall.

As the Apple and Pear-tree are nearly of the same temperature, manner of growth, and mode of bearing, they require the same culture; and having treated more fully on the Pears in respect to pruning in walls and espaliers, which for the general part may be applied to Apples, we refer to that article for particulars. See *PYRUS Communis*, PRUNING, and ESPALIERS.

In the article Pear-tree, we gave some hints of another method of training in espaliers or for walls, which may also be applied to Apples if any one incline to put it in practice for variety.

Planting them in Standards.

Standard Apples may be planted both in the garden and orchard: in the garden, however, they should be arranged but thinly, to admit of undercrops growing freely without interruption by the shade of their spreading branches.

Observe to plant principally full standards for the general supply, and half and dwarf standards chiefly for variety, or for small gardens.

The standards having been trained in the nursery with tolerable good heads, they should now be planted with all their heads entire: if any are intended for the kitchen-garden, plant them at least thirty feet distance; and for a full plantation to form an orchard, allow thirty feet distance every way. Open for each tree a wide hole, trim any long straggling and broken roots, but leave all the others entire, and plant them with the usual care, as directed in the article *Planting*; and as soon as planted, let every one be well staked to support them firmly upright, and prevent their being disturbed in rooting by tempestuous winds. See ORCHARD and PLANTING, &c.

Smaller growing standards, such as codlins, or other low standards grafted upon codlin stocks, and dwarfs upon these or paradise stocks, may, if required, be planted only at fifteen or twenty feet distance in the rows, and not less than twenty or twenty-five feet between the lines of trees; though, if there is room

room to allow a greater distance both ways, it will be the greater advantage, especially in planting in kitchen gardens, in which it would be proper to allow double that distance between the rows of trees, of the larger growths of these kinds.

The standards being thus planted with their heads entire, let them also in future advance with all their branches at full length, and, for the general part, take their own natural growth; and they will soon form numerous natural spurs in every part for bearing.

With respect to pruning these standards, very little is required, and that probably not once in several years, which is only the retrenching any very irregular cross-placed bough, or reduce to order any very long rambler; or when the head is become greatly crowded and confused, to thin out some of the most irregular growth, likewise all strong shoots growing upright in the middle of the head, all dead wood, and suckers from the stem and root.

As to half and dwarf standards of these trees, they may be dispersed in different parts of a garden to cause variety, managing them as the full standards; they will bear plentifully.

Dwarf standards on the dwarf paradise stock, being very moderate shooters, may be planted in a little compass; and they are sometimes planted in pots for curiosity, to place on a table, amidst a dessert, with the fruit growing. See DWARF TREES.

Gathering the fruit.

Apples arrive to full growth in different sorts successively, one after another, from July until the end of October; the summer kinds continue but a short time, but the autumn and winter-apples will keep from two or three to six or eight months, in different varieties.

The summer Apples ripen, some in July, but principally in August and September, and are generally fit for use immediately from the tree, both for eating and culinary uses, though some of the sorts are fit for kitchen purposes by that time they are half grown, or before, particularly the common Codlin, which boils and bakes in good perfection when quite young, and until full maturity; however, the tokens of perfection, or full growth, of the different sorts of summer Apples, is by their assuming a lively colour, emitting a fragrant odour, frequently falling from the tree, and by quitting their hold easily on being handled. They should then be gathered, and laid in some dry apartment for use; they will not keep long, nor indeed is it required, for they will be succeeded

by much better in the autumn and winter kinds.

Autumn Apples arrive to maturity in different sorts, from about the middle of September till the beginning and middle of October: some being fit for use immediately from the tree, others require to lie a few weeks to mellow, especially for eating: their full growth on the tree is known in some by their changing of a more lively colour, sometimes imparting an agreeable smell, frequent dropping, and on being handled, by a gentle twist or turn upward, they readily quit the tree; at which tokens of maturity, as they occur in the different sorts, they should be gathered in dry weather, and carried into the fruitery, where, with proper preservation, hereafter noticed, they will keep a long time, succeeding one another for use two or three months, or longer, in the later kinds.

Winter Apples attain full growth towards the middle to the latter end of October; it is, however, proper to let them hang on the trees till towards the end of that month, or some of the latest kinds even till November, if the season continues mild: but be careful to take them down before attacked by much frost; gathering them in dry weather, and carry them directly into the fruitery or any dry apartment, and there prepared for keeping as hereafter directed, whereby some may be kept sound and good for use till next June or July.

In gathering all the sorts of Apples for keeping, always chuse dry weather, and when the trees and fruit are also perfectly dry; observe likewise in gathering Apples for the table, and all kind of Apples designed for keeping any considerable time, they should be pulled one and one by hand. Where, indeed, large quantities are designed for cider, or any other immediate use, they may be shaken down. However, all the fine eating and culinary Apples for keeping should be carefully gathered by hand, by a gentle twist or turn upward, so as to detach them readily without breaking the fruit-buds; and as they are gathered, carry them into the fruitery, &c. where, previous to putting them up for good, it will be proper to lay the choicer varieties of autumn and winter kinds in large heaps, to sweat and discharge the watery juices by perspiration, which both prepares them for keeping and improves their flavour; then, after having sweated a week or fortnight, wipe them all perfectly dry, and lay them up where they are to remain. A quantity may be deposited on the shelves and floor of the fruitery, and closely covered down a foot thick with

straw to exclude the air. And it is proper to pack a quantity of the finest winter kinds in large baskets or hampers, thickly lined round within with straw, covering the fruit down also closely with the same material, to exclude the external air as much as possible, whereby they will keep much longer in perfection; and if some are packed up in large earthen jars, and closely plugged down, they will keep longer still; for it is by these methods that the fruit is kept so fine and fair even until the return of Apples next year; observing, the drier and closer the room in which the fruit is deposited in all the above methods, the better they will keep; being careful to examine the fruit occasionally, in order to pick out all that discover any tendency to corruption; those in the open fruiteries are easily looked over, but those in the baskets and jars not so readily, nor indeed will they need it so much; however, it is proper, after some considerable time, to examine them occasionally.

In London, great quantities of the finest winter Apples are deposited in the proper season in the close warehouses in Thames-street, and other parts contiguous to the river, for sale in winter and spring, many also packed closely in hampers and baskets, &c. as aforesaid, and placed in very close apartments where but little air can come; where they are kept perfectly sound and beautiful all winter, even until May, June, and July, selling them out to the retailers, and we may see them in the fruiterers' shops, and in stalls in the streets, exceeding fine in May and June; but, at this time, after being exposed to the open air a day or two, they shrink, lose colour, and soon decay.

It should therefore be remarked, that close packing these fruit, and keeping them in as close apartments as possible, keeping the doors and windows always closely shut to exclude the external air, damps and cold, is a certain method of preserving them long in full perfection; for the more they are exposed to the air, the sooner they will decay; keep them therefore always as close as possible.

Quince kinds.

Pyrus Cydonia, Quince-tree.

The Quince-tree (*Cydonia*) was long ranged as a distinct genus, but is now a species of *Pyrus*. It is of the tree kind, of moderate growth, and deciduous; producing large, round, golden-yellow fruit, of a high fragrance; but generally too austere and harsh to eat raw, being employed principally for culinary purposes.

Class, order, and characters, the same as the Pear, &c. (*Pyrus Communis*.)

There is but one species, viz.

Pyrus Cydonia.

(*Cydonia*)—or *Quince-tree*.] Grows ten or twelve feet high, having slender branches and shoots, forming a low moderately spreading head, garnished with large, oval, entire leaves, very hoary underneath, and large, solitary, whitish-red flowers all along the sides of the branches, succeeded by large, round and pyramidal, golden-yellow fruit.

The botanic description is,—*Pyrus* with entire leaves and solitary flowers.

Varieties.] There are several varieties of this fruit, but the following are the most valuable sorts.

Apple-Quince.—A large, short, roundish, apple-shaped, golden-yellow Quince.

Pear-Quince.—A large, pyramidal, or pear-shaped, deep-yellow Quince.

Portugal Broad-leaved Quince.—The tree is of larger growth, and with broader leaves; pear-shaped fruit, having a tenderish pulp, which bakes and boils to a fine purple colour.

Eatable-Quince.—A middle-sized downy Quince, having a tender pulp, of a milder eatable flavour than the others; more especially when prepared by baking, stewing, &c. to serve up whole.

Most of these fruit, though remarkably beautiful to the eye, are too harsh and unpalatable to eat raw; their chief uses being for baking and stewing, to make marmalade, and to mix in apple pies, tarts, &c. to improve the flavour.

The trees, however, merit culture in every curious collection, some for the fruit, and others for ornament; but considered as fruit-trees, a few are sufficient to produce fruit enough to supply a large family, and may be trained both in standards and espaliers to effect the greater diversity; and as ornamental trees, they are eligible furniture for the shrubbery, &c. their numerous large flowers and golden fruit will effect a delightful variety; the flowers in spring, and the fruit in autumn. Young Quince-trees are also in repute for stocks, on which to graft and bud Pears, to dwarf them for walls and espaliers. See *Pyrus Communis* and *Stocks*.

They are very hardy, and will grow anywhere, but delight most in somewhat moist situations, and are therefore often planted by the sides of ponds or ditches of water.

Method of Propagation, and general Culture.

The trees may be raised from the kernels of the fruit sown in autumn; but there is no depending

depending on having the same sort of good fruit from seedlings, nor will they soon become bearers.

But the several varieties may be continued always the same by the propagation by cuttings and layers; also by suckers from such trees as grow upon their own roots, and may likewise be propagated by grafting and budding upon their own or Pear-stocks raised from the kernels.

The propagation by cuttings, layers, and suckers, may be performed in autumn, winter, or spring. Chuse young wood for the cuttings and layers, which plant and lay in the common method, and they will be rooted by next autumn, then transplanted into nursery rows two feet asunder; plant the suckers also at the same distance, and here train the whole for the purposes intended: if for standards, run them up with a stem, to any desired height, from three to five or six feet, then encourage them to branch out at top, to

form a head; and those designed as dwarfs must be headed near the ground, and trained accordingly for espaliers, or dwarf standards, as may be required, as directed under those articles, and by grafting or budding is effected on Quince or Pear-stocks, and trained as above.

When they have formed tolerable heads, plant them out finally:

Standard Quinces, designed as fruit-trees, may be stationed in the garden or orchard, and some by the sides of any water, pond, watery-ditch, &c. as they delight in moisture, suffering the whole to take their own natural growth.

And as espaliers, they may be arranged in assemblage with other moderate-growing trees, such as Apples and Pears on Paradise and Quince-stocks, Cherries, &c. and train them as directed for Apples and Pears in espaliers.

In shrubberies they may be planted either as full or low standards, and permit them to take their own way of growth.

Q.

Q U E

Q U E

Q U E R C U S, Oak-tree.

This famous genus comprises a noble collection of most eminent forest and ornamental trees, both deciduous and evergreen kinds, obtaining in stature from twenty to near a hundred feet, in different species, garnished with oblong and mostly sinuated leaves, and monœcious apetalous flowers, of little appearance, succeeded by oval nuts, called acorns.

Class and order, *Monœcia Polyandria*.

Characters.] CALYX, male and female, flowers separate on the same plant; the males disposed in loose amentums, each floret having a monophyllous four or five-parted calyx; and the females sitting close to the buds, have monophyllous, hemispherical, coriaceous, rough, entire cups. COROLLA, no petals. STAMINA, many short filaments in the males, having didymous antheræ. PISTILLUM, a small oval germen in the females, quinqued styles, and simple permanent stigmas. PERICARPUM, none; the seed, an oval nut or acorn, with a leathery unilocular shell, is fixed by its base into the calyx.

There are about fourteen species in our

nurseries and plantations, nine deciduous, and five evergreen kinds; but the *Common English Oak* is the glory of the collection, for its superior growth, and great worth and value, as a timber-tree, for bulk, strength, and duration. Several of the other species have also their share of merit, some as forest-trees, others to diversify ornamental plantations.

Deciduous Kinds.

Under this head, Deciduous Oaks, is comprised the common Oak of our woods and forests, and several species of North America, and some foreign parts of Europe, as France, Spain, Portugal, and Italy, as expressed in their titles; all of which are of the tree kind, deciduous, and of hardy growth.

I. QUERCUS Robur.

Common English Oak.] Grows from about sixty or seventy to a hundred feet high, with an exceedingly large trunk, and monstrous spreading head, oblong leaves, broadest towards the top, the edges acutely sinuated, having the angles obtuse.

Varieties.] Striped-leaved Oak, having the leaves finely striped with white.—Dwarf Oak.

This species grows in great abundance all over England in woods, forests, and hedge-rows; is naturally of an amazing large growth, there being accounts of some above an hundred feet stature, with wonderful large trunks and spreading heads, and is supposed will continue its growth many centuries.

2. *QUERCUS Prinus.*

Chestnut-leaved American Oak.] Grows fifty or sixty feet high; having large, oblong-oval, smooth leaves, pointed both ways, the edges sinuated-ferrated, with the sinuses uniformly round.

Varieties.] With oval leaves—with oblong leaves.

3. *QUERCUS Phellos.*

Willow-leaved American Oak.] Grows forty or fifty feet high, having long, narrow, smooth, entire leaves like those of willow.

Varieties.] Dwarf Willow-leaved Oak, with short leaves—variable leaved.

4. *QUERCUS alba.*

White Virginian Oak.] Grows thirty or forty feet high, having a whitish bark, long, obliquely-pinnatifid, light-green leaves, the sinuses and angles obtuse.

5. *QUERCUS nigra.*

Black Virginian Oak.] Grows thirty or forty feet high, having a dark-coloured bark, large, wedge-shaped, slightly-trilobated leaves.

6. *QUERCUS rubra.*

Red Virginian Oak.] Grows about sixty feet high, having a dark-greyish bark, long obtusely-sinuated leaves, with the sinuses terminated by bristly points, and have sometimes red spotted veins, but generally dying in autumn to a reddish colour, remaining on the trees late in the season.

Varieties.] With broad leaves—with scarlet leaves.

7. *QUERCUS Esulus.*

Cut-leaved Italian Oak.] Grows about thirty feet high, having a purplish bark, oblong, deeply-sinuated-pinnatifid, smooth leaves, and long, slender, close-fitting acorns in very large cups.

8. *QUERCUS Ægilops.*

Large prickly-cupped Spanish Oak.] Grows seventy or eighty feet high, or more, with a very large trunk, and widely spreading head, having a whitish bark, large, oblong-oval, deeply-ferrated, smooth leaves, the ferratures repand and bowed backward, and large acorns placed in singularly large prickly cups.

This is a noble species, almost equal in growth to our common English Oak.

9. *QUERCUS Cerris.*

Smaller prickly-cupped, or Turkey Oak.] Grows thirty or forty feet high, oblong, lyrc-

shaped, pinnatifid-transversely-jagged leaves, downy underneath, and smaller acorns, placed in prickly cups.

Varieties.] With rough leaves—with narrow leaves.

All the above species of deciduous Oak may be cultivated both as forest-trees and in diversifying large ornamental plantations; as timber or forest-trees, however, is their principal merit, but the English Oak claims the preference for general use, as the most valuable for timber; and should raise a greater quantity of it accordingly.

They are all easily raised from seed, i. e. the acorns, sown in the autumn an inch or two deep. See their *Propagation*.

Evergreen kinds.

Of evergreen Oaks there are five species—Common evergreen Oak—Holly-leaved Oak—Cork-tree—Scarlet Oak—and Moluccan or Live Oak; some as timber-trees, others for ornament, all of which retain their leaves the year round; are originally of foreign growth, mostly from the southern parts of Europe, and one from America, but have been long in the English gardens as ornamental trees, and some are arrived to a considerable growth, they being all very hardy, and prosper in any open ground.

10. *QUERCUS Ilex.*

Common Evergreen Oak.] Grows forty or fifty feet high, having a smooth bark, oval and oblong, undivided, denticulate-ferrated, petiolated leaves, downy and whitish underneath.

Varieties.] Broad-leaved.—Narrow-leaved, and with sometimes both sorts, and other different shaped leaves on the same tree; also sometimes with sawed and prickly leaves.

11. *QUERCUS granuntia.*

Montpelier Holly-leaved evergreen Oak.] Grows forty or fifty feet high; oblong-oval, close-fitting, sinuated, spinous leaves, downy underneath, bearing a resemblance to the leaves of holly.

12. *QUERCUS Suber.*

(Suber)—or Cork-tree.] Grows thirty or forty feet high, having a thick, rough, fungous, cleft bark, oblong-oval, undivided, serrated leaves, downy underneath.

This species furnishes that useful material Cork; it being the bark of the tree, which becoming of a thick fungous nature, under which, at the same time, is formed a new bark; and the old being detached for use, the tree still lives, and the succeeding young bark becomes also of the same thick spongy nature in six or seven years, fit for barking, having likewise another fresh bark forming under it, becoming

becoming Cork, like the others, in the like period of time; and in this manner these trees wonderfully furnish the Cork for our use, and of which are made the corks for bottles, bungs for barrels, and numerous other useful articles.

The tree grows in great plenty in Spain and Portugal, and from which countries we receive the Cork.

13. *QUERCUS coccifera*.

Scarlet-bearing, or Kermes Oak.] Grows fourteen or fifteen feet high, branching from the bottom upward, in a bushy growth; large, oval, undivided, indented-spinous leaves; and producing small glandular excrescencies, called kermes or scarlet grain, used by dyers.

The small scarlet glands, found on this tree, are produced by the effect of certain insects depositing their eggs betwixt the bark of the branches and leaves, causes an extravasation of the sap, and forms the excrescence or substance in question, which being dried, is the kermes or scarlet pastel.

14. *QUERCUS molucca*.

Molucca Oak, commonly called American Live Oak.] Grows about forty feet high, having oval-spear-shaped, smooth, entire leaves, and small, oblong, eatable acorns.

All the above fourteen species of *Quercus* produce flowers annually in the spring, about April and May, of a yellowish colour, but make no ornamental appearance, and are males and females separate in the same tree; the males being in loose amentums, and the females sitting close to the buds in thick leathery hemispherical calyxes, succeeded by the fruit or acorns, which are oval nuts fixed by their base into rough permanent cups, mostly sitting quite close, and some on short foot-stalks, ripening in autumn, which in the common English Oak is in great abundance, and often in tolerable plenty on some of the other sorts; those of all the kinds serve for propagating their respective species; they are also excellent food for swine and deer, the common Oak in particular from its great abundance.

Oak-trees, of all the above sorts, may be employed in gardening, to diversify large ornamental plantations in out-grounds, and in forming clumps in spacious lawns, parks, and other extensive opens; the evergreen kinds in particular have great merit for all ornamental purposes in pleasure-ground plantations.

But all the larger growing kinds, both deciduous and evergreens, demand esteem also as first-rate forest-trees for their timber: the *English Oak*, however, claims precedence as a timber-tree, for its prodigious height and bulk; and superior worth of its wood, and is

supposed will stand one thousand years before it totally decays, so is singularly valuable for all strong and durable purposes, such as ship-building, some parts of house-building, park-paling, posts, railing, and innumerable other uses. But all the other large-growing Oaks may likewise be introduced in forest tree plantations; for Oaks in general prove valuable timber, and of all others the most durable; and besides their value as timber-trees, their annual crops of acorns prove most excellent food for fattening hogs and deer; and when the trees are felled for use, their bark, being stripped off, proves a most valuable material to the tanners for tanning leather; and after having served that purpose, is of great use in gardening for making bark hot-beds, commonly called bark-beds, being the most eligible kind of hot-beds for the culture of the pineapple, and all other tender exotics of the hot-house temperature. Oaks, therefore, being of such superior value, every possessor of considerable estates ought to be particularly assiduous in raising woods of them, which is effected by sowing the acorns either in a nursery, and the plants transplanted where they are to remain, or sown at once in the places where they are always to stand. See their *Propagation, PLANTATIONS, and FOREST TREES*.

All the sorts will prosper in any middling soil and open situation, though in a loamy soil they are generally more remarkably prosperous; however, there are but few soils in which Oaks will not grow; they will even thrive tolerably in gravelly, sandy, and clayey land, as may be observed in many parts of this country of the common Oak.

Their Propagation and general Culture.

Oaks in general are raised from the acorns, which, of the common Oak, are produced abundantly all over England, and should be gathered in autumn when quite ripe, just as they drop from the trees; but the acorns of most of the foreign oaks are generally procured from abroad; and those of all the species are sold by the seedsmen.

Observe to sow all the sorts as soon after they are obtained as possible, because they are apt to sprout if they remain long out of the ground. Prepare for their reception a spot of light ground in the nursery, dividing it into four-feet wide beds, and in which sow the acorns, either in drills two inches deep, in five or six rows, lengthwise the bed, or rake the mould off the bed, the depth of two inches, into the alleys, then sow the acorns all over the surface, about two or three inches apart, press them down with the spade, and spread the

the earth evenly over them two inches thick.

They will come up in the spring; give them occasional waterings and weeding, and when the plants are one or two years old, it is proper to plant them out in nursery-rows: this may be done in autumn, winter, and early in the spring, taking them carefully up out of the seed-bed: shorten their perpendicular tap-root, and trim off any lateral shoots from the stem, leaving their top perfectly entire; then plant them in lines two feet and a half asunder, and fifteen or eighteen inches in the rows, where let them stand, with the usual nursery care, till of a proper size for final transplantation, either as forest-trees, or some for ornament, training them up as full standards, with clean straight stems, and with their tops still entire.

Remark, the propagation of the striped-leaved varieties of the common Oak, and any particular variety of the other species, must be effected by grafting, as they will not continue the same from seed; so the grafting may be performed upon any kind of Oakling-stocks raised from the acorns, and train them for standards like the others.

Transplanting them finally.

All the sorts of deciduous Oaks may be transplanted any time in open settled weather, from the fall of the leaf in November, till February or March, and the evergreen kinds, in October, November, and in the spring; or in a mild open season, may be occasionally planted in any of the winter months.

When the trees of all the sorts are from about three or four to six feet stature, they should be planted out for good, though, considered as forest or timber-trees in particular, it is more eligible to plant them out finally whilst they are quite young, not advanced above from two to three or four feet in height; or if planted immediately from the seed-bed, where they are finally to remain, it may prove a greater advantage, as the quite young Oaks root more freely than older trees, and take a freer growth.

However, in this final transplantation, observe to plant those designed as forest or timber-trees, in large open tracts of grounds to form woods, placing them in rows only four or five to ten feet asunder, and two or three to five or six feet in the rows, to allow for a gradual thinning. See PLANTATIONS and PLANTING.

Sometimes, however, large plantations of these trees, for woods, are raised by sowing

the acorns at once in the places where they are to remain, as formerly noticed; it being generally observable in many instances, that the trees, raised at once from the acorn, receiving no check by removal, much outstrip the transplanted trees in growth. The method is this; the ground being prepared by good ploughing and harrowing, then, in autumn, having procured a proper quantity of acorns, draw drills across the ground four feet asunder, and two inches deep, drop the acorns therein six or eight inches asunder, allowing for some failing and thinning hereafter, covering them in evenly with the earth the depth of the drills; or instead of drilling them in, they may be planted with a dibble, the same depth and distance.

As to the general management of these trees in woods or timber plantations, it is the same as directed for forest trees in general, under the article PLANTATION, which see.

In planting any or all the species of Oak, for ornament or variety in large pleasure-grounds, some may be disposed in assemblage in any continued plantation, some in clumps, and others as single objects.

QUINCUNX Planting.

The Quincunx order of planting signifies trees planted by fives, four of them forming a square, and the fifth placed in the middle,

thus * * and may be repeated over and * *

over in one continued plantation, with as many trees in several ranges as thought proper, and was formerly a fashionable mode of planting groves and other regular plantations in the following arrangement:

```

* * * * *
* * * * *
* * * * *

```

Somewhat of this mode of arrangement should generally be observed in the disposition of shrubbery plants, &c. though not in a regular Quincunx, but something nearly in this order, which both gives the shrubs a greater scope of growth, and they show themselves to greater advantage.

This mode of planting is also proper in the kitchen-garden, in transplanting many kind of esculent plants, such as lettuce, endive, strawberries, and even all the cabbage kinds, and many other plants; which gives them a greater scope to grow than if planted exactly square at the same distance.

R.

R A C

RACEMUS, a Cluster, or mode of cluster-flowering, being a long close Cluster of flowers or fruit, consisting of one common peduncle or foot-stalk, branching and supporting many short lateral ones all along its sides, these immediately sustaining the flowers and fruit: examples of a *Racemus* are bunches of grapes, and currants. See *VITIS* and *RIBES*.

RACER, or sward-cutter, a cutting implement used in racing out or cutting through the surface of grass sward, dividing it into proper widths, lengths, and thickness, for turf intended to be cut up for laying in gardens, and is always necessarily used preparatory to the work of flaying or cutting up the turf with the turving-iron.

It is a simple but useful tool for the above purpose; consisting of a strong wooden handle about four feet long, having the point-end of an old scythe for a cutter, fixed at the lower end, with the point and edge downward, to cut into the sward; the handle should be about an inch and half thick, growing gradually thicker towards the lower end, and somewhat bending or sloping at the bottom to rest on the ground, having at the bottom part a slit, to receive the cutter, which should be five or six inches long, placing it with the point and edge downward, as aforesaid, projecting an inch and a half out at the back of the bottom of the handle in a slanting manner, with the point inwards, fixing it firmly in that position, so as when pushed before you it may expeditiously cut the sward as you race it along.

Having this instrument, and proceeding to mark out on the sward the width of turf intended to be cut, which should be generally a foot wide and a yard long, and about an inch or inch and a half deep, straining a line tight, first lengthways, then strike the racer into the sward close to the line, run it along, it will expeditiously cut its way, and divide the sward to a proper depth; directly place the line a foot farther, and race it out as before, and so on to as many widths as may be wanted; and then with the line placed cross ways, race out the sward accordingly in yard lengths: being thus raced out, the turf cutter with his turving-iron proceeds to cut them up, and he

will flay them off at a great pace in exact widths and thickness. See *TURF*, &c.

RADIATUS flos, a radiated flower.—Such compound flowers as are furnished with a radius or spreading circumference. See *RADIUS*.

RADIUS, the Radius, or circumference, or outer spreading part of compound flowers, consisting of many flat florets set round the edge of the disk or middle, and spread out all around, resembling the figure of a radiant star, exemplified in *aster* or start-wort, marigold, sun-flower, and many others of the compound tribe, and of which there are both single and double flowers; the singles having only one series of florets in the radius, but the doubles have from two or three to many series, continued sometimes to the very centre. See *COMPOSITUS flos*.

RADICULA (from *Radix*) Radicle or Little Root, or small fibrous part issuing first either immediately from the seed, or that which terminates the stock or main root, penetrates into the soil, and draws nourishment for the production and support of the plant, and is the principal and essential part of every root of all vegetables.

RADIX, the Root, or lowermost part of a vegetable, situated within the ground, destined to draw nourishment from the soil for the production and support of all the other parts of the plant.

A Root consists of two parts, viz. 1. The stock or main Root (*Caudex*) that strikes downward into the earth, and puts forth radicles or fibres. 2. The radicle (*Radícula*) small thread-like roots or fibrous parts, terminating the stock or main Root, or proceeding from any part thereof, and is the principal or essential part of every Root, as it penetrates far into the soil, and attracts nourishment to the main stock, thence communicated to the stem, branches, and other parts of the vegetable.

From the various structures and directions of the stock or main Root, the botanists distinguish them by the following terms.

Perpendicular Root.] Descends in a straight line downwards. *Radix perpendicularis*.

Horizontal

Horizontal Root.] Runs in a horizontal or transverse direction along under the surface of the earth. *Radix horizontalis.*

Simple Root.] Such that is single and not subdivided.

Branched Root.] Divided into lateral branches, which also subdivide into ramifications. *Radix ramosa.*

Spindle-shaped, or tapering Root.] Is oblong, thick upwards, and tapers gradually to the lower extremity, such as common radish, carrot, parsnep, &c. *Radix fusiformis.*

Bulbous Root.] Roundish and oval swelling bulb, composed some of many succulent imbricated scales, others of many involving coats, and consist of three sorts: 1. Scaly bulbs, (*Bulbus Squamosus*) formed of many scales lying over one another, as in the lily. 2. Tunicated or coated bulbs (*Bulbus tunicatus*) formed of several tunics or coats closely involving one another, as in the onion, &c. 3. Solid bulbs (*Bulbus solidus*) as in tulip, *Radix Bulbosa.*

Tuberous Root.] A thick fleshy knob, formed of a solid lump, some roundish, others irregularly knobbed, and some oblong, composed either of one single knob, or several collected into bundles; examples of the tuberous-rooted tribe are the potatoe, Jerusalem artichoke, anemone, pæony, orchis, filipendula, and hemerocallis; the turnep, carrot, and parsnep, may also be considered of the same kind, and all other Roots that are formed of a thick, fleshy, solid substance. *Radix tuberosa.*

Fibrous Root.] Composed wholly of a number of radicles, or slender fibrous parts, and may be said to be the most common sort of Root, to numerous herbaceous plants in particular, and consists of perpendicular Roots, horizontal Roots, simple Roots, branched Roots; some being very thin and fine like threads, others somewhat fleshy, &c. *Radix fibrosa.*

Creeping Root.] Runs along just under the surface of the earth to a considerable length, emitting at certain distances small fibres below and shoots at top. *Radix repens.*

Globular Root.] Roundish, fleshy, solid Root of the tuberous kind, such as earth-nut, bulbous fumatory, &c. *Radix globosa.*

A grumous or bundled Root.] Composed of many small, oblong, fleshy, kernelly parts, or knobs, all connected at top, and terminated below in radicles or fibres, such as *Ranunculus*, &c. *Radix fasciculata.*

Granulous aggregate Root.] Consists of many small roundish knobs like grains of

corn, all clustered together, as in white saxifrage. *Radix granulosa.*

Pendulous clustered Root.] Composed of several fleshy, roundish knobs, or tubers, suspended, as it were, at the ends of fibres, as in filipendula, pæony, potatoe, Jerusalem artichoke, asphodelus, hemerocallis, &c. all of which are of the tuberous-rooted kind. *Radix pendula.*

Handed tuberous Root.] An oblong tuberous Root, dividing and spreading like an open hand, as in handed-orchis. *Radix tuberosa palmata.*

Testiculated Root.] Composed of two roundish tuberous knobs joined in a testiculated manner, as in some sorts of orchis. *Radix testiculata.*

Jointed Root.] Long, thickish, and jointed at certain distances. *Radix articulatus.*

Woody Root.] Becoming of a hard, tough, woody texture, such as the Roots of all trees, shrubs, and under-shrubby plants. *Radix lignosa.*

Tap Root.] Any main Root that runs straight downward in a perpendicular direction, like a carrot, parsnep, &c. and is often applicable to the tree and shrub kind, when the main Root runs directly downright; and in transplanting seedling-trees in the nursery, &c. it is occasionally recommended to shorten the Tap-Root, with a design both to prevent their penetrating too deep into the bad soil, and to force out horizontal or lateral roots, to extend horizontally nearer the surface into the good earth, where they may draw better nourishment. See PLANTING.

As to the duration of Roots, they are either annual, biennial, or perennial, viz.

Annual Roots.—Such that endure but one year at most, then totally perish; as of all those vegetables denominated annual plants. *Radix annua.*

Biennial Roots.—Continue but two years, then wholly decay. *Radix biennis.*

Perennial Roots.—Being of many years' duration, and in some plants both Root and stem subsist for many years, particularly all the tree and shrub kind: many herbaceous vegetables likewise enjoy the same privilege, though the greater part are only perennial in Root, renewing the stalks, &c. annually: however, all herbaceous plants having durable or perennial Roots, are from this circumstance denominated perennials. *Radix perennis.*

Roots, we observed for the general part, penetrate within the ground to seek nourishment from the soil; there are however some exceptions;

exceptions; the mistletoe plant attaching itself to the branches of trees, with its Root uppermost, which penetrates between the bark and wood, drawing moisture for its sustenance. Mosses and some of the fungi likewise attach their Roots to the bark of trees; lichens to stones and rocks; and some aquatics swim, both Root and top, on the surface of the water.

RADIX, PERENNIS FIBROSA, a perennial fibrous root; applicable to the tribe of fibrous-rooted Perennial plants, commonly called Perennials.

Under this description are comprehended a numerous tribe of valuable garden plants, both of the herbaceous and woody kinds, hardy and tender; but under this head shall only principally consider the hardy, Fibrous-Rooted herbaceous Perennials, perpetuated by their roots for a series of years, producing new stems every spring; comprising chiefly those of the ornamental flowery kinds, for the decoration of the different compartments of the pleasure garden, and flower borders, beds, &c. and arranged here, in this list, in the order similar to those of the other different tribes, already given under separate heads, according to their nature of growth, such as *Annual Plants*,—*Biennial Plants*,—*Bulbous Roots*, &c. and as those now under consideration are very numerous in different species and varieties, and being all fully described under their proper respective genera, shall only under this head give a general list of the proper generical names, botanic and English, of each genus, in which the different principal species and varieties of this tribe of Fibrous-Rooted herbaceous Perennials occur; such as are eligible for garden culture, in which some are also of a biennial-perennial nature, and some likewise of small, under-shrubby, herbaceous-like growth.

In the whole, the intention of this arrangement is, by exhibiting the different genera to which the various species belong, and arranged therein accordingly, to assist the memory occasionally, in recurring to the particular genera in the body of the work, in which the respective species, alluded to in this arrangement, are inserted, proceeding in the following order.

ACANTHUS, (*Acanthus*) or Bear's-Breech—several species.

ACHILLEA, Milfoil or Yarrow—many species.

ACONITE, Winter, (See *Helleborus*)—one species.

ACONITUM, Aconite, Wolf's-bane or Monk's-Hood—six or eight species.

ACORUS, Sweet Rush—one species.

ACTEA, Herb-Christopher—three or four species.

ADIANTUM, Maiden Hair—two species.

ADONIS, Adonis flower,—one perennial species.

ADOXA, Tuberous Moschatel, or Hollow-Root—one species.

AGRIMONIA, Agrimony—three or four species.

AGROSTEMMA, (Wild Champion) Rose Champion—several species and varieties.

AJUGA, Bugle—several species.

ALCEA, Holly-hock—two species, many varieties.

ALCHEMILLA, Lady's Mantle—three or four species.

ALETIS, Bastard or Guinea Aloe—several species.

ALTHÆA, Marsh-mallow—two or three species.

ALYSSUM, Madwort—several species.

ANCHUSA, Bugloss—three or four species.

ANEMONE, Anemone—several species, and many fine varieties.

ANGELICA—three or four species.

ANTHEMIS, Chamomile—several species.

ANTHERICUM, Spiderwort—three or four sorts.

ANTHYLLIS, (Kidney Vetch), Lady's Finger, &c.—two species.

ANTIRRHINUM, Snap-Dragon—different species.

APOCYNUM, Dog's-Bane—two or three species.

AQUILEGIA, Columbine—three species, and many varieties.

ARALIA, Berry-bearing Angelica—two species.

ARISTOLOCHIA, Birth-wort—three or four species.

ARNICA, Leopard's-bane—two species.

ARTEMISIA, Mugwort, &c.—two or three species.

ARUM, Wake Robin, &c.—three or four species.

ARUNDO, Reed—two species.

ASARUM, Asarabacca—three species.

ASCLEPIAS, Swallow-wort—seven or eight species.

ASCYRUM, St. Peter's-wort—two or three sorts.

ASPHODELUS, Asphodel, or King's-spear—two or three species.

ASTER, Star-wort—many species.

ASTRAGALUS, Liquorice Vetch, or Milk Vetch—three or four species.

ASTRANTIA, Black Master-wort—two species.

ATROPA, Deadly night shade—two species.

AURICULA, (see *Primula Auricula*)—numerous fine varieties.
 BELLIS, Daisy—one species, having many varieties.
 BETONICA, Betony—three different sorts.
 BORAGO, Borage—one species.
 BRYONIA, Bryony—one species.
 BUBON, Macedonian Parsly—one species.
 BUPHTHALMUM, Ox-Eye—two species.
 BUPLEURUM, Hare's-Ear—one species.
 BUTOMUS, Flowering Rush—one species.
 CACALIA, Foreign Colt's-foot — three species.
 CALTHA *palustris*, Marsh-Marigold—two varieties.
 CAMPANULA, Bell-flower—many species and varieties.
 CANNABIS, Hemp—one species.
 CARDAMINE, Lady's-Smock — two or three sorts.
 CATANANCHE, Candy Lion's-foot—one species.
 CENTAUREA, Centaury—many species.
 CERINTHE, Honey-wort—two species.
 CHEIRANTHUS, Wall-flower, Stock-gilliflower, &c.—two or three species, and many varieties.
 CHELONE, Chelone—four species.
 CHRYSANTHEMUM, Corn Marigold—several species.
 CHRYSOCOMA, Goldy Locks—two species.
 CHRYSOSPLENIUM, Golden Saxifrage—two species.
 CLEMATIS, Virgin's Bower—two species.
 COCHLEARIA, Scurvy-grass—two official species.
 COLUTEA, Bladder Sena—one species.
 CONVALLARIA, Lily of the valley, &c.—four or five species.
 CONVULVULUS, (*Convolvulus*), — Bind-weed—see the genus.
 CONYZA *candida*, White Flea-Bane.
 CORTUSA, Bear's-Ear Sanicle—two species.
 COTYLEDON *umbilicus*, Navel-wort—one species, several varieties.
 CRAMBE, Sea-Cabbage,—see Kitchen garden plants.
 CREPIS, Bastard Hawk-weed—two species.
 CRITHMUM, Samphire—one species.
 CYCLAMEN, (*Cyclamen*), Sow-Bread — four species, many varieties.
 CYNOGLOSSUM, Hound's Tongue — four species.
 CYPRIPIEDUM, Lady's Slipper—three or four species.
 DELPHINIUM, Larkspur—two species.
 DENTARIA, Tooth-wort—two or three species.
 DIANTHUS, Pink, Carnation, Sweet Wil-

liam, &c.—three or four species, comprising numerous varieties.
 DICTAMNUS *albus*, White Dittany.
 DIGITALIS, Fox-glove—three or four species.
 DODARTIA *orientalis*, Eastern Dodartia—one species.
 DODECATHEON *Meadia*, American Cow-slip—one species.
 DRACOCEPHALUM, Dragon's Head—three species.
 ECHINOPS, Globe Thistle—two species.
 EPILOBIUM, French Willow—five or six species.
 EPIMEDIUM, Barren-wort—one species.
 ERIGERON, Erigeron, or greater Flea-wort—three or four species.
 ERYNGIUM, Eryngo, or Sea Holly—several species.
 ERYSIMUM, Hedge Mustard—one species, some varieties.
 ERYTHRONIUM, Dog's Tooth—one species, several varieties.
 EUPATORIUM, Hemp Agrimony — several species.
 FERULA, Fennel Giant—several species.
 FRAGARIA, Strawberry—one principal species, many varieties.
 FUMARIA, Fumatory—several species.
 GENTIANA, Gentian—several species.
 GERANIUM, Crane's Bill—seven or eight species.
 GEUM, Herb-bennet—three or four species.
 GLOBULARIA, Globular, or Blue Daisy—one species.
 GLYCYRRHIZA, Liquorice—two species.
 GNAPHALIUM, Cud-weed, &c.—three species.
 HEDYSARUM, French Honeysuckle—several species.
 HELIANTHUS, Sun-flower—several perennial sorts.
 HELLEBORUS, Hellebore, or Bear's-foot ; comprising the Christmas-rose and Winter Aconite—four species.
 HELONIAS, Helonias—two species.
 HEMEROCALLIS, Day Lily—two species.
 HEPATICA, (See *Anemone Hepatica*).
 HESPERIS, Rocket, &c.—three species.
 HIERACIUM, Hawk-weed—one species.
 HUMULUS, Hop Plant—one species.
 HYDRASTIS, Yellow-root—one species.
 HYSSOPUS, Hyssop (under-shrubby)—one species.
 IBERIS, Candy-tuft—one species.
 IRIS, Flower-de-luce, &c.—many species.
 Ixia, (*Ixia*) (Bulbous and tuberous-rooted)—two species.
 LATHYRUS

LATHYRUS, (Chickling Vetch) Everlasting Pea—one perennial species.
 LAVATERA, (*Lavatera*) Cretan, and Tree Mallow—two or three species, perennial.
 LIGUSTICUM, Lovage—two species.
 LINUM, Flax—one perennial.
 LOBELIA, Cardinal-flower—two species.
 LUNARIA, Moon-wort—one species, perennial.
 LUPINUS, Lupine—one perennial.
 LYCHNIS, (*Lychnis*) or Campion—three or four species.
 LYSIMACHIA, Loose-strife—five species.
 LYTHRUM, Willow Herb—one species, some varieties.
 MALVA, Mallow—two species, sometimes cultivated for variety, &c.
 MATRICARIA, Fever-few—one species, several varieties.
 MEDICAGO, Medic—one hardy perennial.
 MELISSA, Balm—three species.
 MENTHA, Mint, Penny-royal — several species.
 MIMULUS, Monkey-flower, &c.—one species.
 MOMORDICA, Male Balsam Apple—one species.
 MONARDA, Oswego Tea—three species.
 MORINA, (*Morina*)—one species.
 NAPÆA, Virginia Mallow—two species.
 NEPETA, Cat mint—one species.
 NYMPHÆA, Water Lily—two species.
 CENOTHERA, Tree Primrose—several species.
 OPHRYS, Twyblade, Bee-flower, &c.—four or five species.
 ORCHIS, (*Orchis*) Fool-stones—several species.
 ORIGANUM, Origany or Marjoram—two species.
 OROBUS, Bitter Vetch—several species.
 OXALIS, Wood Sorrel—two species.
 PÆONIA, Peony—two species, with several varieties.
 PANAX, Genseng—two species.
 PAPAVER, Poppy—two perennials.
 PENSTEMON, Bastard Asarum—two species.
 PHLOX, Lychnidea—several species.
 PHYSALIS, Winter Cherry—two hardy perennials.
 PHYTEUMA, Horned Rampion.
 PHYTOLACCA, American Night-shade—two species.
 PISUM, Pea—one species.
 PLUMBAGO *Europæa*, European Lead-wort.
 POLEMONIUM, Greek Valerian—three or four sorts.
 POLYANTHUS (see *Primula*).

POLYGALA, Milk-wort—two or three species.
 POLYGONUM, Bistort or Knot-grass—two or three species.
 POTERIUM, Burnet—one species.
 POTENTILLA, Cinquefoil—several sorts.
 PRIMULA, Primrose, Polyanthus, Auricula, &c.—three or four species, and numerous varieties.
 PULMONARIA, Lung-wort—two species.
 PULSATILLA, Pasque-flower, (see *Anemone Pulsatilla*).
 PYROLA, Winter-green.
 RANUNCULUS (*Ranunculus*) Crow-foot—several species, and numerous fine varieties.
 RANUNCULUS, Globe, (see *Trollius*)—two species.
 RESEDA, *Luteola*.
 RHEUM, Rhubarb—several species.
 RHENIA, American Loofestribe—two or three species.
 RUBIA, Madder—two species.
 RUBUS, Raspberry, &c.—one or two species.
 RUDBECKIA, Dwarf American Sun-flower—several species.
 RUMEX, Dock, Sorrel, &c.—several species.
 SALVIA, Sage, Clary, &c.—several species.
 SAMBUCUS *Ebulus*, Dwarf Elder, one species.
 SANGUINARIA, Puccoon—one species.
 SANTOLINA, Lavender Cotton—two species.
 SAPONARIA, Soap-wort—one species, some varieties.
 SARRACENA, Side-saddle Flower—two species.
 SATUREIA, Savory—two species.
 SATYRIUM, Lizard-flower—three species.
 SAXIFRAGA, Saxifrage—many species.
 SCABIOSA, Scabius—many species.
 SCANDIX, Shepherd's-needle—one species.
 SCORZONERA, (*Scorzonera*) Viper-grass—one species.
 SCROPHULARIA, Fig-wort—two species.
 SCUTELLARIA, Skull-cap—three species.
 SEDUM, Lesser House-leek, Orpine, Stonecrop, &c.—many species.
 SEMPERVIVUM (Ever-living) Greater House-leek—three or four species.
 SENEIO, Groundsel—two species.
 SERRATULA, Saw-wort—six or seven species.
 SIDERITIS, Iron-wort—one species.
 SILENE, Viscous Campion—three or four species.
 SILPHIUM, Bastard Chrysanthemum—three or four species.
 SISYMBRIUM *Nasturtium*, Watercress.
 SISYRINCHIUM, Bermudiana—one species.

SIUM, (Water Parsnep) Skirret—one species.
SMILAX, Rough Bind-weed—different species.

SMYRNIUM, Alexanders—one species.

SOLANUM, Nightshade—different species.

SOLDANELLA, Soldanel—one species.

SOLIDAGO, Golden Rod—many species.

SOPHORA, Sophora—two species.

SPIGELIA, Worm-grass—one species.

SPIRÆA, Spiræa-Frutex, &c.—three or four species, several varieties.

STATICE, Thrift, or Sea Pink—several different species.

SYMPHYTUM, Comphry or Comfrey—two or three species.

TABERNÆMONTANA, (*Tabernæ*)—two species.

TAMUS, Black Bryony.

TANACETUM, Tansey—three species, some varieties.

TELEPHIUM, True Orpine—one species.

TEUCRIUM, Germander—many species.

THALICTRUM, Meadow Rue—many species.

THYMUS, Thyme—several different sorts (under-shrubby).

TRACHELIUM, Umbelliferous Throatwort—one species.

TRADESCANTIA, Virginia Spider-wort—one species, some varieties.

TRAGOPOGON, Goat's Beard—two or three species.

TRIFOLIUM, Trefoil, or Clover—different species.

TRILLIUM, Herb True-love of Canada—two species.

TROLLIUS, Globe Ranunculus, &c.—two species.

TUSSILAGO, Colt's foot—several species.

URTICA, Nettle—two or three cultivated sorts, for variety.

VACCINIUM, Whortleberry—different species.

VALERIANA, Valerian—several species.

VERATRUM, White Hellebore—three species.

VERBASCUM, Mullein—many species.

VERBENA, Vervain—one or two species.

VERONICA, Speedwell, &c.—many species.

VICIA, Vetch—several species.

VINCA, Periwinkle—two species, several varieties—see also the list of *Evergreens*.

VIOLA, Violet—many species and varieties.

YUCCA, Adam's Needle—two hardier species. See also the green-house plants' arrangement.

ZYCOPHYLLUM, Bean Caper—one species.

The foregoing list comprises the names of the genera, in which are arranged all the principal species and varieties of hardy, fibrous-

rooted, herbaceous perennials of our gardens, very numerous, and mostly considered principally as ornamental-flowering plants, and for variety, &c. including some of a biennial nature, but considerably the most abundant of the perennial tribe; and most generally herbaceous, except some few that may be introduced, which are of an undershrubby, herbaceous-like growth, such as hyssop—sage—savory—thyme—wall-flower—stock-gilliflower—&c. having all abiding stalks and branches, and in the four former particularly, may be considered as rather belonging to the shrubby tribe; though, exclusive of these sorts, there are very numerous kinds, ten or twenty to one, entirely herbaceous in their top growth, wholly renewing their stalks, stems, and tops every spring: and being all more or less of the fibrous-rooted kind, the roots accordingly, in many sorts, consist of a multitude of small radicle fibres; in others of more thick, fleshy, fibrose radicles; some tuberous knobbed, and bunched, terminating in numerous fibres, and some of large fleshy roots, either roundish, oblong, forked, &c. in different sorts of plants, all furnished also with many fibrose radiculae, whereby to draw nourishment for the support of the vegetable.

Thus, under the denomination of fibrous-rooted perennials, of the above nature of growth in root and stems, &c. are comprised numerous fine and valuable plants, mostly all perennial, or durable of many years' continuance, in their said roots, but mostly annual in the stalks, which, in the greater part, rising directly from the roots in the spring, attain full growth the same year, earlier or later in the different sorts, flowering and produce seeds, then wholly decay to the ground; or others having low tufty abiding shoots, or some of a ligneous, or somewhat herbaceous-under-shrubby nature, with durable stalk and branches, and from which, in both cases, the flower-stalks are generally produced, not rising directly from the root, but also decay when the flowering, &c. is past, and some being of a biennial, or biennial-perennial growth, the whole, both top and root, is generally either only of two or three years' duration, or if any continue longer, they become feeble and straggling, seldom flowering but once in full perfection, in the same individual plants; though, in some sorts, being renewed by slips, cuttings, layers, &c. forming young plants, are thereby continued in a perennial state.

However, in all the naturally perennial kinds, which compose considerably the greater part of the plants alluded to in the preceding list, twenty to one or more, the same roots, continuing, some also the tops, but more generally

rally the roots only, remaining of many years' duration as before intimated; produce new stems, and flower-stalks every year in the spring, that flower the same year, always in equally good perfection, in their proper season; some early, in the different spring months, others, or the principal part, in summer, and many also in autumn; furnishing in the many different species and varieties a constant succession of flowers, from January or February, till November.

And in most of the sorts, the roots increase and multiply abundantly by off-sets, &c. to afford a plentiful propagation: some, however, more sparingly than others, and in default of a sufficient production of off-sets, many sorts are propagated by cuttings of their young flower-stems in summer, some by slips, layers, and pipings, &c. of their bottom shoots; others growing with elevated, branchy heads, are sometimes propagated by slips and cuttings of the lateral young shoots thereof; and numerous sorts are raised from seed: all which is fully explained in the cultural directions for the various different species and varieties separately, in their respective genera, which being exhibited in the foregoing register, by their generical names, shows at once all those different genera, in the process of this work, wherein the various species of this kind occur; and may be readily recurred to accordingly, for the description, culture, and method of propagation in any sorts required; and which being once raised by any of the different methods of propagation, they continue many years by the root in the perennials, but those of a biennial nature are of much shorter duration, as before observed. (See *Biennial and Perennial Plants*.)

The general plants alluded to in this list of the generical names of the genera, containing the different sorts, are principally of hardy growth, such as grow freely in the full ground in beds, borders, &c. and many also to plant in pots to remain, and move to any compartments required; and as the greater part are of the flowery tribe, are proper to introduce for the embellishment of the pleasure-garden and flower borders, &c. as principal ornamental-flowering plants, and some for variety and observation, exhibiting, in the whole, or in a proper collection of different sorts, a great and pleasing diversity, both in their varied seasons of flowering, and many different growths from one or two inches, to ten or twelve feet height in their flower-stalks, in different species, together with their various modes of flowering, shapes, sizes, and colours of the flowers, &c. as expressed in their several descriptions, under their respective genera.

All the sorts may be removed for transplantation, into the different compartments required, principally in the spring, about February, March, and April, and in the autumn season, from August or September, till the latter end of October or November, in open mild weather: and those planted in the spring will mostly all flower the same year; some in the spring months, others in summer and autumn, according to their respective times in those seasons: and those planted in autumn flower the year following.

Their general culture consists principally in keeping them clear from over-bearing weeds, by hoeing, raking, &c. in spring and summer; supporting the stems of tall growths, and running or long feeble kinds; and according as the different sorts go out of flower, and the stalks decay, cut the stalks down close to the head of the plants, which clear also from decayed leaves; likewise observe, that when any sorts multiply exceedingly by bottom or root off-sets into large bunches, they should be reduced either by taking up some sorts entirely, and slip or divide them less or more, and replanted; or others, remaining in the ground, have the outward off-sets slipped off all round, or as it may seem necessary, less or more, whereby to reduce the main plant within bounds, or to proper regularity: and some very large spreading sorts having greatly increased, will sometimes require reducing considerably, or cutting in all round with the spade; as in some sorts of Asters, Golden-rods, perennial Sun-flowers, &c. in all of which, the slips or detached off-sets may be planted, as many of the best of particular sorts as shall be required, the larger ones planted at once where they are to flower, and the smaller, in nursery beds for a year; and the superabundant, if any, cleared away to the rubbish heap.

The propagation of the various sorts is performed at different times, according to the nature of the plants; but in that by off-sets, slipping, or parting the roots, is performed either generally in autumn, after the flowering is past and the flower-stalks decayed, or in the spring, before they begin to shoot considerably; and by cuttings of young top-shoots and flower-stalks, is generally in the early part of summer; or that by layers, and piping slips and cuttings, is principally in June and July; and by slips of bottom young shoots, is effected both in spring and summer, or by off-set side heads and sucker young plants, may be in spring, summer, and autumn, according as they occur of proper growth. See *Cuttings—Off-sets—Layers—Parting roots—Suckers, &c.*

RAKE,

RAKE, a Garden-Rake for raking ground, and raking in seeds, &c.

To suit every department of gardening completely with Rakes, there should be three or four different sizes from about six to eighteen inches long in the head, having handles from six to eight or nine feet in length, and the head toothed with iron teeth two or three inches long, and placed from one to two inches asunder, according to the respective sizes of the Rakes for particular uses, as below.

A large RAKE.—Having the head about fifteen to eighteen inches long, the teeth three inches, and placed two inches asunder; being proper for raking stubborn or rough dug ground, and for raking in large kinds of seeds, raking off large weeds after hoeing, and for many other purposes in large gardens.

Common middle-sized RAKE.—Having the head twelve inches long, the teeth three inches, and placed one inch and half asunder; being proper for all common raking in ordinary light ground, and for raking in most kinds of small seeds, and many other purposes.

A small RAKE.—Having the head about nine inches long, the teeth two and a half, and placed one inch asunder; proper for fine-raking beds, borders, &c. and raking in some particular fine seeds; and raking between rows, &c. of certain plants occasionally, where larger rakes cannot be introduced.

A little RAKE.—Having the head six inches long, the teeth two and a half, and placed one inch asunder; being very useful for raking between small plants in beds and borders and other small compartments where the plants stand close, and in several other purposes in occasional small raking.

Garden Rakes are made both with wooden heads and iron teeth, and with the head wholly of iron; and in both of which, the teeth are generally flattened, the back edge rounded off and narrowing gradually to the point, the other straight; and are placed on the head edge-ways across, with the back edge outward, and with the points all inclining very moderately inward, in the most regular manner: the wooden-headed rakes having each end of the head hooped with a thin flat iron ring, to secure it from splitting; and either or both of which being properly fixed on a straight firm pole handle, six to eight or nine feet long, according to the size of the head, the largest have the longest and strongest shaft or handle, in proportion.

With regard to the utility of the two different sorts of rakes, wooden and entirely iron heads, the former are generally lightest and

cheapest, and are very eligible for any kind of garden raking; and the latter, iron-headed rakes, when made neat, and as light as possible, the teeth well set, in a proper position, as above, and firmly fastened, are also equally proper, and in some cases preferable, such as in wetish or moist soils, are not liable to clog so much as wooden rakes, and are more durable; though I would observe, they are more eligible for middling and small rakes, than for large ones; as, in strong raking, the teeth are more liable to get loose, than in the wooden-headed rakes; however, both the sorts are occasionally used effectually in all raking work in garden departments.

Both the sorts, in their different sizes, are sold at most of the principal iron-mongery shops, both with and without handles.

Entire wooden Rakes, having the head, teeth, and handle, wholly of wood, are sometimes used for particular purposes, such as raking in some light kinds of kitchen-garden seeds in very light ground, and for raking off large hoed-up weeds in vacant or wide clear spaces, raking up swarths of mowed short grass before the sweepers, also fallen leaves of trees in autumn, and clippings of hedges, &c. and for several other uses.

RAKING. Raking ground is a necessary culture in many cases, to break the surface of the soil small, and render it fine for the reception of particular sorts of small seeds and plants previous to sowing and planting.

Likewise, after sowing seeds in the broadcast way on rough ground, we rake them in to bury them a proper depth for germinating. Raking in seeds is the most expeditious mode of covering them in garden-sowing all kinds of small seeds of hardy plants; the ground being dug, &c. and the surface remaining rough after the spade, the seed is then sown, and then raked in with an even hand, raking only once or twice in a place, a back and a fore stroke, which being generally sufficient to cover most sorts of seeds effectually; and is the most eligible and expeditious method in the sowing most kinds of esculent or kitchen-garden seeds, and of many kinds of hardy flower seeds, and some sorts of small tree and shrub seeds. See **SOWING SEEDS.**

Raking the ground also among growing plants that stand distant enough to admit the rake is in many cases of service, particularly where the surface is inclinable to bind; or where numerous small seed-weeds appear, it will loosen the soil, and retard the growth of the weeds, and promote the growth of young plants: and raking is also good culture at particular seasons, to annoy flugs, especially in kitchen-

kitchen-gardens, to rake between rows of small plants in autumn and winter, &c.

And Raking ground is in many cases necessary for ornament, such as raking smooth the beds, borders, and other compartments of pleasure-grounds; which being now and then repeated, gives an air of culture and neatness to the premises.

Likewise, after hoeing up weeds, Raking them off is eligible in all conspicuous parts of the pleasure-ground, in particular where neatness is required, also in other districts where the weeds are large, or like to grow up again or shed their seeds as they lie on the ground.

All Raking should generally be performed in dry weather and when the ground is also moderately dry, for if raked in rainy weather, or when the ground is very moist and cloggy, the surface is apt to cake and bind hard; this should be particularly attended to in sowing seeds; nor will rough digged ground rake well when it is become very dry at top, especially if it was digged wet, and suffered to lie till the clods have become very dry and hard, in which case it will not rake well until mellowed or pulverised by a shower of rain.

But most of our common light garden-ground generally rakes best when fresh digged, perhaps the same day, or day after at the farthest, before dried too much by the sun and wind, or rendered wet by rain, &c.

However, Raking should be performed when the ground is in such order as the clods will readily break and fall to bits under the rake without clogging much thereto.

With respect, however, to Raking ground sown with seed, particularly in spring and summer, it is of importance to sow the seed generally when the ground is fresh turned up, provided it will readily rake without clogging as abovesaid; and fresh digged ground is always promotive of a free germination in the seed sown therein.

RANDIA, (*Randia*.)

In this genus are two tender exotic evergreen shrubs of America and the West Indies, introduced here in our stove collection for variety, growing eight or ten feet high, branching by opposite pairs, alternately crossing; garnished with small, oval, and roundish, thick, opposite leaves; and small funnel-shaped, white flowers, having monophyllous, five-lobed, permanent calyxes; a tubulous, funnel-shaped corolla, five-parted above; five stamina; an oval germen, bifid style, crowned with two stigmas; and the germen becomes an oval, capsular, unilocular berry, containing many compressed, cartilaginous seeds.

Class and order, *Pentandria Monogynia*.

The species are,

1. *RANDIA mitis*.

Mild, or Smooth American Randia.] Having smooth, or almost unarmed, or thornless branches, and ovalish, thick, firm leaves.

2. *RANDIA aculeata*.

Prickly Jamaica Randia.] Having the branches armed with spinous aculei, or prickles, in pairs; and roundish-oval, shining leaves.

Both these exotic shrubs being very tender evergreens of South America and the West Indies, &c. require a constant residence here in a hot-house or stove, in which they will effect an agreeable variety all the year, as evergreens, and produce flowers in summer.

They are propagated by seed in the spring, sown in pots, plunged in a hot-bed, or the bark-bed of the stove; and when the plants are up three inches high, prick them in small pots singly, watered and plunged into the bark-bed, &c. to forward their fresh rooting and renewed growth; and afterwards managed as other similar exotics of the stove: or the propagation by cuttings and layers may also be tried by the above assistance.

RANUNCULUS, *Ranunculus* and *Crow-foot*.

This genus comprises a large collection of hardy herbaceous perennials of the grumous, and fibrous-rooted tribe; some of them most beautiful flowery plants of the gardens, others common weeds of the fields and meadows; the garden kinds having great merit as flower-plants for adorning the flower-garden and pleasure-ground, garnished with divided and entire leaves in different species, and mostly upright branchy flower-stalks, from half a foot to two feet high, terminated by pentapetalous, polyandrous flowers, which in some species abound in numerous double varieties of exceeding beauty.

Class and order, *Polyandria Polygynia*.

Characters.] CALYX, five oval, concave, coloured leaves. COROLLA, five obtuse petals, having small ungues, and a nectarium formed of a small open cavity near the base of each petal. STAMINA, numerous filaments half the length of the petals, having oblong, erect, didymous antheræ. PISTILLUM, numerous germina, collected into a head; no styles, but very small reflexed stigmas. PERICARPIMUM, none; numerous irregular seeds attached to the common receptacle by very short pedicles.

There are forty or more different species of this genus, six or eight of which claim general esteem as flowery plants for ornamenting the gardens, and a great number are common weeds in the fields, waters, and pasture ground, not having merit for garden culture: of the garden.

garden kinds, the principal sort is the *Asiatic* or *Turkey and Persian Ranunculus*, which comprise many hundred varieties of large, double, most beautiful flowers of various colours; but several other species having varieties with fine double flowers, make a good appearance in a collection; though as those of each species consist only of one colour, some white, others yellow, they are inferior to the *Asiatic Ranunculus*, which being large and diversified a thousand ways in rich colours, in different varieties; however, all the garden kinds in general, described below, effect a very agreeable diversity in assemblage in the flower compartments, &c. and they being all very hardy, succeed in any open beds and borders, &c.

The most noted kinds for garden culture are the following eight species.

1. *RANUNCULUS asiaticus*.

Asiatic, or Turkey and Persian Ranunculus.]

Hath a small grumous or bundled root, composed of many very small oblong-knobbed parts connected at top; crowned with ternate and double-ternate leaves, having trifid-cut lobes; upright flower-stalks branching below, and rising from six to ten or twelve inches high, terminated each by one large flower of many different colours and properties in the varieties; flowering in April, May, and June.

Is a native of Asia, and introduced here long since from Turkey and Persia, and by way of distinction is mostly called simply *Ranunculus*.

Varieties.] The varieties of this species are amazingly numerous, and are divided into two classes, the Old Turkey kind and the Persian kinds, the varieties of the latter amounting to many hundreds, and are considerably more various, rich, and beautiful in colour, than the others.

Old Turkey kinds.] Rise with a strong generally unbranching stalk a foot high, terminated by one large double flower, sometimes emitting one or two smaller ones from its sides, and of which there are Red-flowered—Scarlet flowered—Yellow flowered—and Scarlet turban flowered, &c.—they being seldom tinged with different colours like the Persian kinds.

Persian varieties.] Rise eight or nine inches high, generally branching from the bottom, producing from five or ten to twenty or more flowers on each root, and of which there are Single flowered—Semi-double flowered—Full-double flowered, being large and full like a double rose, generally filled with petals to the very centre, forming a regular, globular body of admirable elegance, of all sorts of the most beautiful colours in different varieties, and of numerous degrees of deeper and lighter shades, stripes, and tinges in the several colours, so

as to cause an astonishing diversity of Reds,—Scarlets,—Crimsons,—Flesh-colours—Purples—Blues—Violet colours—Whites—Cream-colours—Ash-colours—Yellows—Orange-colours—Lemon-colours—Golden-yellow—Olive-yellows—Browns—Copper-colours—Blacks—Black-purples—Black-violets—Tawny-colour—Coffee-colour, &c.—and with flowers of all the above colours variously tinged and striped with two, three, or more different colours, in a very curious manner, forming the numerous varieties, amounting to above a thousand, described in some of the eminent flower-dealers' catalogues, varying from one another in some particular in different colours, tints, stripes, and variegations; and a farther increase of new varieties are annually obtained from seeds: the seedlings generally flower the second or third year, and the select kinds are continued and increased plentifully by off-sets from the-root, every summer, after they have done flowering.

All the varieties flower commonly in April and May, but by late planting the roots, the blow may be continued till June; and the single and half-double flowers are succeeded by abundance of seed, but rarely any from the full doubles: the semi-doubles, however, are preferable to the singles, from which to save the seed for sowing, as there will be a greater probable chance of having double-flowered seedlings in return.

The roots of all the varieties of this species are of the keeping kind, and being lifted in summer soon after flowering, the off-sets separated and properly dried, they may be kept out of the ground several months; but it is proper to plant a quantity in autumn, and the rest in spring, in order to procure a longer succession of the flowers.

These roots are sold by all the nurserymen and seedsmen in great variety, at from two or three shillings to four or five pounds per hundred, and sometimes considerably more, for some very curious varieties.

They are all hardy enough to succeed in any common light garden-earth in open beds or borders, planted some in autumn about September, October, or November, but principally the two latter months, and the rest in February; the fine sorts being commonly deposited in beds by themselves, in rows six or eight inches asunder and two or three deep, both to exhibit a grand show of the numerous varieties all together, and for the convenience of giving occasional shelter from cutting frosts; especially of the early autumnal plantings in particular, that appear above ground in winter or early in spring: though the latter autumnal plantings

plantings put in about November, as they will not come up so early, do not require so much care, and the spring plantings need no protection at all. As to the common or more ordinary kinds, they may either be bedded like the others, or distributed about the open borders in little patches of three or four roots in each, in assemblage with other border flowers. See their *General Culture*.

2. *RANUNCULUS aconitifolius*.

Aconite-leaved White-mountain Crow-foot, or Fair-maid of France.] Hath a strong fibrous perennial root joined in a head, crowned with large quinate, or five-lobed leaves, all the lobes spear-shaped, cut and serrated; upright, strong flower-stalks, a foot and a half or two feet high, divided into many branches, garnished with small leaves like the lower ones, and all the branches terminated by pure white flowers, appearing the end of May and beginning of June.

Varieties.] Common single-flowered,—Larger double-flowered, very beautiful, and worthy of a place in every garden.

3. *RANUNCULUS acris*.

Acrid Upright Meadow Ranunculus, or Yellow Crow-foot.] Hath a fibrous clustered root, joining in a head, crowned by tripartite-multifid, or much divided leaves; upright flower-stalks a foot high, branching at top, having the upper-leaves cut into many narrow segments, and all the branches terminated by a bright-yellow flower, appearing in May.

Varieties.] Common single-flowered of the pastures,—double-flowered of the gardens,—Proliferous double-flowered, one flower growing out of the middle of another. The double kinds only are proper for garden culture.

This species in its single state is found in abundance in every pasture ground, and is seldom admitted into gardens; but the double varieties are very pretty, and merit a place in every good collection of perennials.

4. *RANUNCULUS repens*.

Creeping, or running Yellow Crow-foot.] Hath fibrous, perennial roots, crowned with compound leaves, trailing, creeping shoots, rooting as they run along, and furrowed pedunculi terminated by bright yellow-flowers, having spreading cups; flowering in May and June.

Varieties.] Common single-flowered of the meadows and pastures,—Double-flowered of the gardens.

5. *RANUNCULUS Ficaria*.

(*Ficaria*)—*Fig-wort, or Pile-wort.*] Hath a grumous or bundled tuberos root, heart-shaped, angular, smooth leaves, on strong foot-stalks, and upright simple stalks rising four or five inches high, terminated by large

shining yellow flowers, in March and April. *Varieties.*] Common single-flowered of the meadows, &c.—Double-flowered of the gardens.

6. *RANUNCULUS amplexicaulis*.

Amplexicaulous, Plantain-leaved, Alpine Ranunculus.] Hath a bundled perennial root, oval, acuminate, glaucous leaves embracing the stalk, the stalk rising from six to eighteen inches high, branching and terminated by several single white flowers; appearing in April.

7. *RANUNCULUS gramineus*.

Grass-leaved Pyrenean Ranunculus.] Hath a bulbo-tuberos, perennial root, spear-shaped, narrow, grassy, sessile leaves; upright stalks about a foot high, branching upwards, each branch terminated by a small, pale-yellow flower; appearing in May.

Varieties.] Common single-flowered—Double-flowered.

8. *RANUNCULUS grandiflorus*.

Great Yellow-flowered Oriental Ranunculus.] Hath a fibrous perennial root, multifid or many-parted leaves; erect stalks a foot or more high, garnished with two alternate close-fitting leaves; and terminated by one large yellow flower; appearing in May.

The flowers of all the above eight species of *Ranunculus*, in their single or characteristic state, consist each of five obtuse bright petals, and the middle filled with numerous stamina, &c. succeeded by abundance of seed; but in the double-flowered varieties the petals are multiplied in many series, which in the full doubles are continued to the very centre, like a double-rose, in which consists their excellence as garden-flowers for ornament: though in these very luxuriant or full double-flowers, the multiplicity of petals often supplant all the stamina that no seed is produced. This however is amply compensated by the singles and half-doubles, which are succeeded by great plenty of seed, ripening in June and July; but it is only of the *Asiatic Ranunculus* that seed is required, which in this species in particular is always productive of a great variety of new sorts, but not in any of the other species, remarking, that the finest semi-doubles are the sorts from which to save the seed for propagation.

All the species are perennial in root, and annual in leaf and stalk, which rise in spring and decay in summer and autumn soon after they have flowered; the roots of all the sorts being abiding, increase abundantly by off-sets every year for propagating the particular varieties.

Considered as garden-flowers, all the sorts demand attention; the Asiatic kinds however stand foremost considerably in point of beauty, elegance, and variety, but some of all

the sorts are proper furniture for the borders and other compartments of the pleasure-garden, where being disposed in assemblage they will effect a good diversity in flower for two or three months, and some of the finest of the Asiatic varieties should also be deposited in beds by themselves, as before observed, in order to exhibit a grand blow together; observing, that the roots of the fine varieties of this species should be lifted every year after blowing, to separate the off-sets and fresh prepare the mould, &c. but all the other fibrous-rooted species being distributed about the borders may remain undisturbed two or three years, or as it shall seem necessary, according as they may want trimming to keep them within bounds, or to have the roots taken up occasionally to part them for propagation.

Culture of the Asiatic Kinds.

The *Asiatic Ranunculus* in particular is in high estimation among the florists, and is deservedly an object of admiration on account of the great number of the varieties; and the beauties the flowers possess, in their elegance of form and vast variety and richness of colour, render them superior to most other flowers of the season, and highly merit culture in every garden.

This species in all its varieties will succeed in any light, rich garden earth; but the florists often prepare a particular compost for the fine varieties, consisting of good garden mould or pasture-earth, sward and all, a fourth-part of rotted cow-dung, and the like portion of sea-sand (see COMPOST); and with this, after having remained in a compost heap several months, for all parts to rot, and incorporate properly together, they prepare beds four feet wide and two deep: however, in default of such compost, use beds of any good light earth of your garden; or if necessary, it may be made light and rich with a proportion of drift-sand and rotten dung; cow-dung is most commonly recommended; but they will also thrive in beds of well wrought garden earth, and they often prosper well in the common flower borders.

The season for planting the roots is both in autumn and spring; the autumn plantings generally flower strongest and soonest by a month at least, and are succeeded by the spring planting in May and June. Perform the autumnal planting in October and early part of November, but some plant towards the latter end of September in order to have a very early bloom; but those planted in that month and beginning of October often come up with rank leaves soon after, in winter, so as to require protection in hard frosts; especially in the capital varieties, in order to pre-

serve them more effectually in growth, to flower in best perfection: those however planted about the middle or latter end of October and beginning of November rarely shoot up strong till towards spring, and will not require so much care of covering during winter; and the spring planting may be performed the end of January or beginning of February, or as soon as the weather is settled; they will not require any trouble of covering, and will succeed the autumnal plants regularly in bloom, and will flower in good perfection. Thus by two or three different plantings you may obtain a succession of these beautiful flowers in constant bloom from April till the middle of June; but the autumnal plants for the general part not only flower strongest, but the roots increase more in size, and furnish the best off-sets for propagation: it is however proper to plant both in spring and autumn.

Prepare for the choicer sorts four-foot beds of light earth, as aforesaid, by good digging, breaking the earth fine, but not sift any part thereof, laying them of a moderately rounding form, and rake the surface smooth, then plant the roots in rows lengthwise the beds, either by drilling them in two inches deep and six inches distance in the row, and the rows six or eight asunder, or may plant them by bedding-in or by dibble-planting the same depth and distance. See PLANTING.

Those designed for the borders should be planted generally towards the spring in little clumps or patches, three, four, or five roots in each, putting them in either with a dibble or trowel about two inches deep, and three or four asunder in each patch, and the patches from about three to five or ten feet distance, placing them rather, variedly, forward in the border.

As to their general culture after planting, observe in winter, that such of the forward autumnal-planted roots of the choice sorts in beds as have shot above ground, should, where possibly convenient, have occasional shelter from hard frosts by mats supported on low hoop-arches; or in very severe weather may cover them close with dry long litter, but remove all covering in open weather: and in the spring when the flower-buds begin first to advance, it will be of much advantage to shelter them in frosty nights with supported mats, suffering them however to be open to the full air every day; but the latter plantings that do not come up in winter or very early in spring whilst frosty nights prevail, will not require any protection, and all those distributed in patches about the borders must also take their chance in all weathers; those of the different seasons of planting will succeed one another

in flowering from the beginning of April until the middle of June, though the May blow generally shows to the greatest perfection.

After the blow is past, and the leaves and stalks withered, take up the roots, and dry them in the shade, then clear them from all off-sets and adhering mould, and put them up in bags or boxes till next planting seasons, when they must be planted again as before directed.

But in each season of planting, it is highly necessary, in the principal fine varieties, to plant them either in entire new beds, or the old refreshed with some fresh rich earth or compost, working the old and new well together, this being necessary in order to invigorate the growth of the plants.

Their Propagation.

All the varieties of the *Asiatic Ranunculus* propagate abundantly by off-sets from the root, and new varieties are gained by seed.

By off-sets.—The time for separating the off-sets is in summer when the flower is past, and the leaves and stalks are withered, then taking up all the roots in dry weather, separate the small off-sets from each main root, and after drying the whole gradually in some shady airy room, put them up in bags or boxes in the dry till the autumn and spring seasons of planting, then plant them as before, placing all the off-sets in separate beds, many of them will blow the first year, but in the second they will all flower in good perfection.

By seed.—Save a quantity of seed from the finest semi-double flowers, and sow it either in August or in March or April, though to save trouble of winter covering may defer sowing till spring; it should be sown in light rich mould, either in an east border, or in wide pots placed in a similar situation, sowing the seed evenly on the surface, and cover it in lightly with fine earth; or if in a bed or border, may sow it in shallow flat drills three or four inches asunder, earthing it in similarly: giving frequent refreshments of water in dry weather, and in a month or six weeks the plants will rise with small leaves; observing to continue the light waterings in dry weather to preserve the soil moist during their summer's growth to increase the size of the roots; and in June, when the leaves decay, take up the roots and preserve them till the season for planting, then plant them in common beds, as before directed, and they will flower the spring following, when all the doubles of good properties should be marked, and the singles thrown away.

Culture of the other seven Sorts.

All the other seven species of *Ranunculus* succeed in any common soil and situation, so

may be dispersed about the different flower compartments, where they may constantly remain, only trimming them occasionally; and once in a year or two, or when they have increased into large bunches they may be taken up in autumn or spring to divide them for farther increase, and replant them again directly.

Their propagation is very easy, for they multiply exceedingly by the roots.

So that when intended to propagate them, the roots may be slipped or parted in autumn when past flowering, or in the spring before they begin to shoot, and the slips may either be planted at once where they are to remain, or in nursery rows for a season, then planted out finally.

RAPHANUS; *Radish.*

The plants are herbaceous, annual esculents of the kitchen-garden, valuable for their eatable roots for spring and summer service, and some for winter eating; having fusiform and globose roots in different varieties, broad rough leaves, and cruciform flowers.

Class and order, *Tetradynamia Siliquosa.*

Characters.] CALYX, four oblong, erect, deciduous leaves. COROLLA, four heart-shaped, spreading, cruciform petals, and four melliferous glands. STAMINA, four long and two short filaments, having simple antheræ. PISTILLUM, an oblong ventricose germen, scarcely any style, crowned by a capitated stigma. PERICARPIUM, an oblong, gibbous, or swelling, smooth, bilocular pod, filled with roundish seeds.

This genus retains three species, one of which only, *Common Radish*, is for our purpose; for the botanists admit but of one species of this sort: all the different varieties of the spindle-rooted and round Radish, both red, purple, white, and black sorts, are supposed varieties only of the same species; and, indeed, we may often observe here and there some of all the varieties degenerate both in shape and colour; however, by care in saving the seeds of the different sorts separate and distant from one another, the different varieties are continued distinct.

The species is,

RAPHANUS *sativus.*

Cultivated or common Garden Radish.] Hath oblong-taper, and round-orbicular, fleshy roots, crowned by broad, rough leaves; and when they shoot for seed, send forth upright, strong, widely branching stalks, a yard or more high, having all the branches terminated by cruciform, whitish light-purplish flowers, succeeded by taper swelling pods with two cells.

Varieties.] There are several different varieties; though some of them appear as distinct species by the shape, size, and colour of the

root, yet as they all bear exactly the above specific distinction, they are considered all as varieties only of one another, belonging all to the species *Raphanus sativus*, and the principal sorts are the following, which may be divided into two classes,—Common fusiform or spindle-rooted Radishes, and the globular or turnep-rooted kinds.

Common spindle-rooted Kinds in different Varieties.

Short-topped Radish.] Having an oblong, taper, reddish-purple root, some deep, others pale-coloured, crowned with only a small short top of leaves, which is a particular merit peculiar to this sort, as the plants require both less room to grow, and the root swells faster in proportion, attaining perfection much sooner than the large-topped kinds, being also a firm, crisp, tender-eating Radish, so is preferable for general culture, both for all early crops in frames and borders, and for the general crops in the open quarters; the pale rooted sort is generally milder to eat than the deep red or purple kind.

This may be sown at different times, from October or November until May; but from January till March and April is the general sowing season, at two or three weeks' intervals, for the main crops.

Salmon-coloured Radish.] Having a fine long, taper, pale-scarlet root, crowned generally with a pretty large top of leaves, but if allowed room, the root swells freely to a handsome size, and is a firm, crisp, excellent Radish for the later crops, sown in March, April, and May, in open situations.

Variety.] Short-topped early Salmon Radish.

Long-topped Red Radish.] Having an oblong, taper, red root, crowned with a large top of leaves;—not proper for general culture.

Deep-red Radish.] Having an oblong, taper, deep-red root, apt to become soon hot and sticky; not proper for general culture.

Salad Radish.] Any sort of Radish may be used as such, being sown thick like cresses, and mustard, to gather whilst young in the seed leaf, to mix in sallads; but seed of any of the common long-topped sorts may be sown for this purpose. See SALLAD HERBS.

Turnep-rooted Kinds.

Small White Turnep-rooted Italian Radish.] Having a small, round-orbicular, turnep-shaped, white root, being very like young Dutch turneps; and if used whilst quite young, they eat very crisp, mild, and well tasted, and make an agreeable variety at table; are in highest perfection in April and May, or in autumn: sow them in February, March,

and April, for spring and summer use; and in June, July and August, for autumn eating.

This sort is cultivated abundantly about London, and brought to the markets in the spring, March, or April, and in May, June, and in autumn, generally in bunches; having the appearance of young turneps.

Small red Turnep-rooted Radish.] Having a small, round, turnep-shaped, red root nearly similar in shape to the last sort, though often inclining more to the oblongish form than that kind, is generally of a pale red, or sometimes less or more of a deeper colour, and is rather inferior to the former for mildness, and crisp eating; though is very good, and makes an agreeable variety at table.

Black Turnep-rooted Spanish Radish.] Hath a large, roundish-oblong, black-coated root, but white within, greatly esteemed by many for autumn and winter eating either alone or sliced in sallads: and is the hardiest of the Radish tribe to stand the weather for use all winter, &c. should be sown in any open situation, principally in July and beginning of August, they will come in for use in September and October, and continue in perfection all winter.

White Turnep-rooted Spanish Radish.] Having a middling large, round-orbicular, turnep-shaped, white root; proper to cultivate principally for autumn eating and early part of winter, not being so hardy as the black sort, and is not so very generally known or cultivated as that kind; may be sown in June, July, and beginning of August.

Of the above two different classes of Radishes, Spindle-rooted and Turnep-rooted kinds, should generally allot the former for all the principal crops, both early and successional, and smaller portions of the latter sorts as secondaries, which, in the small white, and red kinds, may also be cultivated successionally for spring, summer, and autumn; but the Spanish Turnep-rooted Radishes are principally for autumn, and winter; so that for the general spring, and summer Radishes, allotting the largest supply of the common Spindle-rooted kinds, are proper to sow from the earliest to the latest season, from December or January, until May, June, or all summer; and the small Turnep-rooted sorts, as secondaries, may be sown any time from February or March, till May, or occasionally in summer and autumn, till August or September, and the Spanish Radishes are always sown principally in July and August.

All the varieties of both classes of Radishes are annual plants, which being sown in the spring attain perfection in two or three months, and shoot up soon after into stalk for

flower and seed, which ripening in autumn, the whole plant, root and top, perishes; so that fresh supplies must be raised annually from seed in the spring, and summer, &c. performing the sowings at several different times, from about Christmas until May, or June, of the common Spindle-rooted in particular, or some also of the small Turnep-rooted kinds, in order to continue a regular succession of young tender Radishes throughout the season; allowing only a fortnight or three weeks interval between the sowings; for one crop will not continue good longer than that space of time, before they will either run to seed, or become tough, sticky, and hot to eat.

They are all tolerably hardy, except very early raised plants in their infant state, which are liable to suffer by frost; and they all succeed in any common garden earth, and almost any situation and exposure open to the sun and free air; though for the early crops a warm south border, or other sheltered sunny situation, is proper, both to bring the crop forwarder, and for protecting the plants from cold, as being impatient of frost whilst young, as above said; therefore when they are sown early, December, or January, &c. it is proper to cover them in frosty nights with straw or mats; but the main crops sown in February and March, &c. may be in any open situation, as they want no protection.

Culture of the common Spindle-rooted Radish.

To have Radishes as early as possible, they are sown both on warm borders and in hot-beds, under frames and lights.

But first of their culture in the open ground. To have early Radishes in warm borders, you may begin sowing a few short-topped Radish in November, and December, but not any general early sowing till about Christmas, or early in January, if the weather is open; or in cold wet grounds not till the end of that month or beginning of February; for the very forward sowings performed before the middle or end of December, are not to be depended on, though such of them as survive the winter's frost, will be fit to draw sometimes in February; they however will be hard and sticky; but as they may be deemed a rarity at a very early season, and as the seed is cheap enough, and a small space of ground will be sufficient, it may be worth the trial to sow some in November and December, and let them take their chance of the winter; and if they should fail, the same ground will do to sow again time enough for a good spring crop. However, for the general early crop, the end of December, or the beginning or middle of January, according to the temperature of the

season, and nature of the soil and situation, in respect to being warmer or colder, is time enough to begin, when, if open weather, it is proper to think of sowing a good crop in a warm dry border, or any warm-lying light ground; and about the end of January, or beginning of February, sow a more general crop.

Let the ground for the reception of the seed be digged or trenched one good spade deep at least; or it will be of advantage, if it has been previously trenched up in ridges, then levelled down, the clods well broken, and the surface laid even.

Then being provided with some good early short-topped Radish-seed, and with which, if you thing proper, you may mix a sprinkling of cos-lettuce, they will come in for use after the Radishes, and be some weeks earlier than the main crops. Sow the whole together broadcast all over the surface tolerably thick in the early sowings, and rake them well in with a large rake; or, if in a large open plat of ground, or considerably wide border, or where the ground is rather wettish, it is proper, for the early sowings in particular, to divide it into four or five feet wide beds, with foot and a half wide alleys between; then sowing the seed, strike it in with the teeth of the rake, and then cast some earth of the alleys over the whole half an inch deep, and rake it smooth.

After performing the main early sowings from about Christmas till the beginning of February, generally cover the ground directly with clean wheat straw, about two inches thick, to keep the surface warm, and keep off birds from the seed, and forward its vegetation, suffering it to remain till the plants are fairly come up, as it contributes to their more early rising, and is then raked off lightly every mild day.

However, covering these early crops is very eligible, both before and after the plants come up, every frosty night; for this purpose have either a quantity of dry wheat-straw, or dried fern, &c. laying it ready in the alleys, and every night, or especially when there is an appearance of frost, throw it over the border or beds with a pitchfork, two inches thick, or more, if the weather should prove severe; and always after the plants are up, rake it off lightly every mild morning with a wooden rake; but in severe weather must remain night and day: and this covering, if carefully spread on and taken off, will no ways bruise the plants, but will not only protect them from the frost, but continue them greatly forward in their growth. But instead of straw some use large garden-mats, especially after the plants are up, to keep off the perpendicular frosts, generally sticking two or three rows of stout

stout wooden pegs along the border or beds, in a slanting manner, two or three inches above ground, to support the mats from the plants, or where there is only a small quantity, you may arch the beds with hoops for the support of the mats.

The above work of covering early Radishes may to some appear tedious and troublesome, but it is soon done when every thing is laid ready, and is universally practised by the London gardeners, to large tracts of ground, continuing it till the plants are fairly in the rough leaf, and firmly rooted; for the early quite young plants, being not only liable to be greatly cut at top by the frost, but even those exposed thereto and seemingly survive, are often started at the root; that is, the frost heaving the ground, it draws the plants up along with it, and breaks the tender radicle or lower perpendicular fibre, which not only retards their growth till they form new fibres, but the terminal downright fibre being broken off, prevents their shooting in length, that they can never form handsome Radishes, but become what the market gardeners call chumps: so those gardeners, who raise large quantities for the supply of the London markets, find their account in allowing the early main crops occasional protection, which by insuring fuller crops, coming in earlier and in greater perfection, always pay them sufficiently for the trouble of covering.

When the Radishes however, are a little advanced in growth, being in the rough leaf, it is proper to thin them, where they stand too thick, to two inches distance, which, as you will begin drawing them for use when quite young, may be room enough at present, as the daily thinning for the table or market will give them more and more room every day.

In very dry weather, in March and April, it is advisable to give them a good watering every evening or morning, which will both forward their growth considerably, increase the size of the root, and render them more crisp and mild to eat.

Continue repeating the sowings every fortnight or three weeks, till March, then sow every fortnight until the end of April: or where a long succession of young Radishes is required, the sowings may be continued all May, or even during the summer, until the middle or end of August, if required; those sown in July or August will be very fine in September and October; observing in sowing the latter crops of Radishes, from the middle of February during the rest of the sowing season, they may be sown in any open ground, and want no covering in any weather; and in the main crops of radishes, if the extent of

ground intended for sowing this main crop is any thing considerable, and that it is necessary to make all possible advantage of every compartment of ground, as is often the case in market gardens, and some others, you may mix a sprinkling of cos-lettuce and round-leaved spinach seed, sowing the whole together broad-cast, and rake them in evenly with a large rake as aforesaid; the three crops will be coming forward all at the same time, without interruption to one another; the Radishes come in first, then, after these are drawn off, the spinach flourishes, and soon becomes fit for use, which is succeeded by the lettuce; and between these may introduce other succession crops, in May or June: however, in the culture of smaller portions, it is not material to sow any other crop with the radishes; and in general it would be preferable to have the whole distinct.

But in sowing the main general crops of Radishes in the open quarters, the market gardeners generally sow them on the same ground where they plant out their main crops of cauliflowers and cabbages, mixing spinach with the Radish seed, as above said, sowing the seeds first, and rake them in, then plant the cauliflowers or cabbages; the Radishes and spinach come in for use before the other plants begin to spread much, and as soon as those small crops are all cleared off for use, then hoe the ground all over to kill weeds and loosen the soil, and draw earth about the stems of the cauliflowers and cabbages.

With regard to the culture of these general crops of Radishes, they require very little, which is occasional thinning where they are too thick, performing this when the plants are come into the rough leaf, either by hoe or drawing them out by hand; though for large quantities, small-hoeing is the most expeditious mode of thinning, as well as prove very beneficial to the crop by loosening the ground; however, in either method, thin the plants to about two or three inches distance, clearing out the weakest, and leave the strongest to form the crop.

Early crops in hot-beds, &c.—When it is required to have young radishes as early in the spring as possible, they may be greatly forwarded by aid of hot-beds under frames and glasses, or other shelters.

This work may be begun any time in winter, if thought proper; but from Christmas till Candlemas is the most eligible season to insure a thriving crop. Make a hot-bed for one or more three-light frames, long-ways, about two feet depth of dung, to furnish sufficient heat to bring up the plants, and set them a going a little at first; put on the frame directly,

directly, and earth the bed six or seven inches deep with light rich mould; then having the true dwarf short-topped Radish-seed, sow it on the surface of the bed moderately thick, and cover it evenly half an inch thick with light mould, and put on the lights, and the plants will come up in a week, or probably in less time, if there is a tolerable warmth in the bed; observing, when they appear, to admit air every day, either by tilting the lights considerably in the front or behind, according to the temperature of the weather, or in fine mild weather take them quite off in the middle of the day; for a large portion of fresh air is necessary every day, otherwise the plants will draw up to shank, and go off; remarking, that after the plants have had a week or fortnight's growth, they should be thinned where they have risen too thick, leaving them about an inch and a half apart; then observing, if the plants have unavoidably drawn up with long shanks, it is advisable to sift some light mould out of a fine sieve in amongst them evenly all over the bed, so as to mould their shanks about half an inch or an inch, or as there shall be occasion: this will greatly strengthen their growth, and promote the goodness of the roots; still remembering to indulge them with a large portion of fresh air every mild day, and cover them on nights; observing likewise, if in the advanced state of the plants, the heat of the bed is considerably declined, it may be proper to revive it by application of a moderate lining to continue a very mild bottom heat, to forward the Radishes in a regular growth: thus, by the above proceedings of culture, the plants will advance fast to perfection, and be fit to draw in six weeks.

But in want of frames and glasses for the above purpose, you may cover occasionally with mats, making the hot-bed as before, and mould it the same depth, securing the sides of the mould with boards or wreaths of strawbands; then cradle or arch it over with hoops or rods for the support of the mats, which must be used every night and all bad weather, till the plants are ready for use.

Or in case of scarcity of dung for making hot-beds as above, you may sow some seed in beds of common earth under garden frames, and put on the lights every night and all bad weather; and thus you may raise the plants for use sooner by a fortnight than in the common open borders.

Culture of the Turnep-rooted Kinds.

Respecting the turnep-rooted Radishes, the small round white, and the red sorts are proper to sow as secondaries, as before intimat-

ed, or as required both for spring, summer, and autumn eating; but the large black Spanish Radish, and white kind, are principally in estimation for autumn and winter, more generally the black sort, as superior both for eating, and hardy to stand the winter weather, and is the most commonly known and cultivated, as was formerly observed; all of which, both of the small and large turnep-rooted kinds, may be sown in any free open situation in lightish ground; or the small white and red sorts sometimes sown in warm borders in spring, to have them earlier, or the white sort occasionally in a hot-bed, to have them in the most early season.

The small round sorts may be sown in spring, in February, March, or beginning of April; or for autumn use, sow them in July, August, and beginning of September; at either season sow them broad-cast thinly, and rake them in evenly, and when the plants come up and get into the rough leaf, they must be thinned either by hoe or hand, setting them out four or five inches asunder.

To obtain them early, sow in a warm border or under a frame, &c. in February; or the white sort in a hot-bed. See the *Culture by Hot-bed*.

The large Spanish turnep-rooted kinds should be sown principally in autumn, about the middle or end of July, in any open situation thinly, and raked in; and when the plants have got rough leaves about an inch broad, hoe them out to six or eight inches distance, they will attain full growth for use in September and October, and continue good great part of winter, particularly the black sort; however, it is proper to take up a quantity in November or December, before attacked by severe frosty weather, and depositing them in any sheltered place in land, they may be kept in good perfection till the spring.

Saving Seed of all the Sorts.

To save Radish-seed, you may either leave some plants of the first main crops to run up, or transplant a quantity into an open spot of ground; the latter is more particularly to be recommended for general practice, because, by drawing up the roots for planting, you can judge of the goodness in respect to shape and colour; they should be planted in an open situation.

The proper season therefore for planting out Radishes for seed is the beginning or towards the middle of May, just when the roots are in their prime, and before they begin to run, chusing showery weather if possible.

Observe of the common taper-rooted Radishes to select them with the shortest tops, and

and the longest straight roots of the best colours in the respective varieties, remarking particularly of the short-topped kind, to chuse them always with the very smallest tops, and as of this sort there being some with roots of a deep reddish-purple colour, and others having pale-coloured clear roots, the latter of which are generally more crisp and mild than the former, and are particularly esteemed about London; so that in drawing them to plant for seed, you should keep them separate, observing also the same of the other varieties: then having previously digged an open space of ground for their reception, plant the Radishes, with their leaves entire, by a dibble, in rows two feet and a half asunder, and the same distance in the lines, placing them in the quincunx order, and each root down to its leaves, directly giving them a good watering, to settle the earth close about the roots, and forward their striking, repeating the waterings in dry weather till they have taken fresh root, and show signs of growth.

As to the turnep-rooted kinds, some should be sown in the spring, about March, purposely for seed, and may either remain where sown, hoeing them out to wide distances, or when the roots are arrived to perfection in May or beginning of June, a quantity may be transplanted, chusing the roundest, best-shaped, fairest roots, and planted in rows two feet and a half asunder, as before observed, and water them.

Observe, however, if any of the large Spanish turnep-rooted kinds of the autumn crops should stand the winter, some may be left, or planted out for seed in February.

All the sorts will soon take root, and shoot up to stalk in June, branch widely every way, flower in July, and the seed will ripen in September.

Their ripening is discovered by the pods and seeds changing brown; then cut up the stalks, and spread them in the sun a week or two to dry and harden the pods and seeds, and then thresh them out, observing the seed-pods being of a tough nature, they do not readily break to discharge the seed, so that sometimes they require to be exposed to the weather some considerable time, to render the husks brittle, and sometimes they require to be threshed two or three times over; when they, however, are threshed out, clean the seed from the rubbish, and put it up in bags out of the way of mice.

RAUVOLFIA,—(*Rauwolfia*.)

A genus furnishing two species of shrubbyish tender exotics of South America, retained in our stove collections for ornamental variety: rising with several ligneous stems, six or

eight feet high; adorned with oblong, shining and downy leaves, in the different species, generally by four in a verticillus round the stem and branches; and funnel-shaped, lateral flowers, having each a five-parted permanent calyx, a tubulous corolla, globose at the base, cut into five at the brim:—five stamina, a roundish germen and one style, succeeded by small globular, bilocular, two-seeded berries.

Class and order, *Pentandria Monogynia*.

The species in our gardens are,

1. *RAUVOLFIA nitida*.

Glossy smooth Rauwolfia.] Having smooth stems; and oblong, narrow, smooth leaves by fours.

2. *RAUVOLFIA canescens*.

Hairy Rauwolfia.] Stems somewhat hairy, or hoaryish, and oblong, broader, hairyish leaves by fours.

These two species are retained in many of our principal hot-house collections, in which they form a distinguishable variety in their verticillate foliage, as well as in their flowers appearing great part of the summer months, succeeded by ripe berries, by which the plants may be raised; sown either in autumn, as soon as ripe, or in the spring; sowing them in pots of light earth, and plunged in a hot-bed; and may also be propagated by layers and cuttings in spring and summer, struck by the same means, or in the bark-bed of the stove; and afterwards have the general culture of other stove exotics of the same nature, and always retained in that department.

REED HEDGES.

Reed Hedges are temporary internal fences made with dried reeds, which may be had cheap enough all over the kingdom, and may be expeditiously formed into Hedges by the assistance of posts and railing, and make a cheap temporary fence of great utility for occasional use in gardens, to inclose particular internal spaces of ground, to afford shelter to certain seedling plants, both in nurseries and large kitchen gardens.

But Reed Hedges are particularly useful in some nurseries, to form places of shelter for many sorts of seedling trees and shrubs, &c. which being tender whilst young, require the shelter of a fence in winter to break off the keen edge of cutting blasts two or three years, till they gradually gather strength and a greater degree of hardiness; and for which occasion, in default of other immediate shelter fences of growing hedges, walls, palings, &c. these may be soon erected as at once to form a fence in any part required; these kind of fences are also useful in nurseries for training several sorts of wall-fruit-trees against, to form

form them for walls in gardens, being what the nurserymen call *Trained Trees*; so that these Reed fences being cheap and soon formed, are often used in the nurseries for a double purpose, that is, serving both for shelter, and affording an opportunity of planting trees against each side, six, eight, or ten feet asunder, for the purpose of training for walls, as aforesaid. See NURSERY, &c.

Likewise in large open kitchen gardens Reed Hedges are often employed to good advantage for sheltering tender plants and early crops; such as inclosing particular spaces for a melonary, or place wherein to raise early melons and cucumbers, and often as cross internal fences, running across the ground at considerable distances, under which forming warm borders for the purpose of raising various early crops of esculents more plentifully; serving also to break the force of cutting and tempestuous winds from the crops in the adjacent quarters, and for which purposes many of the kitchen-gardeners about London use these kind of Hedges.

Remark however, these Reed Hedges are not at all adapted for outward fences, as they may be very easily broke through.

But as internal fences for sheltering plants, they are accounted better than walls or pales, because the Reeds generally deaden the winds without reverberating them back again.

The proper Reeds for making these fences are the dried stems of the *Arundo Phragmitis*, or Common Marsh Reed, growing in great abundance by river sides, and in lakes, and marshy places all over the kingdom, furnish a crop of stems annually fit to cut in autumn, and being then bound in bundles, are stacked up or housed to remain for use; great quantities are annually brought to London by water, and deposited in warehouses near the river, where they have great demand for them for the above and some other purposes.

As to the method of making these fences, they are sometimes erected in fixed ranges, and sometimes formed into movable pannels. When to be formed into fixed fences, arrange some stout posts six or eight feet asunder, and five or six high, and from post to post carry two or three ranges of flat thin railing, one range near the bottom, another near the top, and a third in the middle; against this railing place the reeds about two inches thick, having other railing fixed directly opposite, so that the Reeds being placed all along between the double railing, the bottoms resting either upon a plate of wood, or let into the ground, as may be convenient; but

the former is preferable for preserving the bottom part from rotting: and as soon as one pannel is formed, nail the railing as close as possible, and either drive some long spike nails through each double railing, or bind them with strong withy bands, or tar rope-yarn, but nailing is the best, in order to bring them as close as may be, to secure the Reeds firmly in the proper position; and thus proceed till you have completed the range of fencing, the top cut even.

But when intended to have any of these fences formed into movable pannels, to remove to different places occasionally, a framework of railing is prepared as above, each pannel six or eight feet long, and the Reeds fixed therein as before directed; then where-soever it is intended to place them, posts must be ranged six or eight feet distance, to support the several pannels.

Or sometimes the movable pannels are used to defend tender young plants, in narrow borders under walls, &c. placing the pannels inclining against the wall or other fence, in time of severe weather.

RESEDA, Bastard Rocket, *Mignonette*, &c.

It consists principally of herbaceous annuals, biennials, and perennials; some of the biennials in particular merit culture, one as an odoriferous garden plant, another for field culture, for the use of the dyers, &c. growing from one to three feet high, having oblong and lanceolate leaves, and terminated by spikes of small unequal flowers.

Class and order, *Dodecandria Trigynia*.

Characters.] CALYX is monophyllous, many-parted, and permanent. COROLLA, several small, unequal, generally trifid petals, the upper being gibbous at the base, containing a honey juice; and a glandular, plane, erect nectarium at the upper side of the receptacle, between the stamina and upper petal, connivent with the base thereof. STAMINA, twelve or fifteen short filaments, having obtuse erect antheræ. PISTILLUM, a gibbous germen, three or more very short styles, having simple stigmas. PERICARPIUM, a gibbous, angular, unilocular capsule, with apertures between the styles, having many kidney-shaped seeds adhering to the angles of the capsule.

There are many species, the most noted of which, for our purpose, are the two following, the first for the pleasure-ground, the other for field culture.

1. RESEDA *odorata*—(annual-biennial and tender.)

Odoriferous Reseda, commonly called Mignonette.] Hath a tough fibrous root, sending

forth several weak branchy stalks, growing eight or ten, to twelve or fifteen inches long, having oblong, entire, and trilobate leaves, and all the branches terminated by long spikes of greenish-white sweet-scented flowers, having the calyx equal with the petals.

This plant is annual and biennial, is in high estimation for its agreeable fragrance, though is not ornamental neither in its growth nor flowers, but the latter impart a most delightful odour widely around, flowering in summer, continuing several months, even all the winter, if sheltered in a green-house, &c.

Is a native of Egypt; succeeds here in the open air in summer, but requires shelter in winter.

2. RESEDA *Luteola*—(biennial and hardy.)

(*Luteola*)—*Yellow Herb, called Weld, Wild Woad, or Dyer's Weed.*] Hath tough fibrous roots, crowned with long, narrow, spear-shaped, entire leaves, spreading on the ground, upright stems a yard high, garnished also with spear-shaped narrow leaves, and terminated by long loose spikes of yellow flowers, having quadrifid cups; grows wild on old walls and the sides of banks and sterile places in England, &c. but is cultivated in fields for its flower-stems, for the use of the dyers.

Both these species are biennial plants: the first is somewhat tender, requiring shelter from frost: but the second is very hardy; observe however the first sort may be deemed annual as well as biennial; for being sown early in spring, will flower and perfect seeds the same year, and totally perish in winter, if not sheltered; being sheltered all winter in a green-house, it will continue till next summer; it however may more generally be considered as an annual: but the second sort is perfectly biennial; for being sown one year, it does not run up to stalk till next summer, when it flowers and ripens seed, and wholly decays soon after.

Method of Propagation.

They are both raised from seed sown annually, the first sort principally in a hot-bed, or warm border; the other in the open ground.

The first sort, odoriferous Reseda, or Mignonette; being an exotic of somewhat tenderish quality, is generally ranked among the tender annuals, and as such is commonly raised in a hot-bed in the spring, whereby to have the plants flower as early as possible in summer; but for a common general blow, it may also be sown in a bed, border, or pots of natural earth in April, or sooner in pots under shelter: however, when required to have an early bloom for the sake of its fragrance, in

which consists the whole merit of this diminutive plant, some seed should be sown in March or April, in any moderate hot-bed, as directed for tender annuals, sowing some in small pots to remain, and some for transplantation into the full ground, in the end of May or June; however, whilst they remain in the hot-bed, indulge them with fresh air daily, and occasional waterings in common with the other plants; and if some, when advanced an inch or two in growth, are pricked upon a fresh hot-bed, or into small pots, three or four plants in each, and plunged in the hot-bed, it will forward them considerably: in May or in June, according to the strength of the plants and temperature of the season, taking opportunity of mild moist weather, remove them into the full air, retaining some in pots, others transplant with balls into the borders, observing, when the stalks of the plants advance, to place short sticks for their support, and to which tie the stems in a neat manner.

Or in want of a hot-bed, some seed may be sown in one or more middling small pots in March or April, placed under a frame and lights, or hand-glass, or some other protection occasionally, of nights and cold spring weather; it will forward the plants in growth for earlier flowering than if raised entirely in the open ground exposed wholly to the full air; and may afterwards be managed as above.

But the seed of this plant will also grow in the full ground, sown in the middle of April and in May, when the season is become warm and settled, sowing them in light earth, either in a bed by themselves, and raked in lightly, or in patches about the flower-borders, covering them a quarter of an inch deep; and in either method the plants may mostly remain where raised, or some transplanted, as thought expedient, giving occasional waterings.

And if some plants are raised in pots in May, or any time in summer, or towards autumn, and the pots plunged in an east border, or where they may have only the morning sun, well watered all summer, and in October placed in a green-house, glass-case or garden-frame, they will stand the winter, and some of them raised forward in the summer, will flower all the winter season, others raised towards autumn, will continue increasing in growth, and flower strong early next spring and summer.

They ripen seeds in September, when they should be carefully gathered in dry weather.

The culture of the Weld, or Woad, is generally in large quantities in fields, and thrives in any poor land, though it will consequently be more prosperous in a rich soil; the beginning

ning of August is the best season for sowing it, allowing about one gallon to an acre, and sow it broad cast evenly, and harrow it in; the plants will soon come up the same season, and when they are a little advanced in growth, hoe them to thin the crop and kill weeds, leaving the plants six inches asunder; they will shoot up into stalk next spring, and flower in June, at which time the plants should be pulled for use, laid to dry, then tied in bundles and housed.

A quantity of the plants should be suffered to stand every year for seed.

RHAMNUS, (*Cerva spina*) Buckthorn.

The plants are of the tree and shrub kind, comprising several deciduous and evergreen species for adorning the pleasure-ground and green-house collection, garnished with oval and oblong leaves, and small monopetalous, infundibuliform flowers mostly in bunches, succeeded by small round berries.

Class and order, *Pentandria Monogynia*.

Characters. **CALYX**, none. **COROLLA** is monopetalous, funnel-shaped, four or five-parted, and spreading, having a small scale at the base of each division. **STAMINA**, five, or generally as many filaments as there are divisions in the corolla, inserted under the squamulae or scale of the petal, and terminated by small antherae. **PISTILLUM**, a roundish germen, filiform style, crowned by an obtuse stigma, and divided into fewer segments than the corolla. **PERICARPIUM**, a round naked berry of three or four cells, having the like number of roundish hard seeds.

Late improvements in botany have ranged several genera of former authors as species only of this genus, such as the *Frangula*, or Berry-bearing Alder—*Paliurus*, or Christ's Thorn—*Alaternus*—and *Zizyphus*, or Jujube-tree; all of which bearing the *characters* exactly of *Rhamnus*, are to be now considered as species of that genus.

They consist of deciduous and evergreen kinds, mostly of hardy growth, and some of tender quality.

Hardy deciduous Kind.

Under this head is comprised the common Buckthorn, *Frangula*, and *Paliurus*.

1. **RHAMNUS catharticus**.

Cathartic, or Common Purging Buckthorn.

Grows twelve or fourteen feet high, branching numerous and irregularly, smooth, and armed with terminal spines, oval-spear-shaped, sawed, smallish leaves, on long foot-stalks, and at the sides of the branches clusters of small, quadrifid, greenish flowers, succeeded by black berries in autumn, having four seeds.

Varieties. Dwarf Buckthorn, growing a-

bout a yard high.—Dwarf long-leaved Buckthorn, growing five or six feet high.

The common sort grows wild in hedges in many parts of England, but is admitted for variety in the shrubbery plantations; the berries of it are used in medicine, being made into a syrup, good for many disorders, given as a cathartic or purge, said to be good to purge watery humours, and against the dropsy, jaundice, itch, and all eruptions of the skin, &c.

2. **RHAMNUS Frangula**.

(*Frangula*) or Common Berry-bearing Alder.]

Rises with a woody stem, branching numerously ten or twelve feet high, without thorns; oval-spear-shaped, entire leaves, two inches long; and small, greenish flowers, terminating the shoots in clusters; succeeded by round berries, ripening to a black colour in autumn, having generally but two or three seeds.

Varieties. Dwarf Berry-bearing Alder, growing two or three feet high—Dwarf long-leaved.

The common sort is an inhabitant of our woods in many parts of England, but has been long admitted in garden plantations, to increase the variety of hardy deciduous shrubs.

3. **RHAMNUS alpinus**.

Alpine rough-leaved Berry-bearing Alder.

Rises with a woody stem, branching numerously twelve or fourteen feet high, without thorns; larger oval-spear-shaped rough leaves, doubly crenated; and flowers in small clusters.

Variety. Smooth-leaved Alpine *Frangula*.

4. **RHAMNUS Paliurus**.

(*Paliurus*) or Christ's Thorn.]

Rises with a shrubby stem, branching ten or twelve feet high, having numerous weak pliant branches, armed with sharp thorns by pairs, at every joint, having the lower one reflexed; oval leaves alternately, near an inch long, and trigynous yellowish flowers in clusters at the axillas of the branches, succeeded by small, roundish, compressed berries, surrounded by a membranous border.

It grows naturally in Palestine; also in Spain, Portugal, and some parts of France, and is retained here in our shrubberies as a curiosity, as being supposed to be the plant of which the crown of thorns was composed, to place on the head of our Saviour at his crucifixion, the probability of which is supported by accounts of some travellers, by observing that the shrub grows naturally in great plenty about Jerusalem and in Judea.

5. **RHAMNUS lineatus**.

Lineated-leaved Chinese Rhamnus, or Supple Jack. Slender pliant branches without thorns,

6 l. 2

ovate,

ovate, lineated, or line-marked, repand leaves, netted underneath.

Most of the above deciduous species flower about June, but the flowers are not ornamental, being small and mostly of a greenish colour, which in the first three species are succeeded by abundance of berries in autumn, effecting a tolerable variety; but the *Paliurus* rarely ripens its berries in England.

They are all hardy shrubs, and will prosper in any common soil, and may be planted to increase the variety of the shrubbery and other hardy plantations.

They are propagated by seed and by layers, and sometimes by cuttings.

By Seed.—In autumn, or as soon as the seeds can be procured after they are ripe, sow them in light earth, covering them near an inch deep; they sometimes rise the spring following, if sown early in autumn; otherwise are apt to remain a year longer in the ground; when however the plants are a year or two old, plant them out in nursery-rows, to have two or three years' growth, and then may be planted out finally.

By Layers.—Choose the young shoots in autumn, and give them either a little twist or nick in the bark at a joint, then lay them in the usual way; they will be rooted in one year.

By Cuttings.—The first three sorts in particular grow by this method; choose the young twigs for cuttings in autumn, and plant them in rows; most of them will strike.

Evergreen Kinds.

Of these sorts there is but one species common to our gardens, which was formerly a distinct genus (*Alaternus*), but now a species of *Rhamnus*, and comprehends several varieties—all beautiful, hardy, evergreen shrubs.

6. RHAMNUS *Alaternus*.

Alaternus, commonly so called.] Rises with a shrubby upright stem, branching numerously all the way from the bottom, four or five to twelve or fifteen feet high, the branches having a smooth, greenish and reddish bark, closely garnished with oval, stiff, shining green, serrated leaves, placed alternately, and at the axillas dioecious greenish flowers in clusters, with three-parted stigmas, succeeded by round soft berries in autumn, having three seeds.

It is a native of the southern parts of Europe.

Varieties.] Large-growing *Alaternus*—Small-growing *Alaternus*—Broad-leaved *Alaternus*—Narrow-jagged-leaved *Alaternus*—Gold-striped-leaved—Silver-striped-leaved—Blotched leaved—Yellow-striped jagged-leaved—White-striped jagged-leaved—All of which

are evergreen shrubs, varieties of the same species, and of hardy growth, succeeding in any common soil in the open shrubberies and other plantations, and exhibit a very ornamental appearance the year round.

This species and the *Phillyrea* bearing a great external resemblance, are often mistaken for one another; but the *Alaternus* in all its varieties have the leaves placed alternately, and the *Phillyrea* in pairs opposite, so that there is a very obvious distinction, besides being of different genera by the characters of their flowers and fruit. See PHILLYREA.

All the varieties of the *Alaternus* are very ornamental evergreens for adorning the shrubbery compartments, and if the plain green sorts and variegated kinds are intermixed in assemblage with other evergreens, they will effect a very distinguishable variety at all seasons: these plants were also formerly used for ornamental hedges, and at present are often employed to form hedges as blinds to hide any naked wall, or other disagreeable fence, &c. in fore-courts and other conspicuous places contiguous to the dwelling; the variegated kinds being mostly esteemed for this purpose, or the green and striped sorts intermixed alternately, will effect an agreeable variety; which being planted close against the fence, two or three feet asunder, and their branches nailed thereto, they will soon cover it effectually.

They are propagated by seed and by layers; the plain green sorts may be raised by both methods, but the variegated sorts by layers only, whereby to continue them the same with certainty.

By Seed.—The berries ripening abundantly in September or early part of October, should be gathered and sown as soon after as possible; otherwise they will hardly come up till the second spring. Sow them in beds of light mould an inch deep; they will probably come up in the spring; but if not, keep the beds weeded, and they will all come up the spring following; which, after having two years' growth, transplant them in March in nursery rows, to remain till wanted for the shrubbery, &c.

By Layers.—All the sorts may be raised this way, which is the only certain method to continue the variegated sorts. Choose the young shoots of the year in autumn, give them a slit at a joint, and lay them; they will be most of them well rooted by the autumn following; then take them off and plant them in the nursery way, to have two or three years' growth.

Green-house and Stove Kinds.

Consist principally of some species of *Zizyphus*,

zyphus, formerly a genus of itself, but now ranged in the family of *Rhamnus*; and the following are cultivated in some gardens for variety.

The two first are green-house plants, and the other two for the stove.

7. *RHAMNUS Zizyphus*.

Common Zizyphus, or Fijube tree.] Rises with a woody stem, branching irregularly eight or ten feet high, armed with straight prickles by pairs; oval, oblong, smooth leaves, and small digynous, close-fitting, yellow flowers, succeeded by large oval berries.

8. *RHAMNUS Fijuba*.

Indian Fijube Tree.] Rises with a shrubby stem, branching eight or ten feet high, armed with solitary or singly-placed recurved spines, roundish retuse leaves, downy underneath, and aggregate pedunculi supporting small, semidigynous, yellowish flowers, succeeded by large round berries.

9. *RHAMNUS Spina Christi*.

African Christ's Thorn, or Fijube.] Rises with shrubby stems, dividing into slender branches, armed with straight sharp spines by pairs; oval leaves, and small yellowish flowers.

10. *RHAMNUS Cœnolia*.

Ceylon Fijube.] Rises with a woody stem, branching eight or ten feet high, armed with solitary recurved spines; roundish heart-shaped leaves, and aggregate almost close-fitting pedunculi supporting yellowish flowers.

Of the above four kinds, the two first are for the green-house collection, the other two for the stove; so must always be kept in pots, and placed among the plants of those departments.

They are propagated by sowing the stones of the fruit in pots, and plunged in a hot-bed.

Likewise by suckers from the root and by layers.

RHEUM, Rhubarb.

The plants are luxuriant herbaceous perennials, of tall upright growth; for variety in gardens and medical purposes; having very thick, fleshy, branched roots, crowned with singularly large, simple, spreading foliage, one or two feet in length and breadth; and strong erect annual stalks, from about three to six or eight feet high, terminated by large spikes of numerous small six-parted flowers.

Class and order, *Enneandria Trigynia*.

Characters.] **CALYX**, none; or otherwise appears as the **COROLLA**, monopetalous, narrow at the base, and impervious, divided above into six parts, alternately smaller. **STAMINA**, nine capillary filaments inserted into the corolla, and terminated by oblong didymous antheræ. **PISTILLUM**, a short triquetrous ger-

men, three scarcely visible styles, and three reflexed plumose stigmas. **PERICARPIUM**, none; one large, triquetrous, acute seed to each flower, having a membranous border.

There are about six species, all herbaceous and of foreign growth, but grow freely here in the open ground. Are in great estimation as very salutary medical plants, the root being the useful part, which, however, in one or two sorts is of superior quality; one in particular, the *Rheum palmatum*, is esteemed superior to all the others.

1. *RHEUM Rhaponticum*.

Rhapontic, or Common Rhubarb.] Hath a large, thick, fleshy, branching, deeply-striking root, yellowish within, crowned by very large, roundish-heart-shaped, smooth leaves, on thick, slightly-furrowed footstalks; and an upright strong stem, two or three feet high, adorned with leaves singly, and terminated by thick close spikes of white flowers.

It grows in Thrace and Scythia, but has been long in the English gardens; its root affords a gentle purge; is, however, of inferior quality to some of the following sorts; but the plant being astringent, its young stalks, and foot-stalks of the leaves in spring being cut and peeled, are used for tarts.

2. *RHEUM palmatum*.

Palmated-leaved True Chinese Rhubarb.] Hath a thick fleshy root, yellow within, crowned with very large palmated leaves, being deeply divided into acuminate segments, expanded like an open hand; upright stems, five or six feet high or more, terminated by large spikes of flowers.

This is now proved to be the true foreign Rhubarb, the purgative quality of which is well known.

3. *RHEUM compactum*.

Compact thick-leaved Tartarian Rhubarb] Hath a large, fleshy, branched root, yellow within, crowned by very large heart-shaped, somewhat lobated, sharply indented, thick smooth leaves; and an upright large stem, five or six feet high, garnished with leaves singly, and branching above; having all the branches terminated by nodding panicles of white flowers.

This has been supposed to be the true Rhubarb, which, however, though of superior quality to some sorts, is accounted inferior to the *Rheum palmatum*.

4. *RHEUM undulatum*.

Waved-leaved Chinese Rhubarb.] Hath a thick, branchy, deep-striking root, yellow within, crowned with large, oblong, undulate, somewhat hairy leaves, having equal footstalks, and an upright firm stem, four feet high, garnished

nished with leaves singly, and terminated by long loose spikes of white flowers.

5. RHEUM *Ribes*.

(*Arabian Ribes*) or *Granulated, Warted-leaved Persian Rhubarb*.] Hath a thick fleshy root, very broad leaves, full of granulated protuberances, and with equal footstalks; and upright firm stems, three or four feet high, terminated by spikes of flowers, succeeded by berry-like seeds, being surrounded by a purple pulp.—This is a plant of curious singularity.

6. RHEUM *tataricum*.

Tartarian Heart-leaved Rhubarb.] Having heart-ovate, plane, smooth leaves; the petioles half cylindric-angled.

All these plants are perennial in root, and the leaves and stalks are annual; the roots being thick, fleshy, generally divided, strike deep into the ground; of a brownish colour without, and yellow within; the leaves rise in the spring, generally come up in a large head folded together, gradually expanding themselves; having thick foot-stalks, and grow from one to two feet or more in length and breadth, spreading all round; amidst them rise the flower-stems, which are garnished at each joint by one leaf, and are of strong and expeditious growth, attaining their full height in June, when they flower; and are succeeded by large triangular seeds, ripening in August.

Some plants of each sort merit culture in gardens both for variety and ornament; they will effect a singularity with their luxuriant foliage, tall stems, and large spikes of flowers; and may be cultivated in any common soil in beds, borders, or other compartments; planted in autumn or spring.

And as medical plants, they demand culture both for private and public use, they being eminently salutiferous on many occasions; and for which several of the sorts are indifferently used, though the Rhaphontic kind is the most generally cultivated in our gardens for that purpose, and hence is commonly called English Rhubarb; however, most of the sorts may be used similarly; and some are of superior virtue, such as the *Rheum palmatum*, before observed, very distinguishable from the others by its palmated-divided leaves.

They are propagated by seeds sown in autumn soon after they are ripe, or early in the spring, in any open bed of light deep earth; remarking, those intended for medical use should generally be sown where they are to remain, that the roots, being not disturbed by removal, may grow large; scatter the seeds thinly, either by broad-cast all over the surface, and raked well in; or in shallow drills

a foot and half distance, covering them near an inch deep. The plants will rise in the spring, but not flower till the second or third year; when they, however, are come up two or three inches high, thin them to eight or ten inches, and clear out all weeds; though those designed always to stand, should afterwards be hoed out to a foot and a half or two feet distance; observing, if any are required for the pleasure-ground, &c. for variety, they should be transplanted where they are to remain, in autumn when their leaves decay, or early in spring before they shoot; the others remaining where sown, must have the ground kept clean between them; and in autumn when the leaves and stalks decay, cut them down, and slightly dig the ground between the rows of plants, repeating the same work every year.

The roots remaining, they increase in size annually; and in the second or third year many of them will shoot up stalks, flower, and perfect seeds; and in three or four years the roots will be arrived to a large size; though older roots are generally preferable for medical use.

RHEXIA, American Soap-wort.

Consists of hardy herbaceous perennials for the pleasure-ground, rising with stalks a foot high, garnished with spear-shaped leaves, and terminated by tetrapetalous, spreading, red flowers.

Class and order, *Ostendria Monogynia*.

Characters.] CALYX is monophyllous, tubular, ventricose below, four-parted above, and permanent. COROLLA, four roundish patent petals. STAMINA, eight slender filaments inserted in the calyx, having declinated, linear, obtuse, versatile antheræ. PISTILLUM, a roundish germen, simple style, and oblong thick stigma. PERICARPIUM, a roundish, quadrilocular, quadrivalved capsule, in the belly of the calyx, having numerous roundish seeds.

There are several species: those of our gardens are the two following, both of America.

1. RHEXIA *virginica*.

Virginia Rhexia.] Rises with an erect tetragonous stalk above a foot high, garnished with spear-shaped, serrated, sessile, opposite leaves; and the stalks terminated by forked pedunculi, crowned with red flowers, having smooth cups.

2. RHEXIA *mariana*.

Maryland Rhexia.] Rises with erect stalks, ten or twelve inches high; having spear-shaped, ciliated, opposite leaves, and the stalks terminated by pedunculi, crowned with red flowers.

They

They both flower in June, but rarely ripen seeds here.

These perennials succeed here in the open ground all the year, in a dry sheltered place, though it is proper to keep some also in pots, to move under shelter in very severe frosts.

They are propagated by seed sown in autumn, or spring, in pots, to be sheltered from frost; or if placed in a hot-bed in March, it will forward their growth; and when the plants are two or three inches high, plant them out.

RHODIOLA, Rose-root.

It is a low, herbaceous, succulent, odoriferous perennial, for variety in the pleasure-ground, having succulent leaves and stalks, and tetrapetalous dioecious flowers.

Class and order, *Diæcia Octandria*.

Characters.] CALYX, male and female flowers distinct on two separate plants, having monophyllous, erect, four-parted, permanent cups. COROLLA, in the males, four oblong obtuse petals longer than the calyx, and deciduous; with four erect nectariums, shorter than the calyx; and in the females, four obtuse petals, equal with the calyx and permanent, with three or four nectariums like the males. STAMINA, eight subulate filaments longer than the corolla, having simple antheræ. PISTILLUM, four oblong acuminate germens, straight simple styles, having obtuse stigmas. PERICARPIUM, four corniculate capsules opening in the inner side, and many roundish seeds.

There is only one species, grows wild on mountainous parts in England, &c. but has been long a resident of gardens, viz.

RHODIOLA rosea.

Rose-root.] Hath a fleshy, thick, knotty root emitting an odour like roses; sending up annually erect succulent stalks, eight or ten inches high, garnished with numerous, oblong, thick, succulent, serrated leaves, alternately; and terminated by clusters of yellowish-green flowers.

It flowers in June, and the seeds ripen in autumn.

This plant delights in a dry soil, and may be planted in any of the common borders, where it will abide for years.

It is propagated both by parting the roots in autumn or spring, and by cuttings of the stalks, which being cut off early in the summer, laid in a room a week to dry the succulency of the cut; then plant them in a shady border, and if covered close with a hand-glass, they will strike in less than two months.

RHODODENDRON, Dwarf Rose-bay.

It comprises hardy, deciduous, and beautiful

evergreen flowering shrubs for ornamenting the shrubbery and other pleasurable plantations, growing two or three to eight or ten feet high; garnished with lanceolate and oval leaves, and wheel and funnel-shaped flowers in clusters at the ends of the branches.

Class and order, *Decandria Monogynia*.

Characters.] CALYX is five-parted and permanent. COROLLA is monopetalous, wheel or funnel-shaped, five-parted, and spreading at top. STAMINA, ten declinated filiform filaments, having oval antheræ. PISTILLUM, a pentagonous retuse germen, slender style, and obtuse stigma. PERICARPIUM, an oval quincucular capsule, having numerous small seeds.

There are about nine species, the principal of which, in the English gardens, are the following deciduous and evergreen kinds.

Deciduous Kinds.

1. RHODODENDRON ferrugineum.

Ferrugineous Alpine Rhododendron.] Rises with a shrubby stalk, branching irregularly three or four feet high; closely garnished with smallish, spear-shaped, smooth leaves, ferrugineous or iron-coloured underneath; and clusters of funnel-shaped red flowers at the ends of the branches.

2. RHODODENDRON hirsutum.

Hairy Alpine Rhododendron.] Hath a shrubby stem, branching numerously about two feet high; oval-spear-shaped, ciliated, naked leaves, having many iron-coloured hairs underneath, and clusters of funnel-shaped pale-red flowers at the end of the branches.

3. RHODODENDRON Chamæcisus.

Dwarf Rose-bay of Mount Baldi.] Hath a shrubby stem, branching numerous and irregularly two or three feet high; small, oval-spear-shaped, ciliated leaves, and clusters of wheel-shaped flowers at the end of the branches.

Evergreen Kinds.

4. RHODODENDRON maximum.

Large American Laurel-leaved Rhododendron.] Rises with a shrubby stem, branching eight or ten feet high; large, oval, obtuse, veined, shining, green leaves, the margin acutely reflexed, and pale-red flowers at the ends of branches, each pedunculi having but one flower.

Grows naturally in Virginia.

5. RHODODENDRON ponticum.

Pontic Dwarf Rose-bay.] Grows four or five feet high, spear-shaped, smooth, shining leaves, and the branches terminated by clusters of bell-shaped purple flowers.

It grows naturally in humid places in the East, and about Gibraltar.

All these shrubs, both deciduous and evergreen kinds, flower mostly in June; the flow-

ers are monopetalous, funnel and wheel-shaped, in different species, cut at top into five segments; and are sometimes succeeded by seed here in England, especially the second, third, and fourth sorts; the other but seldom.

The plants are all of foreign growth, residents mostly of mountainous, rocky, shady places; and the last generally in moist situations.

They may all be employed to adorn the shrubbery, in which they will appear very ornamental; will grow in any common soil of our gardens as most other shrubs, or sometimes superiorly in soils and situations nearly similar to that where they naturally grow.

They are raised commonly from seeds sown in autumn, or as soon as they can be obtained, in a shady border; the seeds being very small, make the surface of the ground smooth; sow them thereon evenly, and cover them very lightly with fine mould; they will come up in the spring; and after a year's growth, prick them out into a shady situation.

Their propagation may also be tried by layers of the young wood.

RHUS, Sumach and Toxicodendron, &c.

This genus comprehends many species of the tree and shrub kind, for the shrubbery, green-house, and stove; obtaining from five or six, to ten or twelve feet stature; garnished mostly with pinnate and trifoliate leaves, and pentapetalous flowers, mostly in clusters at the ends and sides of the branches.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX is monophyllous, five-parted, and permanent. COROLLA, five oval, erect, patent petals. STAMINA, five very short filaments and small antheræ. PISTILLUM, a roundish germen as large as the corolla; scarcely visible styles, but three small heart-shaped stigmas. PERICARPIUM, a roundish unilocular berry, some hairy, others smooth in different species, having a roundish hard seed.

To this genus is now added the *Toxicodendron*, or Poison tree.

There are, of the *Sumachs* and *Toxicodendrons* together, about eighteen species, all of which are of the tree and shrub kind, of foreign growth, of different parts of the world; consisting of several hardy deciduous kinds for the shrubbery; several tenderer sorts for the green-house; and one for the stove; the most material species found in the English gardens, are the following.

Hardy Sumach deciduous Kinds.

1. *RHUS Coriaria*.

Tanner's Sumach.] Hath a strong woody

stem, dividing and branching irregularly, ten or twelve feet high; having a brownish hairy bark; large pinnated leaves, of seven or eight pair of oval bluntly-sawed lobes, terminated by an odd one, and hairy underneath; and large paniculated spikes of whitish flowers at the ends of the branches.

It grows wild in the south of Europe and in Turkey, where the branches are used instead of oak-bark for tanning leather.

2. *RHUS typhinum*.

Stag's Horn Virginia Sumach.] Hath a shrubby stem, branching irregularly eight or ten feet high, having crooked spreading branches, dividing into thick shoots, covered with a soft velvety down, and resemble the form, colour, and texture of a young stag's horn; pinnated leaves of six or seven pair of spear-shaped acutely-sawed lobes, terminated by an odd one, and downy underneath; and at the ends of the branches, large tufts of flowers, succeeded by close downy clusters of purple seeds, having a singular appearance in autumn and winter.

Variety.] Dwarf Stag's-Horn Virginia Sumach.

3. *RHUS glabrum*.

Smooth American Sumach.] Consisting of the three following varieties.

New England Smooth Sumach.] Rises with a shrubby stem, branching irregularly from the bottom and sides, twelve or fourteen feet high; having spreading branches, dividing into very thick, somewhat downy, smooth, brown shoots; large pinnated leaves, of ten or more spear-shaped lobes, and an odd one, smooth on both sides; and large loose panicles of greenish flowers at the ends of the branches.

Carolina Smooth Scarlet Sumach.] Grows eight or ten feet high, with smooth purple branches, dusted with a greyish powder; long, pinnated, smooth leaves like the other, and the branches terminated by large scarlet panicles of flowers.

Canada Smooth Red Sumach.] Grows eight or ten feet high, having a purplish bark, tinged with a whitish powder; long pinnated smooth leaves, of a shining green above, and whitish underneath; and the branches terminated by large panicles of red flowers.

4. *RHUS Copallinum*.

Lentiscus-leaved American Sumach.] Rises with a shrubby stem, dividing into spreading, smooth, brown branches, four or five feet high; pinnated leaves, of four or five pair of entire lobes, terminated by an odd one; having a membranaceous border running along the footstalk in joints, and large loose panicles of greenish flowers at the ends of the branches.

Variety.

Variety.] Canada Lenticus-leaved Sumach, growing eight or ten feet high, and larger pinnated leaves.

5. *Rhus Cotinus*.

(*Cotinus*)—or *Venetian Sumach*.] Rises with a shrubby irregular stem, branching widely, about ten feet high, having a smooth brown bark; oval, simple, shining-green leaves; and the branches terminated by long hair-like pedicles, dividing into long slender bunches of small purplish flowers.

In Italy and Spain, where this shrub grows naturally, they use the bark for tanning leather.

Hardy Toxicodendron Deciduous Kinds.

These are of the shrub kind and deciduous, natives mostly of America; were formerly ranged as a distinct genus, (*Toxicodendrum*) but are now made species of *Rhus*; most of the sorts abounding with a milky poisonous juice, obtain the appellation of Poison-tree in America, where they grow naturally in great abundance.

6. *Rhus Toxicodendron*.

Common American Toxicodendron, or Poison-Oak.] Hath a low shrubby stem, branching about three feet high, the lower ones trailing and rooting in the ground; ternate or three-lobed leaves, having roundish, angulated, and sometimes entire lobes, generally a little downy; and loose panicles of small whitish flowers at the sides of the branches, succeeded by whitish berries in autumn.

Varieties.] Smooth-leaved—downy-leaved—upright-growing.

7. *Rhus radicans*.

Radican American Toxicodendron.] Rises with a shrubby stem, branching four or five feet high, having trailing, radican, or rooting branches; ternate smooth leaves, with oval entire lobes, petioled; and short spikes of greenish flowers, succeeded by roundish berries in autumn.

Variety.] With upright branches.

8. *Rhus Vernix*.

Varnish Tree, or Pinnated-leaved American Toxicodendron, or Poison-Ash.] Rises with a strong woody stem, branching thinly on every side, seven or eight feet high: pinnated leaves of three or four pair of oblong entire lobes, and an odd one; and at the axillas, loose panicles of small greenish flowers, and roundish berries, not ripening here. The milky juice of this tree being remarkable for staining, is supposed to be the true Varnish-Tree, from which the varnish is collected.

All the above eight hardy species being deciduous, produce their leaves in spring, and shed them in the autumn.

They flower here mostly in June and July, for the general part in clusters and panicles; each cluster composed of numerous small pentapetalous flowers, succeeded in some sorts by seeds, ripening in September.

The plants are all proper furniture for shrubberies, and other ornamental plantations, to increase the variety of the deciduous collection; they may be planted in any open compartments, in assemblage with other hardy deciduous shrubs, and they will effect a very agreeable diversity in summer, and some sorts also in autumn and winter; particularly some of the Sumach kinds, with their stag-horn, brown, velvety branches, and their large red panicles.

Observe, as several of the Sumachs abound in suckers from the root, and some of the *Toxicodendrons* increase exceedingly by their trailing radican branches, they should be cleared therefrom every year in winter.

Method of Propagation.

They are all easily propagated by seeds; several sorts also by suckers and their rooting branches; and all the sorts by layers.

By Seed.—Such sorts as do not furnish suckers, &c. may be easily raised from seed, procured from abroad, which should be sown soon after they arrive, either in large pots or in a bed or border of light earth, and covered half an inch deep; they will sometimes come up in May or June following, though if in pots and plunged in a hot-bed about six weeks, it will forward them; being careful to remove them to the full air soon after the plants appear; however, as those in the natural earth sometimes remain till the spring after, before they vegetate, keep the ground clear from weeds, give water in dry weather in summer, and if a severe winter, give occasional shelter of mats, the first year; and when the plants are one or two years old, plant them out in nursery rows, till large enough for the shrubbery.

By Suckers.—Several of the Sumachs send up abundance from the root; take them up any time in winter, and plant them in nursery-rows for a year or two.

By their radican Branches.—The two first *Toxicodendrons* multiply by their branches, which trail and root in the ground as they advance, which may be taken up in autumn, winter, or spring, with roots, and they will form proper plants.

By Layers.—Any of the sorts furnishing lower branches, may have the young wood layed by slit-laying in autumn, and many of them will be rooted in a year.

Most of the species of *Rhus* abound with a

milky juice, reckoned more or less poisonous, particularly the *Toxicodendrons*; as a slight touch of the leaves of these sorts cause violent itchings, sometimes followed by an inflammation and swelling; and if the juice of the wood or leaves is suffered to remain on the skin but for a few minutes, it occasions pustules like the itch: it is also said, the wood of the Poison tree, when burned, emits a very noxious fume, that will suffocate animals exposed thereto in a room.

Green-house Kinds.

Consists of three African Sumach shrubs, comprehending several varieties; retaining their leaves all the year by shelter of the green-house in winter, and effect an agreeable variety in that collection.

9. *Rhus tomentosa*.

Downy African Sumach.] Hath a shrubby stem, branching irregularly, six or eight feet high; ternate leaves, downy underneath, composed of angular, rhomboidal, sub-petiolated lobes, downy underneath, and slender bunches of whitish-green flowers from the sides of the branches.

Varieties.] Hairy-leaved—Serrated-leaved—Jagged-leaved—Oval-lobed.

10. *Rhus angustifolium*.

Narrow-leaved African Sumach.] Hath a shrubby stem, and irregular brown branches, growing from five or six, to ten or twelve feet high in the varieties; ternate leaves, having linear-lanceolate, entire, petiolated lobes, downy underneath; and small loose bunches of whitish-green flowers from the sides and ends of the branches.

Variety.] Silvery cut-leaved.

11. *Rhus lucidum*.

Shining-leaved African Sumach.] Hath a shrubby strong stem, and irregular brown branches, growing ten or twelve feet high; ternate leaves, having wedge-shaped, sessile, smooth, shining-green lobes; and small bunches of greenish flowers.

Varieties.] Round lobed—Heart-shaped-lobed—Dwarf growing.

These three green-house species must be always kept in pots, in order for moving to shelter in winter, managing them as other shrubby plants of the green-house collection. See GREEN-HOUSE PLANTS.

They are easily propagated by layers and cuttings.

By Layers.—In spring, lay any of the lower young wood in the common way, and they will be rooted and fit to pot off in autumn.

By Cuttings.—Plant cuttings of the young shoots in April, May, or June, in pots; and

if plunged in any hot-bed, they will soon strike, giving occasional shade and watering, and towards autumn pot them off separately.

Stove Kind.

12. *Rhus Cobbe*.

Ceylon Sumach.] Hath a shrubby stem, branching eight or ten feet high; ternate leaves, having oval, acuminate, sawed lobes, and clusters of whitish-green flowers at the ends of the branches, having downy peduncles.

It is a tender exotic, requiring a stove in this country, so must always be kept in pots, and placed in that department and managed as other shrubby hot-house plants.

Propagate it by cuttings in the spring, planted in pots, and plunge them in a bark-beck.

RIBES, Currant-tree and Gooseberry-bush.

The Currant and Gooseberry are hardy deciduous shrubs, species of the same genus, each comprising many varieties, all of bushy growth; garnished with trilobate simple leaves, and very small pentapetalous flowers from the sides of the branches; some in racemous clusters, others singly, succeeded by globular berries, valuable as early summer fruit, both some in their young green state, for several culinary purposes, and wholly in their mature growth of ripeness for the table dessert; continuing for use, in their different stages of growth, from May till September.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is monophyllous, ventricose, cut into five concave segments, and permanent. COROLLA, five small obtuse petals attached to the border of the calyx. STAMINA, five subulate filaments inserted in the calyx, having incumbent compressed antheræ. PISTILLUM, a roundish germen under the flower, bifid style, and obtuse stigma. PERICARPIUM, a globose, umbilicated, unilocular berry, full of pulp, and many roundish compressed seeds.

The Currant and Gooseberry were long considered each as a separate genus; *Ribes* the Currant, and *Grossularia* the Gooseberry; but agreeable to systematic botany, they are now joined together, the *Grossularia* being made a species of *Ribes*; all the Currant kinds having inermous or thornless branches, and racemous clusters of flowers and fruit; and the Gooseberry have spinous branches, and flowers and fruit for the most part singly.

Currant Kinds.

There are three species of the Currant-tree, two of which and their varieties, merit culture for their fruit; the other as a plant of variety or observation; all of which are of

shrubby growth, generally dividing or branching out low into bushy heads; and all smooth or unarmed, having no thorns on the branches.

1. *RIBES rubrum*.

Common Red Currant-tree, &c.] Hath a shrubby stem, dividing low into many branches, forming a bushy head, five or six feet high, or more, without thorns; broad trilobate leaves, and small smooth pendulous clusters of plane greenish flowers, succeeded by clusters of small berries.

It grows naturally in woods and hedges in England, and most parts of Europe.

Varieties.] Comprises all the sorts of Red and White Currants, as common, small, Red Currant—Large Red Dutch Currant—Long bunched Red Currant—Champaigne Pale-red Currant—Common small White Currant—Large White Dutch Currant—Yellow blotched leaved Currant—Silver striped-leaved—Gold striped leaved—Gooseberry-leaved.

All these sorts are varieties of one species, *Ribes rubrum*, or *Common Red Currant*, it being the parent from which all the others were first obtained from the seed, and improved by culture; they all flower in the spring, and the fruit ripens in June and July; and by having the trees in different situations and modes of training, such as plantations of standards in the open quarters, for the general supply, others trained against walls or pales, of different aspects, the fruit may be continued ripe in good perfection, from about the middle of June until October or November, provided the later crops are defended with mats or nets from the birds; the ripe fruit of all the varieties are valuable, not only to eat raw, as being of an agreeable, quick, acid relish, and fine cooling quality in the hot season, excellent to quench thirst and create an appetite; but the red sorts in particular are also made into jellies, tarts, sauces, and other culinary preparations. Likewise, of Currants is made good wine, and they are also used in medicine; so that plenty of the trees should be cultivated in every garden for the fruit, both for private use and in public gardens for the supply of markets: as to the variegated-leaved kinds, they are valued as furniture for the shrubbery, to cause diversity in the different variegations of their leaves; they also bear fruit plentifully like the other kinds; and all the varieties of every sort are very easy of propagation and culture, by cuttings, suckers, and layers. See their *Propagation*.

2. *RIBES nigrum*.

Black Currant-tree.] Hath a shrubby stem, dividing low into many branches, forming a bushy head, five or six feet high; with long

brownish coloured shoots; broad trilobate leaves and racemous clusters of oblong greenish flowers, succeeded by thin clusters of large, black, strong-flavoured berries.—The whole plant, on being handled, imparts a peculiarly rank odour.

The fruit of this species being of a strong flavour and somewhat physical relish, is not generally liked; it however is accounted very wholesome, and of which is also made a syrup of high estimation for sore throats and quinseys; hence the fruit is often called squinancy berries.

Variety.] *Pennsylvanian Black Currant.* Having smaller shoots and leaves; not strong scented; and small fruit of but little value; so the shrub is esteemed only for variety in shrubberies.

The mode of bearing of all the sorts of Currants, is both on the old and young wood, all along the sides of the branches and shoots, often upon a sort of small spurs and snags, producing the fruit in numerous long pendulous clusters.

Grossularia, or Gooseberry Kinds.

Of the *Grossularia* or Gooseberry kinds, there are four or five species, comprehending many varieties, all of which are of bushy growth, from about three or four, to six or seven feet high: some being upright, others of reclined growth; have all their branches armed with spines, and produce their fruit both on the young and old wood, all along the sides of the branches and shoots: sometimes immediately from the eyes or buds; of the young wood in particular, and also on small spurs on the older branches; in all of which the flowers and fruit arise, some singly, others in small bunches; all of the berry kind; useful both when green and ripe; green, for tarts, pies, sauces, and for preserving in bottles for winter use; and when ripe, it is valuable as an early dessert fruit; and the different sorts afford great variety at table, in their different colours and relishes.

3. *RIBES Grossularia*.

(Grossularia)—or Common Gooseberry-bush.] Rises with a low shrubby stem, dividing low into a very branchy bushy head, armed with spines; trilobate smallish leaves, having hairy ciliated foot-stalks, and small greenish flowers, succeeded by hairy berries.

Varieties.] Consists of many varieties of the fruit, of different sizes and colours, as hereafter described.

4. *RIBES reclinatum*.

Reclined bread-leaved Gooseberry-bush.] Rises with a low shrubby stem and reclined somewhat prickly branches; trilobate broadish

leaves, and small greenish flowers, having the pedunculi furnished with triphyllous bractæa.

5. *RIBES oxycanthoides*.

Hawthorn-like, or most prickly Gooseberry-bush.] Hath a shrubby stem, and branches armed on all sides with spines; and largish trilobate leaves.

6. *RIBES Uva crispa*.

Smooth-fruited Gooseberry.] Hath a shrubby stem and branches, armed with spines; trilobate leaves; pedicles having monophyllous bractæa; and smooth fruit.

7. *RIBES cynosbati*.

Prickly-fruited Gooseberry-bush.] Hath a shrubby stem and branches, armed with spines mostly at the axillas; and prickly fruit in clusters.

Varieties of the different species.] Many varieties of Gooseberries have of late years been raised from seeds; some of which are very large, and in the numerous varieties many are round berries, others oval; some hairy and some smooth, and of different colours, as Red—Green—Yellow—White, &c. consisting of the following varieties of each sort.

Red Kinds.—Small early Black-red Gooseberry—Hairy Red Gooseberry—Smooth Red Gooseberry—Deep Red Gooseberry—Damson, or large Dark-red Gooseberry—Red Raspberry Gooseberry—Early large Black-red Gooseberry.

Green Kinds.—Early Green Gooseberry—Hairy Green Gooseberry—Smooth Green Gooseberry—Green Gascoigne Gooseberry—Green Raspberry Gooseberry.

Yellow Kinds.—Great oval Yellow Gooseberry—Great Amber Gooseberry—Hairy Amber Gooseberry—Early Amber Gooseberry.

White Kinds.—Large White Crystal Gooseberry—Common White Gooseberry—White-veined Gooseberry.

Other Varieties of different Sorts.] Champagne Gooseberry—Rombullion Gooseberry—Large Ironmonger Gooseberry—Smooth Ironmonger Gooseberry—Hairy Globe Gooseberry—Large Tawney, or Great Mogul Gooseberry.

Of each of the above classes of the varieties of Gooseberry, there are many others in the Grossularian catalogues, by name, differing only in the peculiar sizes and various tinges of the respective colours of the fruit, all originally obtained from seed; and in many of which now in culture the berries are remarkably large, particularly in some of those proceeding from what are called the Lancashire gooseberries, but many superior new varieties are now also raised from seed in many other places; and most of the nursery-men are

furnished with plants thereof in great variety: and the particular sorts may be propagated abundantly, and continued the same, by cuttings, suckers, and layers.

All the foregoing species of *Ribes*, both Currant and Gooseberry kinds, and all the different varieties, are very hardy shrubs, that prosper almost any where, both in open and shady situations, and in any common soil; bear plentifully in any exposure, though in open sunny situations, they produce superior fruit, ripening to a richer vinous flavour; but it is eligible to plant them in different situations and aspects, in order to have the fruit as early and late as possible.

They are commonly planted in the kitchen garden mostly as dwarf standards, in the open quarters, for the general supply; being disposed sometimes in continued plantations in rows, eight or ten feet by six asunder, where great quantities of the fruit are required for market or other large supplies; and are sometimes disposed in single ranges round near the outward edge of the quarters, six or eight feet asunder; frequently in single cross rows, in order to divide large quarters of ground into separate wide plats or breaks, of from twenty to thirty or forty feet width; which also serves to shelter the ground a little in winter; in all of which methods of planting them as standards, they should be generally trained up to a single stem about a foot high, then suffered to branch out every way all around into bushy heads, keeping the middle however open, and the branches moderately thin, to admit the sun and free air; though if some are fanned, that is, trimmed on two sides oppositely, so as to make the other branches range in a line like an espalier, whereby they will take up much less of the ground, and, by admitting the sun and air more freely, they will produce large fair fruit.

They are likewise trained against walls or palings, like other wall trees; but principally some of the large red and white Dutch Currants, in which they will produce fine large fruit, and those against any south fence will ripen early and be high flavoured; but it is proper to plant a few both against south, north, east, and west walls, in order to obtain the fruit ripening both early and late, in a long succession. It is also proper to plant a few of the finest sorts of Gooseberries against a warm fence, both to have early green Gooseberries for tarts, &c. as well as to ripen early; and they will grow very large and fine.

Sometimes both Currants and Gooseberries are also trained in low espaliers for variety, and they produce very fine fruit.

All the varieties of these shrubs are raised plentifully in the nurseries for sale.

Method of Propagation.

All the sorts of Currants and Gooseberries are expeditiously propagated by cuttings, suckers, and layers; but as every cutting and slip will most readily grow, that mode of propagating them is most commonly adopted in the nurseries, in raising great quantities for sale; also by seed to obtain new varieties, particularly Gooseberries.

By Cuttings.—Autumn, at the fall of the leaf, is the most eligible season for planting the cuttings; it may also be performed any time in winter, in open weather, and early part of the spring; choosing the young straight shoots, cutting them about ten or twelve to about fifteen inches long, prune the weak tops, and plant them in any shady border, or where most convenient, in rows a foot asunder, each full half way into the ground; they will root firmly the ensuing summer, shoot at top, and form tolerable little plants by next autumn, when every other row may be thinned out, and planted in nursery lines two feet and half asunder; afterwards train the whole for the purposes designed.

Observe, those designed for common standards should be trained up each with a twelve inch stem, then encourage them to branch out all around at that height to form a full head; for if suffered to branch away immediately from the bottom, or to run up in bottom suckers, according to the natural mode of growth of these kind of trees, as is often the case in many gardens, they overspread the ground, that no under-crops can grow prosperously near them, as well as appear unsightly, and render it inconvenient to do the necessary cultural work of the ground under their low-spreading branches: it is therefore of importance to keep them to a single stem, a foot at least high, then suffered to form the first set of branches, trimming off low stragglers, and encourage the more upright growths: thinning them to moderate distances, and reduce long ramblers to preserve a somewhat regular head; the trees will thus assume a decent appearance, admit of small crops under them, and will be more easily kept in regular order.

And if intended to train any of them with fanned branches, either for fanned standards, or for walls and espaliers, they must be encouraged to branch out near the bottom, with the branches ranged the way of the rows, cutting off all cross or foreright shoots, so as to form the side branches in a straight range, like an espalier, &c.

In all the above modes of training these

shrubs, by cuttings, they will attain a bearing state in two or three years.

By Suckers.—All the sorts send up suckers very plenteously from the roots, each sucker forming a proper plant, and is the most expeditious mode of propagating all the varieties, both Currants and Gooseberries; as the suckers being mostly furnished with roots, they at once form immediate rooted plants; they may be taken up in autumn, winter, or spring, with roots, or even such as are without fibres will succeed; for the lower part having been situated in the ground, near the root, acquires a rooty texture, is naturally disposed to send out fibres very soon; planting them either in nursery rows for a year or two, or such as are tall and strong may be planted at once where they are to remain: observing to train the whole for the purposes intended, as directed for the cuttings, and they will form bearing plants after one or two years growth.

But the propagating them by suckers, is by some objected to, as alleging they incline to run greatly to suckers again, and encumber the ground; there is, however, no very material peculiarity in this by suckers more than cuttings, &c. for it is peculiar to these shrubs, let them be raised either by seeds, cuttings, or any other method, to be naturally disposed to send up many suckers from the roots annually, though probably, those raised by cuttings taken from prime bearing trees, may sometimes sooner form full bearers. See SUCKERS.

Sometimes these shrubs having been permitted to advance with several stems, formed by suckers that have arisen directly from the root, the whole forming a large spreading bush, which, if taken up, may be divided into several separate plants, with good roots and branchy heads, and planted out finally to remain, they will at once commence immediate good bearing plants, producing fruit the following summer.

By Layers.—The young branches being layed any time in autumn, winter, or spring, will readily strike root, and next autumn be fit to transplant.

In the general propagation of these shrubs, we would observe, that, as they naturally throw out many suckers from the root, so as often to become troublesome, it is proper, previous to planting the cuttings and suckers, &c. to rub off close all the buds or prominent eyes, from the lower part, as far as they are to be put into the ground, which will in some measure diminish their tendency in the production of suckers: likewise, when transplanting the young plants, if they discover any tendency at

at the bottom for suckers, let all such parts be also carefully rubbed or cut off close.

By Seed.—This is practised occasionally to obtain new varieties of improved properties in the size and flavour of the fruit; but is more generally in practice for Gooseberries than currants, as the former are very prolific in many different varieties from seed, and by which numerous fine sorts have of late years been raised, the berries remarkably large and rich flavoured:—the seed of the ripe berries may be sown in autumn, in any bed or shady border of lightish earth, the plants will rise plentifully, permitting them to have one or two year's growth, then transplant them in nursery rows, to remain till they acquire a proper growth for bearing in some tolerable perfection; training them in the interval the same as those in the other methods of propagation; and, when become eligible bearers, those productive of superior fruit may be transplanted into the garden at the proper season, and the approved sorts thereof may be propagated for increase in the usual way, by cuttings and layers.

Final Transplantation.

When these shrubs, raised by the different methods as above, are grown about two or three feet high, in tolerable branchy heads, they are of a proper size for transplanting finally, into the garden where they are to remain for bearing.

They may be transplanted any time from October until March, in open weather.

Plant them in rows, eight or ten feet distance, both as standards and for walls, &c. observing to plant the principal quantity as standards for the general supply, and a few of the choicer sorts for walls, particularly of the Currants.

In planting them for standards, if a full or continued plantation of them is intended, set them in rows eight or ten feet asunder, as above observed, and six distant in the ranges; and if designed in single rows, either round or cross ways the quarters, allow full seven or eight feet distance in the row, for if closer, they will soon meet and prove troublesome.

And in planting them against walls or espaliers, allot principally a larger supply of red and white Currants, or most abundant of the red, especially where they are also required for culinary purposes, in tarts, pies, jellies, preserving, &c. as being more eligible for those occasions than the white Currants, which, however, is equally excellent as a dessert fruit, and by some preferred to the red sorts; but both the sorts merit admittance abundantly in the above order of training, in every garden,

where there is an eligible portion of walling or paling, &c. to spare for that purpose: and in which it is proper to dispose them in different aspects, some against south walls, or other similar close fences of the garden, for the production of early fruit, and others on west and easterly exposures, for successional ripening in a principal production, and a plentiful supply against northerly walls to continue a regular succession of ripe fruit late in the season: and for all of which, the plants should be trained, each with a very short stem, to branch out within a few inches of the ground, and planted six to eight or ten feet distance, arranging the branches more or less horizontally or upright, according as the allotted space of walling, &c. admits, three or four, to five or six inches asunder; and thus, being managed as hereafter directed, under the article, *Training them against walls, &c.* they will bear very abundantly in superior perfection, in size and goodness of the fruit.

A few prime sorts of gooseberries being planted also in the above order, principally on south walls for earliest fruit, and trained in the same manner, they will yield a desirable early production accordingly.

And where any gooseberries or currants are designed for training in the espalier order, plant and train them as those against walls, as above; and they will bear in similar perfection in a very agreeable variety.

General Culture, both in Standard Bushes, and against Walls and Espaliers.

1. *Their culture in common standard bushes in the open ground.*] In the general standard bushes arranged in the open quarters of the garden, both of gooseberries and currants, continue to train them, as before observed, each with a clean, single stem, about ten or twelve to fifteen inches, or a little more or less, as it may seem necessary on particular occasions, or according to the different growths of the plants; and then let the head branch out full and regularly, three or four feet high, and kept to some regular order, by occasional necessary pruning; either trained concave or hollow in the middle, or permitted to run up full in the centre, convexly, nearly in their natural order; but, in both cases, keep the general principal branches tolerably thin, at moderate distances, five or six inches at least asunder, at the extreme parts, whereby to admit the benefit of the free air and sun more effectually in summer; essentially necessary for improving the size and maturity of the fruit, and to ripen regularly in full perfection and proper flavour; retaining the same general branches several years,

or as long as they continue good bearers; and only according as any casually decline; they must be displaced, and young wood retained in their room; regulating the whole by proper pruning, never with garden shears, as sometimes done, but always with a knife in a regular manner, less or more, as they may require.

In the process of performing the necessary pruning in these standard bushes, the head of branches may either be kept moderately low, not exceeding three or four feet at most, and within proportionable compass; or permitted to advance more fully where they have good scope for their growth; in which, the shoots being suffered to run mostly at their full length, especially the gooseberries, except reducing long rambles, the head will aspire higher, and run more spreading, and, at last, will generally shoot in a more moderate degree, than such as are close pruned down annually to a particular height, &c. and the branches being kept thin with some regularity, will bear plentifully in good perfection; and this mode of growth is more particularly applicable to gooseberries, as above observed, which should be but very moderately shortened, or sometimes not at all in any general manner, as thereby they will not run so considerably to wood every summer, as when the shoots are much pruned down: but as currants generally run more extensively in a straighter upright growth, higher than gooseberries, if permitted to shoot, they require shortening more considerably in proportion, in order to continue them within some moderate compass; though if they are allowed to run in an aspiring growth, they will form large heads, four, five, or six feet high, and if the general branches are kept moderately thin, in some tolerable regularity, will bear fruit abundantly almost their whole length.

However, it may be proper to observe in general of these standard gooseberries and currants, that if the heads, by proper pruning, are kept moderately down to about three, or not exceeding four feet, and the branches continued in some regular order, at moderate distances from one to another, as formerly intimated, and hereafter directed, they will most probably produce larger fruit, ripening sooner, and with a better flavour; but remarking, in this case, that by the annual pruning to keep the shrubs low and regular, it causes them to throw out numerous shoots every summer, and crowd the head with useless wood, which must be regulated accordingly, by pruning them every winter, to retrench all that are evidently superfluous, and reserv-

others occasionally in proper places for young bearers, and to cut out irregular crowding branches occasionally.

But it should be also observed of these bushes in general, that as in every mode of growth, training, and pruning, they naturally send out numerous shoots annually in summer, from the sides and terminations of all the main branches and bearers, they require pruning accordingly, less or more every year, to retrench the superabundant and irregular growths, in order to preserve some degree of regularity, and open expansion in the branches, for the advantage of the fruit.

This general pruning is performed in winter, or any time from the fall of the leaf till February. With your knife retrench all superfluous shoots of last summer from the middle of the plants, and from the sides of most of the mother branches, except leaving a sufficiency where a supply of young wood appears necessary, and generally reserving a terminating shoot to every branch, and some occasional shoots in casual void spaces below, and other parts, either to be coming forward for young bearers, or to fill any present or apparently future vacancy; or in old trees, to supply the place of any worn out branches, or dead wood, which should always be retrenched, and some contiguous shoots retained; and clear the bottom from all suckers, &c.

At the same time observing, that when the branches in general become too numerous and crowding, or grow across, or in any very irregular growth, to cause confusion and disorder, they should also be regulated by pruning out the most irregular, leaving the others five or six inches asunder; likewise, retrench all low stragglers; and according as any of the branches become too long, or advanced higher than you intend, or any long Rambler happening, they should be reduced to order, by shortening them down to some convenient young shoot, or lower young branch terminated by one; for in reducing or shortening the branches, as occasion may require, they should not be stumped off to naked ends, but pruned down to a young shoot or branch, as just hinted, that they may still terminate in a young shoot if possible, for a leader.

The general supply of young shoots may be more or less shortened, according to their strength and situation, but more particularly the currants, if thought necessary to keep the head low and within moderate compass; cutting the upper shoots to six, eight, or ten inches; but the lower ones designed to grow up to fill any vacancy, leave longer in proportion, or at full length, as it shall seem proper, till

arrived.

arrived to the desired height, conformable to the general branches of the head.

But the Gooseberry kinds having the young wood much shortened, it causes them to throw out very numerous lateral shoots in summer, and crowd the bushes exceedingly with unnecessary wood; it is therefore eligible to shorten the shoots of these kinds but moderately, or leave them mostly entire, or at full length; such, however, as recline considerably downward, or ramble away from all the rest, should be reduced with the knife, so as to preserve a little regularity in the head.

To conclude, be careful always, both in the Currant and Gooseberry kinds, not to suffer them to become of straggling growth, spreading near the ground, nor too much crowded at top; but annually clear off all suckers from the bottom, all lower straggling shoots from the stem, and keep the middle of the head open, and the branches in general thin about six or seven inches asunder, as aforesaid, preserving all the small lateral, bearing snags, natural spurs and fruit-buds; and thus these shrubs will always bear large and fair fruit in great abundance.

Their culture in fanned Standards.—If intended to fan any of them in standards, ranging the branches in the manner of espaliers, you must encourage only the branches that range the way of the rows, trimming off all fore and back shoots, and range the others about six inches asunder, at full length, till those of each tree nearly approach, which may be supported occasionally with stakes; giving occasional pruning both in summer to retrench all superfluous and projecting foreright shoots; and in winter to give a general regulation as observed for the common bush standards.

Training them against walls and espaliers.—

Let them branch out near the bottom, as formerly noticed in the nursery culture, clearing off all foreright growers, and train the others horizontally to the wall, &c. three or four to five or six inches asunder, at full length, till they have filled the allotted space; they will naturally form fruit-buds all along their sides, and bear abundantly. Observe to give them a summer and a winter pruning; in summer to retrench close all foreright, and evidently superfluous shoots, and train in only an occasional supply of some of the most regular shoots towards the lower parts, or where it may seem necessary, to remain till winter, in case of a vacancy, or to be in training for young bearers; and if then not wanted, must be displaced; and by this regulation in summer, it not only preserves the uniformity of the trees, but ex-

hibits the fruit to view, and gives access to a due portion of sun and air to improve its growth and flavour. And in winter pruning, see if there are any vacancies, and retain some contiguous shoot left in summer, cutting out any worn out or naked branch, down to some lower shoot or young branch, as observed of the standard bushes; looking occasionally to the lower part of the trees for any well-placed strong shoots, and see if they are wanted either to fill a present vacancy, or for training in to serve future purposes to supply the place of any old branch becoming naked, or unfurnished with bearing parts; in which cases, retain occasional supplies of young wood as you shall see necessary, keep all the main branches at regular distances, preserving all the spurs and fruit-buds, but cut off any long projecting snags, and all dead wood. Then train the whole straight and close to the wall at the distances aforesaid.

These trees, thus properly trained against walls, will grow eight or ten feet high, and extend widely every way.

Of the Fruit.

Young green fruit will be of proper size to gather for tarts, &c. in May, and early part of June; though gooseberries of the early kinds are sometimes advanced in small growth for the above occasions, in April, and more especially in trees trained on a south wall, to gather in small portions, as an early rarity, in some desirable kitchen uses, for which they are adapted.

However, the general production in the standard bushes in the open ground, will advance fast to a more eligible size of growth in May and June, to gather in some considerable portions for the several culinary purposes; though it is not advisable to make very considerable gatherings while the berries are yet in a small, green state of growth, as it would thin the trees considerably in making any great bulk in the quantity together, of small fruit thus gathered; unless the bushes are abundant to admit of gathering only some of the largest berries from many different bushes accordingly; but as they increase in size in the more advanced part of May, and till nearly of full growth in the middle or latter end of June, the gatherings may be more abundant in proportion; which, in the principal sorts, should generally be effected in the thinning order, particularly in those trees on which it is intended to retain a sufficient crop to acquire full growth for ripening.

But for the above occasion, in the young green fruit, it is principally gooseberries that are proper, both for immediate use, in the different

ent culinary purposes; and for bottling to keep for similar future occasions; observing, that for the latter purpose, the berries should be of some tolerable advanced size; and of which growth they are also very proper for most kitchen uses, to which they are applicable.

Though currants of the red sorts are also occasionally gathered while in their green state for tarts, where in particular request to make a variety at table; but they are not very eligible for that purpose, till they are nearly in full growth, and beginning to redden; and are in the greatest perfection for all their applicable purposes when fully grown, and perfectly ripe, both for the table, and for tarts, pies, preserving, &c.

Gooseberries, however, are always best for culinary uses, while in a green, unripe state, proper both in small, middling, and advanced growths, or even till nearly full grown, and beginning to change for ripening: but should attain full maturity of ripeness for table fruit, and for making gooseberry wine, &c.

The fruit of all the varieties, both Currants and Gooseberries, on standards and against walls, begin to ripen in June, but do not attain full perfection till July; those against warm walls ripen soonest by a fortnight, if the trees are properly dressed in summer, and will be succeeded by the standards for the general crop.

When designed to continue a supply of these fruit as long in the season as possible, it is proper to net some of the fullest trees, when they begin to ripen, to defend the berries from the birds; especially currants; and mat others to shade them from the sun, in order to retard their ripening. And if, when full ripe, some are closely matted with large mats, particularly Currants, it will preserve the fruit in perfection on the trees till October or November.

Of forcing them for early Fruit.

Gooseberry and currant trees are occasionally forced for early fruiting, by means of artificial heat in fruit-forcing-houses, hot-walls, or forcing-frames, &c.

For this purpose, some young trees being planted in largish pots, one plant in each, and being advanced to a full state of growth for plentiful bearing, may be introduced in any of the above forcing departments as are in cultivation in that business by fire, or hot-bed heat, or both occasionally, in forwarding any principal fruit-trees, plants, or flowers, at the proper season, January, or February, &c. and in which the same culture, in regard to the degree of heat, and other requisites, necessary for the other trees, &c. therein, is suitable for

these which we are now intimating; giving occasional watering to the earth in the pots, and sometimes after the fruit is set, water lightly over the branches, of a warm sunny day; and they will thus produce ripe fruit in April or May.—See *Forcing-Frames—Forcing, &c.*

RICINUS, Palma Christi.

Consists of tall, herbaceous, tender annuals for the pleasure-ground, rising with strong erect stems from three or four to ten or twelve feet high, adorned with luxuriant, palmated, peltated leaves, on long foot-stalks, and long spikes of apetalous monœcious flowers, in July and August.

Class and order, *Monœcia Monadelphica.*

Characters.] CALYX, male and female flowers, apart in the same spike; the males having monophyllous, five-parted cups, and those of the females three-parted, and deciduous. COROLLA, no petals. STAMINA, numerous filiform filaments, variously connected in the monadelphous way, terminated by roundish didymous antheræ. PISTILLUM, an oval covered germen, three bifid, erect patent styles, crowned by simple stigmas. PERICARPIUM, a roundish trifurcated, trivalved, trilocular capsule, each cell having a single oval seed.

There are three species, one of which only is common to our gardens, comprehending several varieties, some growing eight or ten feet high, others not above half so much, esteemed as ornamental plants for the singularity of their large, beautiful leaves, from one to two feet and half broad, deeply lobated into six or seven segments, expanded in the palmated way, and the foot-stalks, fixed in the middle underneath, in the peltated manner. See FOLIUM.

The species is

RICINUS Communis.

Common Palma Christi.] Rises with an upright, strong, herbaceous, jointed stem, eight or ten feet high; having sub-palmated, peltated, sawed leaves; and at the axillas, long spikes of whitish-green flowers, succeeded by ripe seeds in autumn.

Varieties.] There are many varieties, formerly supposed to be distinct species, but are found to be all varieties only of *Ricinus Communis*; and of which there are,—*Major Palma Christi*, growing from about six or eight to ten or twelve feet high.—*Minor Palma Christi*, growing but three or four feet high—green-stalked—grey-stalked—brown-stalked—red-stalked, &c.—broad-leaved, being more than two feet in breadth—lesser-leaved, being from ten or twelve to fifteen or eighteen

inches wide—deeply-divided-leaved—slightly-divided-leaved—grey-leaved—green-leaved—six-lobed-leaved—seven-lobed-leaved, &c. being all varieties of one species, which, and its varieties in general, are annual or biennial, natives of Africa, America, and the South of Europe, and require a hot-bed to raise them in this country.

They are fine majestic plants, annual, or at most biennial in England; but in their native soil, it is said, they are durable both in root and stem. In England, however, we consider them only as annuals, for being raised from seed in the spring, they shoot up to stem, flower, and perfect seeds the same year, and, if not sheltered, die root and all in the winter: but being sheltered in a green house or stove during that season, they will abide two years.

Their merit in our gardens is as ornamental plants, being raised first in a hot-bed, then transplanted into the borders in summer, they will effect a fine variety.

Their Propagation, &c.

They are raised from seed sown in any hot-bed with other tenderish annuals, such as Africans, China asters, &c. half an inch deep: when they are come up three inches high, pot some of them separately in small pots, which plunge also in a hot-bed; others prick in the earth of the bed, giving plenty of water, and according as they increase in size, shift those in pots into larger sizes; and about the end of May, or beginning of June, remove all of them into the full air, transplanting some with balls about their roots into the open borders, and retain some in pots to move occasionally where wanted: supplying the whole with water in dry weather, particularly the transplanted plants in the borders, &c. till firmly rooted, and the potted plants all the summer, about three times a week. Thus these fine plants will grow to their full height in August, well clothed with their noble foliage, and will produce flowers and seed.

If intended to preserve any in the green-house all the winter for variety, chuse some of the handsomest potted plants, which remove into that repository in October, where they will retain their stems and leaves.

RIDGING Ground—to lie fallow in winter, &c. to mellow, and improve its quality and fertility.

This is an essential cultural work, in the kitchen garden particularly, and occasionally in all the other districts, very beneficial to the ground in general, and is of singular utility in stiff, and heavy soils, and cold wet land; though soils of every degree acquire great improvement by that means; being effected

by trench-digging the ground, laying the earth of each trench in a raised, rough ridge, length-ways thereof, that by thus lying as open and hollow as possible, it may meliorate and fertilise more effectually by the weather.

The ridging of ground is of much utility in all soils, both when intended the ground to lie fallow some considerable time, and even when occasionally required for almost immediate sowing or planting, and being levelled down accordingly for that purpose, is an additional improvement in the more effectual melioration of the soil: for by trenching the ground in Ridges, it, in that order, has not only the greater advantage of receiving every possible benefit of improvement, from the action of the sun, air, and different effects of the weather; but also in general, the levelling it down, as just above observed, which is expeditiously effected, for the reception of the intended seeds, plants, roots, &c. both farther breaks, divides, and pulverises the earth more effectually, greatly beneficial, preparatory to every order of general culture, and additionally promotive of its fertility; that in the whole, the ground, from the above advantages, always considerably improves the growth of the respective vegetables.

So that in the trenching or digging ground, when intending it shall have the advantage of fallow for some time, it is always advisable to dig or trench it in Ridges; generally performed either in the latter end of autumn, or any time in winter, or early in the spring, both as the ground is the most vacant at those seasons, and not generally immediately wanted for any principal sowing or planting, and that it will have the best advantage of all possible improvement by the various changes of different weathers, in the interval to recruit and invigorate its vegetative powers, for the benefit of its future production the ensuing summer: essentially beneficial in all soils, and is particularly eligible in all stiff, and very moist, and cold heavy land.

The method of Ridging ground is effected by proceeding in the work of trenching, as before suggested, by digging it in regular trenches, one or two spades wide, or more generally the latter, and one full spade deep, and the crumbs, or loose earth at bottom, or sometimes two spades deep, or more, on some particular occasions, and according to the general depth of the good staple or fertile earth, not to dig deeper into the bad soil: so laying the earth of each trench ridge ways its whole length, proceeding in the following manner.

Beginning at one end of the compartment of ground intended for Ridging, dig out a trench, the

the above width and depth, length-ways across the ground, and wheel the earth thereof to the finishing end, ready to fill up the last trench: so marking out a second trench close to the first, of the same width, then proceed in the trenching and Ridging, previously paring the top of the second trench with all weeds, rubbish, or dung thereon, if any, into the bottom of the first, and then dig the ground of the second along regularly, the proper width and depth as above; turning the earth spit and spit into the first open trench, laying it in a raised ridge lengthways thereof, without breaking it fine, but rather to lie somewhat rough and hollow, according as the nature of the soil admits, that the whole may thereby have a greater equal benefit of the free air, sun, rains, frost, &c. to meliorate and improve its quality as much as possible for the advantage of its future produce: so thus proceeding with another trench in the same manner, continue the same with the whole, trench and trench, to the end of the plat of ground; filling up the last trench with the earth of the first opened, aforesaid, having been carried thence, and laid convenient for this purpose, laying it now ridge-ways as in the preceding trenches.

Thus the ground remaining in Ridges, one, two, or several months, till wanted for sowing or planting, receives the advantage of fallow more essentially than if digged or trenched level; and is soon levelled down for seeds, plants, &c. according as wanted; in which, by the fresh stirring or moving the ground, proves an additional improvement, as before observed, by farther dividing and loosening the earth.

Observe, that in the work of levelling down the Ridged ground, as occasionally wanted, should proceed regularly, ridge and ridge, long-ways, levelling the earth equally to the right and left, loosening any solid parts, and breaking now all large rough lumps and clods moderately fine; forming the whole in an even regular surface, in order for sowing and planting as required.

Generally in levelling down Ridged ground for sowing of seeds particularly, it is not advisable to lay down more than can be sown the same or next day, while the surface is fresh stirred, especially in broad-cast sowing and raking in the seed, as most generally all tolerably light mellow soils are more yielding to the rake while the surface is fresh moved; or before either rendered wet by rain, &c. or very dry and hardened in the top earth by the sun, air, and winds, in dry weather, in the spring months, &c. and likewise, for sowing seeds by bedding in and covering in with earth

from the alleys, &c. or with earth raked off the beds for that purpose, it would generally be most successful to perform it in a fresh stirred surface; though not so material in drill sowing: and besides, when seeds are committed to the earth while it is in a fresh turned up surface, especially in a dry season, is more promotive in forwarding a free regular germination sooner than in ground that has lain some time after digging or levelling down, as above; though some grounds of a wet, or heavy, stiff temperament, sometimes require to lie a few days after digging or levelling down, in order for the rough cloddy surface to mellow in some degree, either by drying a little, or by having a moderate rain, or sometimes both, to meliorate the lumpy clods, pliant to the rake, in the case of broad-cast sowing and raking in the seed, as above observed.

However, in ground prepared by digging or levelling down, designed for sowing seed in drills, or for any kind of planting, it is not always so material in observing very particularly the above intimations, after the preparation of laying it down, though it is generally most effectually successful in all cases to sow or plant while the prepared ground remains in some tolerably fresh state.

RIVINIA, *Rivinia*.

Two shrubby evergreens for the stove compose this genus: one a low upright plant, the other a high climber; furnished with heart-shaped and oval leaves, and spikes of small apetalous flowers.

Class and order, *Tetrandria Monogynia*.

Characters.] CALYX, four oblong-oval, coloured, permanent leaves. COROLLA, no petals. STAMINA, four, and some eight permanent filaments, having small antheræ. PISTILLUM, a large roundish germen, short style, and obtuse stigma. PERICARPIUM, a globular unilocular berry lodged close in the calyx, having one roundish seed.

The species are,

1. RIVINIA *humilis*.

Dwarf Tetrandrous Jamaica Rivinia.] Hath a low shrubby stem, dividing and branching three or four feet high; heart-shaped leaves, and long spikes of small tetrandrous flowers, succeeded by red berries.

Varieties.] Downy white-leaved—white-flowered—scarlet-flowered.

2. RIVINIA *octandra*.

Climbing Octandrous American Rivinia.] Rises with a shrubby, climbing, branchy stem, fifteen or eighteen feet high. Oval-spear-shaped leaves, and loose spikes of small octandrous flowers, succeeded by blue berries.

Both the species are evergreen, and being tender exotics from the warmest parts of America, must be kept always in pots and placed among the stove plants, where they will flower most times of the year: the flowers are apetalous, separately small, but numerous in each spike, arising in great abundance from the sides and ends of the branches, succeeded by berries.

They are raised from seed sown in pots, and plunged in a bark-bed. Try them also by layers and cuttings, assisted by heat.

ROBINIA, False Acacia.

Consists of hardy deciduous trees and shrubs for ornamental plantations, and tender kinds for the hot-house collection; adorned with pinnated and quaternate leaves; and pendulous clusters of papilionaceous flowers.

Class and order, *Diadelphia Decandria*.

Characters.] CALYX is monophyllous, and four-parted, having the three under segments narrow, the other broad. COROLLA is papilionaceous, having a large, round, patent vexillum, two oval wings, with short appendices, and a nearly semi-orbicular depressed carina. STAMINA, ten diadelphous filaments, and roundish antheræ. PISTILLUM, a cylindric oblong germen, slender bent style, and hairy stigma. PERICARPium, a large, oblong, compressed pod, having kidney-shaped seeds.

There are about seven species retained in our gardens; all of the tree and shrub kind; five of them hardy for the shrubbery, and two tender for the stove.

Hardy Kinds.

These consist of two large tree kinds, and three or four moderate and small shrubs, all deciduous, natives of foreign parts, America, Siberia, and Tartary, but all hardy enough to succeed in our open plantations.

1. ROBINIA *Pseud-Acacia*.

(*Pseudo-Acacia*) False Acacia, or American Robinia.] Rises with a strong, woody trunk, dividing and branching thirty or forty feet high; armed with strong spines; large, long, pinnated leaves of nine or ten pair of oval lobes, and an odd one, having prickly stipulæ, and long pendulous racemous clusters of papilionaceous, white, odoriferous flowers, one on each pedicle, succeeded by smooth seed-pods.

Variety.] Echinated, or Prickly-podded American False Acacia.

Grows thirty or forty feet high, having leaves and flowers like the others, but with short very prickly pods.

2. ROBINIA *hispida*.

Hispid American Robinia, commonly called *Rose Acacia*.] Grows fifteen or twenty feet

high, but appears like a moderate shrub in England, armed with spines, and hispid hairs on every part, having leaves and flowers formed like the other: but the flowers are of a beautiful rose-colour, making a fine appearance.

This is a very beautiful flowering shrub, for the principal compartments of the shrubbery.

3. ROBINIA *Caragana*.

Siberian Abrupt-leaved Robinia.] Rises with a shrubby stem, branching eight or ten feet high, or more: abruptly pinnated leaves of five or six pair of oval lobes, not terminated by an odd one, and simple or unbranched pedunculi, sustaining small yellow flowers.

4. ROBINIA *frutescens*.

Shrubby Quaternate-leaved Siberian Robinia.] Hath a shrubby stem, branching six or eight feet high, quaternate oval leaves, on short foot-stalks, and simple pedunculi, sustaining yellow flowers.

5. ROBINIA *pigmæa*.

Dwarf Quaternate-leaved Siberian Robinia.] Hath a low shrubby stem, branching about three feet high. Quaternate, wedge-shaped, close-fitting leaves; and simple pedunculi, sustaining yellow flowers.

The above five hardy species flower here annually, the first sort in June and the others in May. The flowers are all papilionaceous and tetrapetalous; arising from the sides and ends of the branches; which in the first two sorts and varieties being produced in long clusters, make a fine appearance, particularly the *Rose Acacia*; and most of the sorts are succeeded by seed-pods, ripening in September, particularly the last three species.

They are all proper furniture for embellishing the shrubberies, will succeed any where, and exhibit a fine variety with their pinnated and quaternate leaves, and the *Pseud-Acacia*, and varieties, also with the numerous clusters of flowers, but are most ornamentally beautiful in the *Robinia hispida*, or *Rose Acacia*.

Hot-house Kinds.

Consists of two tree and shrub species, natives of the warm parts of America and India.

6. ROBINIA *violacea*.

Violet American Robinia.] Hath a woody trunk, branching twenty feet high; pinnated leaves of eight or ten pair of oval lobes, and an odd one; and clusters of violet-coloured flowers, two on each pedicle.

Varieties.] With dark-blue-flowers—scarlet-flowered—and with leaves having spear-shaped lobes—oblong lobes, &c.

7. ROBINIA *mitis*.

Smooth

Smooth Indian Robinia.] Hath a smooth shrubby stem and branches; pinnated leaves, of several pair of oval lobes, and an odd one; and clusters of whitish flowers, three on each pedicle.

All the hardy species being for the shrubbery, may be had at the nurseries, particularly the first two species and varieties, and the *Caragana*, &c. and may all be planted in any common soil and situation.

But the two tender species must always be kept in pots, and placed in the stove.

Method of Propagation.

The hardy kinds are raised from seeds, cuttings, layers, and suckers.

By Seeds.—In March, sow them in any bed of light mould, half an inch deep: the plants will come up in less than two months, the first species and varieties in particular, the others sometimes not till spring after, unless sown in autumn: give occasional weeding and watering, and in the spring following plant them out in nursery-rows, to have two or three years' growth.

By Cuttings.—In October or November, having a quantity of cuttings of the young shoots, plant them in a shady border, and they will be rooted well in one year.

By Layers.—Lay the young wood in autumn, they will be rooted by autumn following.

By Suckers.—The first two species generally send up plenty from the root, which transplant any time from October till March.

The tender sorts are raised from seed, cuttings, and layers, assisted by artificial heat.

RONDELETIA.

This genus furnishes the stove with two woody exotics, garnished with oblong-oval leaves, and paniculated flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX, a monophyllous, top-shaped cup, sitting on the germen, with the brim cut into five acute parts. COROLLA, monopetalous and funnel-shaped, the tube is cylindric and bellied at the top, with the border reflexed, roundish, and cut into five parts. STAMINA, five awl-shaped filaments, topped with simple antheræ. PISTILLUM, a roundish germen under the flower, slender style, crowned with a bifid stigma. PERICARPIUM, a roundish, coronated, bilocular capsule, containing many seeds.

The species are,

1. *RONDELETIA americana*.

American Rondeletia.] Rises with a woody stem, eight or ten feet high, with branches covered with a smooth greenish bark, and gar-

nished with oblong, sessile leaves, sitting close to the branches; the flowers are white, and come out on a dichotomous panicle.

2. *RONDELETIA hirta*.

Hairy Rondeletia.] Rises with a woody stem, six or seven feet high, dividing into several branches garnished with oval-oblong, pointed, hairy leaves, standing on footstalks; the flowers are yellowish, and come out on a trichotomous panicle, and are of a fragrant odour.

These plants being natives of the West Indies, must be constantly kept in the stove; their propagation is by seeds which should be sown early on a hot-bed in the spring, and when the plants are come up three or four inches high, must be transplanted into single pots, and plunged in the bark-pit, and afterward treated as other plants of the like nature.

ROSA, Rose-Tree.

This noted genus comprehends numerous deciduous flowering shrubs, and an evergreen; all of hardy growth, and the pride of the shrubby flowering tribe, for adorning the pleasure-grounds, &c. with their large elegant flowers, in great profusion, for several months in summer; are garnished with pinnated rough leaves, of from three to five or seven lobes; and numerous large, pentapetalous, very odoriferous flowers, comprising many double varieties of singular beauty.

Class and order, *Icosandria Polygynia*.

Characters.] CALYX is monophyllous, ventricose, and fleshy below, and divided at top into five long, narrow, spear-shaped segments, two of which alternately having appendices on their sides, two alternately naked, and the fifth sometimes appendiculated on one side only. COROLLA, five obversely heart-shaped petals, inserted into the calyx. STAMINA, numerous short capillary filaments, inserted into the neck of the calyx, and trigonous antheræ. PISTILLUM, numerous germina in the bottom of the calyx, and numerous very short hairy styles, straitly compressed in the neck of the calyx, and inserted into the sides of the germen, crowned by obtuse stigmas. PERICARPIUM, the fleshy base of the calyx becomes a turbinated, fleshy, soft, unilocular berry, having numerous oblong hairy seeds, fastened on each side to the calyx.

The sorts of Roses are very numerous, and the botanists find it very difficult to determine with accuracy, which are species, and which varieties, as well as which are varieties of the respective species; on which account Linnæus, and some other eminent authors, are inclined

to think that there is only one real species of Rose, which is the *Rosa canina*, or Dog-Rose of the hedges, &c. and that all the other sorts are accidental varieties of it; however, according to the present arrangement, they stand divided into eighteen supposed species, each described to have some particular mark of distinction, though in several sorts is not very conspicuous; and agreeable to the specific description of the several species, each comprehends some varieties, which in some sorts are but few, others numerous.

The supposed species and their varieties are as follow :

1. *ROSA canina*.

Canine Rose, or Wild Dog-Rose of the Hedges, or Hep-tree.] Grows five or six feet high, having prickly stalks and branches, pinnated, five or seven lobed leaves, with aculeated footstalks; smooth pedunculi; oval, smooth germina, and small single flowers.

Varieties.] Red-flowered Canine Rose—white-flowered.

They grow wild in hedges abundantly all over the kingdom, and are sometimes admitted into gardens, a few to increase the variety of the shrubbery collection.

2. *ROSA alba*.

Common White Rose.] Grows five or six feet high, having a green stem and branches, armed with prickles; hispid pedunculi; oval, smooth germina, and large white flowers.

Varieties.] Large double White Rose—semi-double White Rose—dwarf single White Rose—maiden's-blush White Rose, being large, produced in clusters, and of a white and blush-red colour.

3. *ROSA gallica*.

Gallican, or Common Red Rose.] Grows from about three or four to eight or ten feet high, in different varieties, pinnated three, five, or seven lobed leaves, and large, semi-double, red, and other coloured flowers, in the different varieties of the plants relatives of the same species.

The specific description is,—Rose, with hispid, prickly branches, and petioles; hispid pedunculi, and oval hispid germina.

Varieties.] This species comprises three or four principal varieties of Roses, supposed originally a progeny thereof, as bearing nearly the above specific distinction; consisting of the following sorts.

Common Red Officinal Rose.] Grows erect, about three or four feet high, having small branches, with but few prickles; and large, spreading, half-double, deep-red flowers.

The flowers being astringent, are used in

medicine, being gathered for that use while in the bud, or before they begin to open; and they fetch a good price at market, where they are sold by the peck, or bushel, and pay sufficiently for the culture of a large quantity of plants; for which purpose the London gardeners plant them in close ranges, forming low hedges, a foot or two high, keeping them down by an annual clipping in autumn; and they produce great quantities of flowers.

Marbled Rose.] Grows four or five feet high, having brownish branches with but few prickles, and large double finely-marbled red flowers.

Double Virgin Rose.] Grows five or six feet high, having greenish branches, with scarce any spines, and large pale-red flowers.

Rosa Mundi, (Rose of the World) or striped Red Rose.] Is a variety of the common Red Rose, growing but three or four feet high; having large spreading semi-double red flowers, beautifully striped with white—and deep-red.

4. *ROSA damascena*.

Damask Red Rose.] Grows five or six to eight or ten feet high, having greenish branches, armed with short aculei, and garnished with oval-lobed leaves, and moderately double, fine red, very fragrant flowers.

The specific description is, — Rose with prickly branches and petioles; pinnated leaves, with oval, pointed, villous leaves, hispid peduncles, semi-pinnate cups, and oval, turgid, hispid germina.

Varieties.] This species is comprehensive in several very noted supposed varieties thereof, viz.

White Damask Rose.] Grows eight or ten feet high, with very prickly branches, oval leaves, and whitish blush flowers, becoming gradually of a pure white colour.

Blush Damask Rose.] Grows eight or ten feet high, with greenish branches, armed with short prickles; oval leaves, and faint-red flowers.

York and Lancaster variegated Rose.] Grows five, six, or eight feet high, or more; bearing variegated red flowers; consisting of a mixture of red and white; also frequently disposed in elegant stripes, sometimes in half of the flower, and sometimes in some of the petals.

Monthly Rose.] Grows about four or five feet high, with green, very prickly shoots; producing middle-sized, moderately-double, delicate flowers, of different colours in the varieties.

Varieties are,] Common red-flowered Monthly Rose—blush-flowered—white-flowered

ered—striped-flowered.—All of which blow both early and late, and often produce flowers several months in the year, as May, June, and July; and frequently again in August, or September; and sometimes, in fine mild seasons, continues till November or December: hence the name Monthly Rose.

It is generally the earliest blowing Rose; but as it begins to shoot early in the spring, the buds are often cut by the frost, so as to prevent their blowing fair and plenteously; the plants should therefore have a somewhat sheltered warm situation; some should also be planted against a warm wall; and is a proper sort to pot for forcing.

Blush Belgic Rose.] Grows three or four feet high, or more; having greenish prickly branches, five or seven-lobed leaves, and numerous, very double, bluish-red flowers, with short petals, evenly arranged.

Red Belgic Rose.] Having greenish and red shoots and leaves, and fine double deep-red flowers.

Velvet Rose.] Grows three or four feet high, armed with but few prickles, producing large velvet red flowers, comprising semi-double and double varieties, all of them very beautiful Roses.

5. *ROSA lutea.*

Yellow Austrian Rose.] Grows five or six feet high, having reddish very prickly shoots; and numerous small, bright-yellow flowers.

The specific description is,—Rose with branches armed with straight prickles, spinulous cup and petioles, with smooth pedunculi, and globose smooth germina.

Double Yellow Rose.] Grows six or seven feet high; brownish branches, armed with numerous large and small yellowish prickles; and large very double yellow flowers.

Red and Yellow Austrian Rose.] Grows five or six feet high, having slender, reddish branches, armed with short, brownish aculei; and with flowers of a reddish copper colour on one side, the other side yellow.

This is a curious variety, and the flowers assume a singularly agreeable appearance.

6. *ROSA turbinata.*

Turbinated, or Frankfort Rose.] Grows eight or ten feet high, is a vigorous shooter, with brownish branches, thinly armed with strong prickles; and produces largish, double, purplish-red flowers, that blow irregularly, and have but little fragrance.

The specific description is,—Rose with sparsely, recurved prickles, villous petioles, pilous peduncles, and top-shaped pilous germina.

7. *ROSA centifolia.*

Hundred-leaved Red Rose, &c.] Grows from about three or four to six or eight feet high, in different sorts, all of them hispid and prickly; pinnated three and five-lobed leaves, and large very double red flowers, having very numerous petals, and of different shades of colours in the varieties.

Specific description is,—Rose with hispid and prickly stalks and branches, inermous or unarmed petioles; hispid pedunculi, and oval hispid germina.

Varities are,

Common Dutch hundred-leaved Rose.] Grows three or four feet high, with erect greenish branches, but moderately armed with prickles; and large, remarkably double red flower, with short regularly arranged petals.

Blush hundred-leaved Rose.] Grows like the other, with large, very double, pale-red flowers.

Velvet Rose.] Grows three or four feet high, armed with but few prickles, producing large velvet red flowers, comprising semi-double and double roses.

8. *ROSA provincialis.*

Provence Rose.] Grows five or six feet, with greenish-brown, prickly branches, and very large double globular red flowers, with large petals folding over one another, more or less in the varieties.

Specific description is,—Rose with branches armed with sparsely sub-reflexed prickles, hispid petioles and peduncles, roundish hispid germina, and oval folioles, villous underneath.

Varities are,] Common Red Provence Rose, —White Provence Rose—and Pale Provence Rose; each of which having larger, and somewhat looser petals than the following sort.—Cabbage Provence Rose; having the petals closely folded over one another like cabbages —Dutch Cabbage Rose, very large, and cabbages tolerably—Childing Provence Rose—Rose of Meaux or Dwarf Rose—Great Royal Rose, grows six or eight feet high, producing remarkably large, somewhat loose, but very elegant flowers.—All these are large double red flowers, somewhat globular at first blowing, becoming gradually a little spreading at top, and are all very ornamental fragrant Roses.

9. *ROSA muscosa.*

Moss Provence Rose.] Grows erectly, four or five feet high, having brownish stalks and branches, very closely armed with short prickles, and double, crimson-red flowers; having the calyx and upper part of the peduncle surrounded with a rough mossy-like substance, effecting a curious singularity.

This

This is a fine delicate Rose, of a high fragrance, which, together with its mossy calyx and peduncles, renders it of great estimation as a curiosity.

10. *Rosa cinnamomea*.

Cinnamon Rose.] Grows five or six feet high, or more, with purplish branches, thinly aculeated; pinnated five or seven-lobed leaves, having almost inermous petioles; smooth pedunculi, and smooth globular germina; and small purplish-red cinnamon-scented flowers, early in May.

Varieties.] With double flowers—single-flowered.

11. *Rosa alpina*.

Alpine inermous Rose.] Grows five or six feet high, having smooth, or unarmed, reddish branches; pinnated, seven-lobed, smooth leaves, somewhat hispid pedunculi, oval germina, and deep-red single flowers; appearing in May.

This species, as being inermous, or free from all kind of armature common to the other sorts of Roses, is esteemed as a singularity; and from its inermous property, is often called the Virgin Rose.

12. *Rosa carolina*.

Carolina and Virginia Rose, &c.] Grows six or eight feet high, or more; having smooth, reddish branches, very thinly aculeated; pinnated, seven-lobed, smooth leaves, with prickly foot-stalks; somewhat hispid pedunculi, globose hispid germen, and single red flowers, in clusters, appearing mostly in August and September.

Varieties.] Spreading Carolina Rose—Upright Carolina Rose—Dwarf Pennsylvanian Rose, with single and double red-flowers—American pale-red Rose—Great Burnet-leaved, single-flowered—Great Burnet-leaved, double-flowered.

This species and varieties grow naturally in different parts of North America; they effect a fine variety in our gardens, and are in estimation for their serotinous, or late-flowering property, as they often continue in blow from August until October; and the flowers are succeeded by numerous, red, berry-like heps in autumn, causing a variety all winter.

13. *Rosa villosa*.

Villous, or Apple-bearing Rose.] Grows six or eight feet high, having strong, erect, brownish, smooth branches, aculeated sparsely; pinnated, seven-lobed, villose, or hairy-leaves, downy underneath; with prickly foot-stalks, hispid peduncles, globular, prickly germen; and large single red flowers, succeeded by large, round, prickly heps, as big as little apples. *Variety*, with double flowers.

This species merits admittance in every collection as a curiosity for the singularity of its fruit, both for variety and use; for it having a thick pulp of an agreeable acid relish, is often made into a tolerable good sweet-meat.

14. *Rosa pimpinellifolia*.

Small Burnet-leaved Rose.] Grows about a yard high, aculeated sparsely; small, neatly pinnated, seven-lobed leaves, having obtuse folioles, and rough petioles; smooth peduncles; globular, smooth germen; and small single flowers.

Varieties.] With red flowers—and with white flowers.

They grow wild in England, &c. and are cultivated in shrubberies for variety.

15. *Rosa spinosissima*.

Most Spinous, or Dwarf Scotch Rose.] Grows but two or three feet high, very closely armed with spines; small, neatly pinnated, seven-lobed leaves, with prickly foot-stalks; prickly pedunculi; oval, smooth germina; and numerous, small, single flowers, succeeded by round, dark-purple heps.

Varieties.] Common white-flowered—red-flowered—striped-flowered—marbled-flowered—yellow-flowered.

They grow naturally in England, and Scotland, &c. the first variety rises near a yard high, the others but one or two feet; all of which are single-flowered; but the flowers being numerous all over the branches, make a pretty appearance in a collection.

16. *Rosa eglanteria*.

Eglantine Rose, or Sweet Briar.] Grows five or six feet high, having green branches, armed with strong spines sparsely; pinnated, seven-lobed, odoriferous leaves, with acute folioles, and rough foot-stalks; smooth pedunculi; globular smooth germina, and small pale-red flowers.

Varieties.] Common single-flowered—semi-double-flowered—double-flowered—blush double-flowered—evergreen double-flowered—yellow-flowered.

This species grows naturally in some parts of England, and in Switzerland.

It claims culture in every garden for the odoriferous property of its leaves; and should be planted in the borders, and other compartments contiguous to walks, or near the habitation, where the plants will impart their refreshing fragrance very profusely all around; and the young branches are excellent for improving the odour of nose-gays and bow-pots; and for which purpose the London gardeners raise great quantities for sale, of the common single kind, which they effect by seed, sowing it in autumn, or spring, in drills an inch deep; and

and the plants may either remain, or be transplanted where required. See the *Propagation*.

But the double-flowered kinds, and yellow variety are continued the same, only by suckers and layers.

17. *Rosa moschata*.

Musk-Rose.] Hath weak, smooth, green stalks and branches, rising by support, from six to eight or ten feet high, or more, thinly armed with strong spines; pinnated, seven-lobed, smooth leaves, the lobes oblong, and pointed; with prickly foot-stalks; hispid peduncles; oval hispid germina; and all the branches terminated by large paniculate clusters, of pure-white, musk-scented flowers in August, &c.

Varieties.] With single flowers—and with double flowers.

18. *Rosa sempervirens*.

Ever-green Musk Rose.] Hath somewhat trailing stalks and branches, rising by support five or six feet high, or more, having a smooth bark, armed with prickles; pinnated, five-lobed, smooth, shining, ever-green leaves, with prickly petioles; hispid pedunculi; oval hispid germen; and all the branches terminated by clusters of pure-white flowers of a musky fragrance; appearing the end of July, and in August.

The sempervirent property of this elegant species renders it a curiosity among the Rosy tribe; it also makes a fine appearance as a flowering shrub.

The two last species and varieties flower in August; and are remarkable for producing them numerously in clusters, continuing in succession till October or November. They should generally be allowed support of stakes, or some planted against a wall, &c.

All the above species of *Rosa*, and their respective varieties, are of the shrub kind; all deciduous, except the last sort, and of hardy growth, succeed in any common soil and situation, and flower annually in great abundance from May till October, in different sorts; though the general flowering season for the principal part of them is June and July; but in a full collection of the different species, the blow is continued in constant succession several months, even sometimes from May till near Christmas; producing their flowers universally on the same year's shoots, rising from those of the year before, generally on long pedunculi, each terminated by one or more Roses, which, in their characteristic state, consists each of five large petals, and many stamina; but in the doubles, the petals are very numerous; and in some sorts, the flowers

are succeeded by fruit ripening to a red colour in autumn and winter; from the seed of which the plants may be raised; but the most certain and eligible mode of propagating most of the sorts is by suckers and layers; and by which methods they may be increased very expeditiously in great abundance.—See their *Propagation*.

All these shrubs are fine ornamental furniture for every garden, in the exceeding beauty and fragrance of their elegant flowers; and as they will all grow any where without much trouble of culture, only a little occasional pruning, and may be obtained at all the nurseries, at moderate rates, every garden may be easily furnished with a full collection; and being possessed of a few of each sort, they will most of them soon increase the stock considerably by suckers.

The season for planting all the sorts is any time in open weather from October till March, and they will all flower in perfection the following summer; but if occasion requires, they may be transplanted so late as any time in April, or even the beginning of May, which late planting is sometimes designedly practised to a few occasionally, to obtain a late bloom in autumn; however, the earlier the planting is performed, the stronger the plants will flower.

When these shrubs are designed for the shrubbery, and common flower borders, they should be planted singly; and may be trained with a single stem, one, two, or more feet high, and then encouraged to branch out into a bushy head; though when they are required to exhibit a more bushy growth, they are often suffered to branch away immediately from the bottom; as they will blow plentifully in any mode of training; however, I should advise keeping them to a short, single stem below, and let them form a bushy head upward two, three, or four, to five or six feet high, according to their respective growths; or some sorts being permitted to run, and have support, will grow much higher; I having, for curiosity, run some with a single stem, from five or six to nine, or ten feet, supported erect, with a tall stake, or small pole, and at that height they formed a small branchy head, and produced plenty of Roses; but for general growth, a moderately-low, full, branchy head, of the former-mentioned heights, is the most eligible; and some may be run up more or less to effect greater variety, or some large-growing sorts being planted against a wall, &c. they may be trained to several feet extent both horizontally and upright. All of which, in their different growths, in regard to culture, is not very material; especially in the common

standard bushes; consisting chiefly in clearing the bottom from suckers, in winter, which will serve for new plants, and thin the head occasionally, when grown too thick and confused, and reduce any long rambling shoot, and cut out dead wood; but as these shrubs produce their flowers generally on the young shoots, some are occasionally cut down a little to a close head in autumn or winter, to force out a greater quantity of flowers, which however will probably be proportionally smaller; though those who want them for sale in the markets, &c. endeavour to procure as large a quantity as possible; however, in their culture in borders, shrubberies, and other compartments for ornamental flowering, they should be mostly permitted to run up, with moderately full heads, and kept to some regularity, as above.

But where large quantities of the flowers are required, particularly for sale, as is the case about London, the gardeners generally plant the shrubs in close rows, forming a sort of hedge, putting them in by *trench-planting*, a foot distance in the row; and in their culture keep them down to one, two, or three feet high, according to the sorts, by shearing or clipping them annually, in autumn or winter, at top and sides, in order to force out a greater quantity of laterals the following year for flowering, as before observed.

Some plants of the best sorts may also be planted against a warm wall, to forward their shooting for an early bloom; a few of the Monthly Roses in particular, also the Provence kinds, and cinnamon Rose, &c. But as the Monthly Rose shoots early in the spring, as formerly hinted, it is always proper to have some plants of that sort against some warm fence, both for shelter, and to forward the bloom.

A few plants of the best sorts of Roses should also be potted to move occasionally to adorn any particular compartment.

Likewise, where there is convenience of forcing-frames, or hot-houses, &c. it is proper also to pot some prime sorts to force for an early spring bloom; for by aid of the above departments of artificial heat, Roses may be forwarded to flowering in winter, or early in spring; for which purpose, having some plants of the monthly Rose, common Provence, and Moss Provence, or any other choice sorts, in pots, which in winter may be placed in any forcing-frames, worked either by dung, bark, or fire heat, or placed in a hot-house, they may be brought to flower in January, February, and March, and continued in succession till the plants in the natural ground begin to

flower, by having different supplies of plants placed for forcing at two or three weeks' interval. A quantity of plants should generally be potted for this use annually, and if they have a summer's growth in the pots, plunged in the ground, previous to the time of forcing, they will be more firmly rooted, so as to flower in greater perfection. See FORCING-FRAME.

Many of the gardeners about London erect forcing-frames, or glass-houses, with bark-pits on purpose for forcing Roses, as they are generally ready sale, at an early season, both the pots of plants in flower, and the Roses gathered as nosegays; and fetch an extraordinary great price, which pays sufficiently for forcing.

Method of Propagation.

The propagation of all the sorts of Roses is by suckers—layers—budding—and some sorts by seeds. But suckers is the most common and expeditious method for propagating most of the species.

By Suckers.—Most of the sorts of Roses send up many suckers annually from the root, attaining from one or two to three or four feet height, or more, in one summer; and by these the shrubs may be expeditiously propagated in great plenty; they may be taken up in autumn, winter, or early in spring, with some radicle fibres to their bottom; and the strongest may be planted out finally, and the weakest in nursery lines for a year or two, or longer; they will readily grow, and will most of them produce flowers the following summer.

When these shrubs have grown into large bunches, with many suckers grown up to stems from the root, the whole may be taken up and slipped, or divided into so many separate plants, and planted out, as above.

Observe, that as the Moss Rose, Musk Rose, Apple-bearing Rose, and some others, furnish suckers but sparingly, so in default thereof must have recourse to layers, or budding; particularly for the Moss Provence.

By Layers.—All the sorts of these plants will grow by layers of the young shoots; and is an effectual method of propagation, for such sorts in particular, that sparingly furnish suckers, as the Moss Provence, &c. as aforesaid; and that to obtain plenty of shoots for laying, a quantity of the plants should be planted for stools; which being headed down low, they will throw out plenty of shoots near the ground in summer, for laying in autumn or winter following, by slit-laying, they will be rooted by next autumn, and fit for transplantation, in nursery rows; though sometimes the Moss Rose, &c. require two years before they are tolerably well rooted; but of these

these sorts, you may also try layers of the young tender shoots of the year, layed in summer, any time in June, they will probably root a little the same season. However, the layers of all the sorts, after being properly rooted, should be taken up in autumn, and planted in the nursery, to have one or two years' growth, or to remain till wanted.

By Budding.—This is sometimes practised in propagating some choice sorts that seldom send up suckers freely, such as the Moss Provence, &c. as aforesaid; also, when intended to have two, three, or more different sorts of Roses upon the same tree, for curiosity; working them upon the Frankfort, or any other strong-shooting Rose-stocks raised from suckers.

By Seeds.—This is sometimes practised to try to obtain new varieties; also sometimes for raising some particular permanent species, such as the Canine Rose, Burnet-leaved Rose, Scotch Rose, Apple-bearing Rose, single Sweet Briar, and such others as continue the same by seedlings; sowing them generally in autumn soon after they are ripe, and they will sometimes rise the following spring; as, if not sown till the spring season, most of the sorts are apt to remain till the second year before they rise freely; sow them however, in any bed of light earth, either in shallow drills, or all over the surface, covering them half an inch deep; and when the seedlings are a year old, transplant them in nursery-rows.

Observe, however, that the double kinds, and other particular varieties of the species in general, cannot be continued the same with certainty by seeds, so must always be propagated by suckers or layers, &c.

But the common single Sweet Briar, when required in any considerable quantity, should generally be raised from seed, sowing it in drills half an inch deep, either to remain, or for transplantation; though when designed to form a sort of hedge of this plant, to produce a crop of shoots to cut for the supply of markets during the summer, it is eligible to sow the seed at once in a drill where the plants are always to stand.

ROSMARINUS, Rosemary.

It consists of one hardy shrubby ever-green, comprising some varieties, proper for the kitchen-garden and shrubbery; all of which are adorned with narrow stiff leaves, and numerous, small, monopetalous, ringent flowers along the sides of the shoots.

Class and order, *Diandria Monogynia*.

Characters.] CALYX is monophyllous, the mouth erect and bilabiate, the upper lip, being entire, the under one bifid. COROLLA

is monopetalous, tubular below, and ringent above, having the upper lip short and bifid, and the under one reflexed and trifid, with the middle segment largest. STAMINA, two subulate filaments, inclining towards the upper lip, and simple antheræ. PISTILLUM, a quadrifid germen; a style like the stamina, of the same length and situation, and a simple acute stigma. PERICARPIUM, none; four oval seeds lodged in the calyx.

The species is,

ROSMARINUS officinalis.

Common Officinal Rosemary.] Hath a shrubby stem branching numerously from the bottom upwards, growing five or six feet high, closely garnished with narrow, linear, stiff leaves; and numerous small purplish flowers all along the upper part of the branches.

Varieties.] Common narrow-leaved Rosemary—broad-leaved—silver-striped-leaved—gold-striped-leaved.

All the varieties are tolerably hardy ever-greens, though the common green sorts are the hardiest; the striped kinds are liable to suffer by hard frosts, if much exposed, or planted in wet ground; so should have a warm situation and dry soil; some of these variegated kinds should also be potted, in order to have shelter of a green-house in winter. It should also be observed, that all the varieties of Rosemary should generally have a dry soil; and if poor, sandy, gravelly, or rubbishy, they will be more durable than in moist, rich land: in wet soils in particular, they are very liable to perish in rigorous winters. However, all the sorts will succeed in any common earth in a dry situation.

As to their uses in gardening, the common green sorts are employed as medical plants, &c. and both green and variegated kinds claim admittance in the shrubbery, to increase the variety in the evergreen collection, allowing them a dry soil, and the striped sorts in particular a warm situation, as above observed: plant some of these sorts also against a warm fence, as a place of greater shelter to protect them in winter.

But it is proper always to keep a few plants of the striped sorts in pots, and place them for winter protection from severe frost, either in a green-house, in which they will also effect a pretty variety; or in a glass-case, or deep garden-frame, &c.

The leaves and flowers of Rosemary are used in medicine.

Method of Propagation.

They are all easily propagated by slips or cuttings, and by layers.

By Slips and Cuttings.—In March, April,

or May, slip or cut off a quantity of young shoots, from about five or six to eight or ten inches long, and strip off the lower leaves; then plant them in a border of light earth, in rows a foot asunder, and give a good watering, repeating it frequently till they are rooted, which they will effect in a short time, the same year, shoot at top, and become tolerable little plants by autumn, when about the beginning or middle of September, or in spring following, they may be transplanted where they are designed to remain.

By Layers.—In spring, summer, or autumn, lay down any of the convenient lower young branches in the earth, they will be well rooted by autumn following.

ROYENA, African Bladder Nut.

The plants are shrubby evergreen exotics for the green-house collection: garnished with oval and spear-shaped leaves, and monopetalous, five-parted, reflexed flowers along the sides of the branches.

Class and order, *Decandria Digynia*.

Characters.] CALYX is monophyllous, five-parted at top, and permanent. COROLLA is monopetalous, with a tube the length of the calyx, and divided above into five oval reflexed segments. STAMINA, ten very short filaments having oblong, didymous, erect antheræ. PISTILLUM, an oval germen, two styles, and simple stigmas. PERICARPIUM, an oval, quadrifurcated and quadrivalved, unilocular capsule, having four oblong triangular nuts.

The species are,

1. ROYENA *lucida*.

Lucid African Bladder Nut.] Hath a shrubby upright stem, branching eight or ten feet high; oval, somewhat rough but shining green leaves, placed alternately; and white flowers at the sides of the branches.

2. ROYENA *glabra*.

Glabrous African Bladder Nut.] Hath a shrubby upright stem, branching five or six feet high; small, lanceolate, smooth leaves; and small white flowers at the sides of the branches.

3. ROYENA *hirsuta*.

Hairy African Bladder Nut.] Hath a shrubby upright stem, branching alternately, six or seven feet high, lanceolate hairy leaves; and purplish flowers at the sides of the branches.

These three shrubs being natives of the Cape of Good Hope, require shelter here in winter, so must always be kept in pots, and placed among the green-house plants; when they will form a good variety, as ever-green and will flower in July or August; but the

flowers are small, and of but little beauty, succeeded sometimes by ripe capsules, particularly the first and second sorts; their culture is the same as other shrubby green-house plants.

They are propagated by seed, layers, and cuttings.

By Seed.—Sow it in spring, in pots, and plunge them in a bark-bed, or other hot-bed; and when the plants are three or four inches high, pot them off separately.

By Layers.—Lay the young shoots of the year in summer, as they are unapt to strike in the older wood.

By Cuttings.—In spring, plant some young shoots in pots, and plunge them in a hot-bed.

RUBIA, Madder.

This genus furnishes two noted hardy herbaceous perennials, valuable for their roots, as a most useful commodity in dying red; they having thick succulent roots; long, thick, procumbent stalks; spear-shaped radiant leaves; and campanulate, four-parted, yellow flowers in spikes at the ends of the branches.

Class and order, *Tetrandria Monogynia*.

Characters.] CALYX is small, placed on the germen, and four-parted. COROLLA is monopetalous, bell-shaped, and four-parted at top. STAMINA, four awl-shaped, short filaments, having simple antheræ. PISTILLUM, a didymous germen under the calyx; slender style bifid at top, and headed stigmas. PERICARPIUM, two smooth berries joined together; each having one roundish umbilicated seed.

The species are,

1. RUBIA *tinctoria*.

Common Dying Madder.] Hath a long, thick, fibrated, fleshy, reddish root, sending up large, four-cornered, jointed, procumbent stalks, five or six feet long, branching by pairs, crossing alternately; garnished at each joint with six spear-shaped leaves in a verticillus, or radius; and small yellow flowers, collected in loose spikes at the sides and ends of the branches.

It is a native of Italy, and about Montpellier in France, but grows freely here in the open ground.

2. RUBIA *peregrina*.

Foreign, or quaternate-leaved Madder.] Hath thickish, fibrated, spreading roots; slender, four-cornered, procumbent, branchy stalks; garnished at each joint with quaternate, short, rough leaves, and clusters of yellow flowers.

This sort is supposed to grow naturally in England; but probably mostly of foreign growth in Turkey, and some other parts.

Both these species of Madder are herbaceous, of hardy growth; perennial in root, send

up stalks in spring, and flower in June and July, succeeded by seeds in autumn; but those of the *Rubia tinctoria* do not always ripen in England; it however multiplies exceedingly by suckers for propagation.

These plants are sometimes cultivated in gardens, in any open compartments, for variety.

But the chief merit of the plants is in their roots, to use for dying red, &c. And are also used in medicine, which taken inwardly, tinges the urine of a deep red colour; but the *Rubia tinctoria*, in particular, is in greatest estimation for the dyers' purpose, and is cultivated in great quantities in fields abroad, in Holland, &c. for the roots aforesaid, as a very valuable commodity both for the dyers and calico printers; being propagated generally by suckers, or off-sets, which are taken off in the spring, and planted in a light deep soil, in rows two feet asunder, and require two or three years' growth for the roots to attain perfection. They are also cultivated in some parts of England for profit, as they are hardy enough, and increase abundantly by off-sets or suckers from the root, and are sometimes raised in tolerable perfection. However, as in some parts, after repeated experiments in its cultivation, the crops have no ways answered the purpose, occasioned probably by the soil not being suitable, or not properly planted and managed; therefore, at the first trial, it is advisable to plant only a small quantity in different situations; and by observing the soil and method of culture of those which succeed best, it may be a direction to the culture of larger quantities; and where crops of it succeed, it proves a very saleable article, and pays exceedingly well for its cultivation; and the roots may either be sold to the dyers, or druggists, or those who prepare them for use; though abroad the great Madder planters erect stoves and kilns for drying it; and stamping-mills for reducing it to powder, to render it more portable to send to distant countries; but the roots for home consumption may also be used fresh for dying; first washing them clean, then cut to pieces, and pounded in a mortar, and then put into the cauldron, or dying copper.

Their Propagation and Culture.

They are propagated by off-sets or suckers, arising from the roots of old plants in the spring; and should be slipped off soon after they appear above ground; at which time, opening the earth round the roots, slip off the side suckers with as much root part and fibres to each as possible, preserving the tops entire; which should be planted directly, as advised below.

The season for taking off the suckers and planting them is about the beginning, middle, or end of April, or beginning of May, when they appear above ground.

Observe, these plants delight in a light, rich, deep soil, or a light, deep, pliable, loamy land; and rather a somewhat low than high situation; which should be deeply digged or ploughed in autumn, or winter; laying it in rough ridges to mellow and pulverise by the weather; and in spring levelled down for the reception of the plants; but for large quantities in fields, the ground should be ploughed cross-ways again, once or twice in the spring, and well harrowed.

Then in April, or early in May, provide a proper quantity of sets, or suckers, as aforesaid; and with a dibble plant them in rows two feet asunder, and one distant in the row, putting each plant low enough in proportion to the length of its root, leaving most of the green top out of the ground, and close the earth well about each set, as you go on; thus they will soon take root, and shoot at top. But some set these plants in beds, three rows length-ways, at two feet distance, with wide alleys between bed and bed, in order for landing up the crown of the roots two or three inches deep, in winter.

In either mode of planting, they will shoot up into stalks the same year; but the roots will require two or three years' growth before they are large enough for use; during which period, observe the following culture.

Keep them clean from weeds all the summer by broad-hoeing, in dry weather; and in autumn, when the stalks decay, cut them down, then slightly dig the ground between the rows, raising it somewhat ridge-ways along the rows of plants, an inch or two thick over their crowns; or if they are in beds, they may be landed up from the alleys the above depth. Next spring the roots will shoot up again stronger than before, keep down weeds, and the plants will soon cover the ground; in autumn following, the decayed haulm must be again cut down, and all weeds cleared away; slightly dig the ground, &c. as in the former year; and next spring the plants will still rise stronger, and the roots continue increasing in size; so as by the following October, having had three summers' growth, they will be fit to take up for use.

The method of taking up the Madder-roots is by trenching the ground the way of the rows; beginning at one end of the ground, and open a two feet wide trench close along by the first row of plants, digging down to the depth of the roots to get them clean out to the bottom;

bottom; then opening another trench close to the next row, turning the earth thereof into the first; and so proceed trench and trench till the whole is taken up.

The madder roots, thus taken up for use, are sometimes used fresh for dying, preparing them by washing, and pounding them as before observed. But commonly when designed for keeping, or to be sent to a distance, are dried in some covered airy shed; then all mould being rubbed off, and the roots sufficiently dry, they may then be sold to those who manufacture them for use, if not performed by the cultivator; which consists of kiln drying them, or drying them in some stove-house, &c. then threshed to beat off the outer skin, in order to separate it from the inner part of the root, as being of inferior quality. The roots being then dried in a kiln about twenty-four hours, are removed to a mill, or pounding-house, where they are pounded in a long hollow oaken block, with stampers kept in motion by the mill; and when thus reduced to powder, is sifted and put up in casks for use.

But in Holland, where great quantities of this plant is cultivated, they have public kilns, mills, &c. where the cultivators send the roots to be manufactured. And there are treatises to be had here, exhibiting the kilns, mills, and other necessary accommodations for manufacturing this valuable material; together with full directions in the management thereof.

RUBUS. Bramble, and Raspberry-bush.

Consists of under-shrubby and herbaceous perennials, valuable, some as fruit-bearing plants, and others for variety in the pleasure ground, particularly the shrubby kinds; some being of erect growth, others long trailers, garnished with pinnated, ternate, and palmated leaves, in different species; and pentapetalous, icofandrous flowers.

Class and order, *Icosandria Polygynia*.

Characters.] **CALYX** is monophyllous, five-parted and permanent. **COROLIA**, five-roundish erecto-patent petals. **STAMINA**, twenty or more short filaments, having roundish compressed antheræ. **PISTILLUM**, numerous germina, many capillary styles from the sides of the germens, crowned with permanent stigmas. **PERICARPUM**, a compound berry, composed of many roundish unilocular acini, each having one oblong seed.

There are many species, nine or ten of which are ligneous and shrubby; the others are somewhat herbaceous; but the most material sorts are principally of the ligneous, or shrubby kind, and of which about five or six of the most noted species are cultivated in our gardens; the first of which, *Rubus Idæus*, or Raspberry-plant, is chiefly valued for its fruit;

and the other sorts as furniture for the shrubbery, &c. They are all deciduous plants of hardy growth, that succeed in any common soil and situation: and consists of upright ligneous kinds, trailing shrubby kinds, and herbaceous kinds.

Upright ligneous Kinds.

Under this head is comprised the common Raspberry-plant, and varieties; and other Raspberry Kinds. All of which rising with several upright ligneous, or under-shrubby stems, from about three or four to six or seven feet high.

1. *RUBUS Idæus*.

Common Raspberry Bush.] Rises with several upright, straight, ligneous, pithy stems from the root; four or five feet high, closely armed with short prickles; pinnated, three and five-lobed rough leaves; and at the axillas and ends of the lateral shoots, small clusters of purplish, and white flowers, succeeded by ripe berries in July.

Varieties.] Purple-flowered Raspberry—white-flowered Raspberry—common red-fruited Raspberry—white-fruited Raspberry—twice-bearing red and white Raspberry, producing the first crop of fruit in July, and the second in September; and is esteemed a curiosity—smooth or cane Raspberry, the stalks, &c. being devoid of armature—large Antwerp Raspberry; strong tall stems, and large fruit.

The common red sort grows wild in woods in England, but has been greatly improved by garden culture.

All the varieties bear plentifully, they being all propagated by suckers, planted in any open situation, in rows four or five feet asunder, and a yard distant in the rows; being planted in autumn, winter, or spring, they bear the summer following. Their mode of bearing is upon the year-old wood; that is, a supply of shoots or stems rising annually from the root; which, when a year old, send out many small laterals, and upon these the fruit is produced the same year; remarking, the same individual stems never bear but once; a succession of young shoots or stems being sent up annually from the root every summer for bearing; those produced one year, bear the fruit the next, and then totally decay to the root, in winter following; they never surviving to bear a second year, but are always succeeded by a plentiful supply that have arisen from the bottom in summer for next year's bearing; so that every winter, all the decayed stalks that bore the fruit the preceding summer, must be cut or broken down close to the ground; they being readily distinguished from the young succession stems, which at the same time must be regularly thinned to four or five of the strongest

shoots on each root; and these should be topped to about three or four feet height, or a little more or less, according to their strength, and they will all branch out laterally the following spring; and upon the laterals the flowers and fruit are produced.—See the *Propagation and general Culture*.

The Raspberry is in estimation both as eatable fruit, and for many culinary purposes, as for tarts, sauces, Raspberry wine, &c.

2. *RUBUS odoratus*.

Odoriferous Virginia flowering Raspberry.] Rises with many upright, large, under shrubby, brown, inermous stems, from the bottom, five or six feet high; very large, simple, palmated leaves; and the shoots terminated by many large purplish flowers, succeeded by small red fruit; rarely ripening in England.

This plant is very ornamental, having beautiful large foliage, and numerous large flowers: continuing near two months, which renders it worthy of admittance in every shrubbery plantation; where it will multiply exceedingly by suckers sent up annually from the root all around.

3. *RUBUS occidentalis*.

Occidental, or Canada Black-fruited Raspberry.] Rises with erect, ligneous, prickly, purplish stems four or five feet high; ternate leaves, hoary underneath, having round footstalks; and the shoots terminated by clusters of small flowers, succeeded by small black fruit.

Trailing Shrubby Kinds.

Consists of the common Bramble, and varieties; and some others of the Bramble kind, being mostly shrubby trailers, of hardy growth, and deciduous.

4. *RUBUS fruticosus*.

Shrubby Rubus, or common Bramble of the Hedges.] Hath very long, shrubby, trailing, channeled, greenish, and reddish stalks closely armed with strong crooked aculei; digitated, five and three lobed leaves, having prickly petioles; and all the lateral shoots terminated by clusters of white flowers, succeeded by ripe black berries in autumn.

Varieties.] Common Bramble, or Blackberry plant of the hedges—double blossomed Bramble of the gardens—white-fruited Bramble—inermous, or thornless Bramble—cut-leaved Bramble—striped-leaved Bramble.

All these varieties are of trailing growth, with very long, luxuriant, durable shoots. The common wild bramble, or Blackberry plant, being the parent species, which grows wild on banks, and in field-hedges, almost every where; so is seldom admitted in gardens, except a plant or two for variety among the climbing-tribe, or where wilds or thickets are

intended. But the double blossomed Bramble, white-berried, and thornless kind, &c. being curiosities, they claim admittance in every shrubbery; and may be trained both as climbers, allowing them support of bushes or stakes; or may be trained as standard shrubs, if staked, and pruned down at top, to cause them to shoot out into bushy heads, continuing to reduce the rambling shoots as occasion requires, to keep the head to the desired form; and where any part of a garden is designed to represent wilds, &c. some plants of all the varieties should be introduced, and suffered to shoot and run according to the course of nature.

5. *RUBUS cæsius*.

Blue-berried Bramble, or Dewberry-bush.] Hath long, cylindric, slender, trailing, prickly stalks; ternate, almost naked leaves; and whitish flowers at the sides and ends of the branches, succeeded by large sky-blue fruit in autumn.

It grows naturally in moist situations in England, and is sometimes admitted into gardens for variety.

6. *RUBUS hispídus*.

Hispid Canada Bramble.] Hath long, ligneous, procumbent, hispid stalks; ternate, naked, cut, ferrated leaves, with hispid footstalks.

Herbaceous Perennial Kinds.

Comprises two dwarfish, somewhat herbaceous, durable plants of erect growth, rising but a few inches high.

7. *RUBUS Chamæmorus*.

(Chamæmorus) Dwarf Mulberry, or Cloud-berry.] Rises with slender inermous stalks, six or eight inches high; garnished with two simple, lobated leaves; and the stalks terminated by one purple flower, succeeded by a small black fruit, resembling a mulberry.

It grows naturally in England and Scotland, &c. in high moorish situations.

8. *RUBUS arcticus*.

Northern Rubus, or Dwarf Siberian Bramble.] Rises with erect inermous stalks, but three or four inches high; ternate leaves, and the stalks terminated by purple flowers, singly; succeeded by small red fruit, having the smell and taste of strawberries.

All the above eight species of *Rubus* are for the general part deciduous, the leaves coming out in the spring, and fall off in the winter; and they flower generally in June and July. The flowers are composed each of five roundish petals, and numerous stamina, succeeded by roundish compound berries, each being composed of many small acini of a pulpy juicy nature; ripening from July till October, in different sorts: remark-

ing.

ing, those of the *Rubus Idæus* and varieties are the principal sorts for general use.

The plants of all the species are very hardy; the ligneous, and shrubby kinds, in particular, will prosper almost any where. But the herbaceous kinds, being naturally residents of moorish or fenny places, require some similar situations when cultivated in gardens.

With respect to the merit of all the sorts as garden plants, observe as follows.

The first species, *Common Raspberry*, and varieties, demand culture in every garden for their fruit; all of which are great bearers: but for the general plantations, chuse principally the common red and the white kind, as being generally the greatest bearers of all. Planting also a share of the twice-bearing sort, both as a curiosity, and for the sake of its autumnal crops of fruit, which, in favourable seasons, ripen in tolerable perfection; likewise introduce a portion of the Antwerp kind, for its large fruit: observing to allow all the sorts some open exposure in the kitchen garden, or any other district occasionally, as they will prosper in almost any situation. It is however advisable to plant the general plantations mostly in a free exposure, in rows a yard and half asunder: some plants may also be disposed singly about the borders or shrubby clumps, for variety: and, in all the modes of planting, they should generally be kept to single bunches of four or five stems on each root or stock. See their *Propagation and general Culture*.

The other seven species are considered as plants of variety, for hardy plantations in the shrubbery: some of which are also very ornamental flowering plants; particularly the Virginian flowering Raspberry, the occidental kind, and the double-blossomed Bramble; all of which having great merit as furniture for ornamental compartments: and the white-berried Bramble is a great curiosity. All the other species and varieties serve to diversify large collections.

Propagation and Culture of the common Raspberry and Varieties

The propagation of the common Raspberry and varieties is expeditiously effected by suckers from the root; all the sorts sending up great numbers on all sides annually, growing from three to four or five feet height the same year, and form proper plants by autumn or winter following, for transplanting for new plantations, and will all bear fruit the following summer.

Therefore, any time from October till March, in open weather, having recourse to some good bearing plantation of Raspberry

plants of some standing; and proceed to take up a sufficient quantity of last summer's suckers, that are situated around the outside of the stools, or main stock, raising them carefully with plenty of fibres; and, having obtained a proper quantity, then let them be trimmed for planting, shortening any long straggling roots, and, if any naked woody parts of the root of the old stool adhere, cut it off; observing at the same time, if one or more buds appear near the root, they being the embryo of future shoots, must be very carefully preserved: and shorten each sucker at top, to about two or three feet long, or more, according to their strength; they are then ready for planting: having, previous to this, chosen an open spot of good ground, as before advised, and having well dunged and trenched it one or two spades deep, proceed to put in the plants above prepared, as soon as possible.

With a line mark out the distances for the plants, in rows, a yard and a half distance, and a yard asunder in the rows, which is considerably more than is commonly allowed: but, if planted much closer, the plants, as they send up numerous suckers in summer, would grow so close, as to form quite a thicket, so as to exclude the due influence of sun and air from the fruit, as well as to render it troublesome to get between the rows occasionally, to gather the produce; therefore allow the above distances: and having drawn lines accordingly, proceed with a spade, and open small apertures in the ground, close along the line, one for each plant, a yard asunder, planting them as you go on, one in each hole erectly, or, if plenty of seeds, may put two or three in a hole, at some little distance from one another: covering in the roots properly with the earth, treading it moderately firm, to preserve the upright position of the plants: observing, if the planting is performed late in the spring, it is advisable to give a good watering, and repeat it occasionally, till the plants have struck fresh root.

Having thus made a plantation of Raspberries, they will readily take root, and set to growing freely in the spring, they being naturally of a free growth, and most of them will bear tolerably the first summer; but in the second they will bear a full crop in the utmost perfection.

As to their general culture, it consists of the following operations—Keeping them clean from weeds all summer by broad hoeing; giving them an annual dressing in autumn or winter, consisting of breaking or cutting down the decayed stems that bore the preceding summer; thinning the young succession bear-

ers; clearing away all intermediate suckers between those of the main stocks, and then dig the ground between the rows of plants; observing the following particulars of the method of performing the operations of their annual dressing.

Previous to the above-mentioned annual dressing of Raspberries, observe, as we before noticed, of their mode of bearing, that as they produce a fresh supply of shoots or suckers every year from the bottom for bearing, those produced one year bear the next, then totally decay to the root in winter, there being at the same time a succession of last summer's shoots, on the same stools, for bearing the summer following: therefore, in the annual dressing, which may be performed any time from October till March, first proceed to clear out all the decayed stems, being last summer's bearers, cutting or breaking them down close to the bottom; then examine the supply of young shoots for the next year's bearing, selecting three or four, but not more than five or six of the strongest on each stool, cutting all the others away close to the ground: likewise draw up all straggling suckers between the main plants; all of which remaining plants should be shortened according to their strength, cutting them generally a little below the bend at top of the shoots, to about three or four feet in length, both to render them more robust to support themselves more firmly upright in summer, and to promote a stronger supply of laterals for flowering and fruiting. Or if you should choose to leave them longer, or at full length, those of each stock may be plaited or tied together, in order to support each other erect: then having cleared away all the rubbish, let the ground between the rows be neatly dug one spade deep. As you proceed in digging, clear out all the roots of straggling suckers between the rows, &c. leaving the earth close and level about and between all the plants: thus far is the whole necessary culture of a plantation of Raspberries, which must always be repeated annually, at the seasons abovementioned.

Allow them a little manure of rotten dung once every two or three years, applying it in the winter dressing, and dig in one spade deep; it will add vigour to the plants, so as to continue them producing fruit in great perfection several years.

However, it is advisable to make a fresh plantation every four, five, or six years, in a fresh spot of ground, as after that period of time, the plants, although they may continue shooting with tolerable vigour, yet they are apt to be less fruitful, and the fruit smaller

than in younger plantations in a fresh prepared piece of ground.

Propagation, &c. of the other Species.

The propagation of the other species of Raspberries, Bramble, &c. is by suckers, layers, cuttings, dividing the roots, &c. and the two herbaceous kinds also by seed.

By Suckers.—All the Raspberry kinds in particular send up many suckers annually, and by which they may be propagated in great abundance, taking them up in autumn, winter, or spring, with roots; and the strongest may be planted at once into the shrubbery, and the others in nursery rows for a year or two, or till wanted.

By Layers.—All the Bramble kind are easily propagated by this method; laying the shoots almost any time, they will readily emit roots at every joint, and be fit to transplant in autumn following.

By Cuttings.—By this method also may the Brambles be propagated in autumn; cutting off some of the younger shoots, and divide them into lengths a foot long, and plant them in a shady border; many of them will strike.

By dividing the Roots.—Any of the Raspberry kind, &c. and the herbaceous species, when increased into large bunches, may be divided or slipped into several distinct sets, and plant them separately.

By Seed.—As the two herbaceous species do not always increase freely by roots in gardens, therefore, in default of which, procure some of the ripe fruit in autumn, or as soon as possible; and chusing some moist situation, either in a nursery, or where you design the plants to remain, sow the seed half an inch deep; observing, if some of the plants are permitted to remain where raised, they will probably be more prosperous than such as are transplanted.

RUDBECKIA, Dwarf American Sunflower.

This genus comprehends several herbaceous flowery perennials, and a biennial, serving to embellish the pleasure ground; rising with annual stalks, from about half a yard to six or eight feet high, garnished with oval, spear-shaped, and divided leaves; and the stalks terminated by large compound radiated flowers.

Class and order, Syngenesia Polygamia Frustanea.

Characters.] CALYX, a general calyx, composed of two orders of broad, plane, short, scaly leaves, containing many florets. **COROLLA** is compound, and radiated; consisting of many tubular, hermaphrodite florets in the disk, and spear-shaped, flat, neuter, barren

ren florets in the radius. STAMINA, five very short hair-like filaments, having cylindric antheræ. PISTILLUM, a tetragonous germen, filiform style, and bipartite revolute stigma. PERICARPIUM, none; the hermaphrodite florets are succeeded each by one oblong seed, quadridented, and crowned with down, and all the seeds lodged in a conic chaffy receptacle.

There are about six species in our gardens; five of them herbaceous perennials, and the sixth a biennial, all natives originally of North America; but grow freely here in our gardens, in any open compartments.

Perennial Kinds.

1. RUDBECKIA *hirta*.

Hairy Dwarf American Sunflower.] Rises with upright stalks, a foot and half high; oval-spatula-shaped, undivided, triple-nerved leaves; and the stems dividing upward into many long pedunculi, terminated each by one large radiated yellow flower, having a prominent purple disk, and the petals of the radius emarginated.

2. RUDBECKIA *purpurea*.

Purple Dwarf American Sunflower.] Rises with upright stalks about two feet high; oval-lanceolate, undivided, alternate leaves; and the stalks and branches terminated by purple flowers, singly; having the petals of the radius bifid.

Varieties.] With a dark-purple disk, and pale red radius—with long purple petals in the radius—with broad petals in the radius.

3. RUDBECKIA *laciniata*.

Jagged-leaved Tall Virginian Rudbeckia.] Rises with upright stems, six or eight feet high; large, compound, mostly five-lobed leaves, having the lobes deeply laciniated, or jagged; and the stems and branches terminated by radiated yellow flowers.

Varieties.] Broad-leaved—narrow-leaved—purple-stalked, with digitated leaves, &c.

4. RUDBECKIA *angustifolia*.

Narrow-leaved Dwarf American Sunflower.] Rises with upright firm stems, two or three feet high, or more; long, linear, or very narrow, entire, opposite leaves; and the stalks terminated by yellow-rayed flowers, having a dark-red disk.

5. RUDBECKIA *oppositifolia*.

Opposite-leaved Dwarf American Sunflower.] Rises with upright stalks two or three feet high; lanceolate-oval, serrated, opposite leaves, and wholly yellow flowers, having the petals of the radius bifid.

Biennial Kind.

6. RUDBECKIA *triloba*.

Three-lobed Virginian Rudbeckia.] Hath

spatula-shaped, trilobed, radical leaves; amidst them upright stems, garnished also with three-lobed leaves; but those on the branches are undivided; and yellow-rayed flowers, having dark-purple disks.

All these six species flower here annually in July and August; often continuing in succession till September or October; and in some sorts, are sometimes succeeded by ripe seeds in autumn, particularly the first and last species.

They are all tolerably hardy: the first five species are mostly perennial in root, but annual in stalk; though the fourth and fifth sorts have often a tendency to a biennial nature; however, the sixth sort is perfectly biennial; all of which send up their flower-stems in the spring, which generally branch out upward, the branches terminated by long pedunculi, each crowned by one moderately large radiated flower, nearly resembling the common sunflower, but smaller; have generally a prominent, somewhat pyramidal disk, and a spreading radius; and are all very conspicuous, even at a distance.

All the species are proper furniture for the open compartments of the pleasure-ground, as being very showy plants when in bloom; and produce many flowers in succession, two or three months; effecting a good ornamental appearance.

Observe to allow most of the sorts a lightish, dry soil, and somewhat warm situation; remarking however, the third sort in particular (*Rudbeckia laciniata*) will succeed almost any where.

Method of Propagation, &c.

Their propagation is by off-sets, and parting the roots, and by seeds.

By off-sets, and parting the roots.—This is practicable for all the perennial kinds; but the first sort in particular generally resolves itself into several off-set heads, at the crown of the root, which being slipped in autumn, or early in spring, each will form a proper plant. Most of the other perennial sorts increase by the root, though the *Rudbeckia purpurea* multiply rather more sparingly than the others; however, the propagation of all the sorts may be effected less or more by parting the roots in autumn, when the stalks decay.

Observe, as some of the perennial kinds sometimes discover a tendency to go off in three or four years, it is eligible to continue propagating them frequently to keep up a stock of vigorous plants. Some sorts being also sometimes inclinable to a biennial nature, are apt to decay soon after they have flowered, without increasing at root, for future propagation, particularly the fourth and fifth sorts;

forts; to prevent which, it is proper to cut down some of the flower-stems of such kinds in May, or early in June, which will encourage their multiplying more effectually by root off-sets, fit for slipping next autumn.

By Seed.—All the sorts may be raised plentifully from seed; but the biennial sorts in particular must always be raised from seed annually; likewise, such of perennials as are biennially inclined; sowing the seeds in April, in a border of light earth, and rake them in; and when the plants are two or three inches high, prick them out in nursery-rows, till autumn; then transplanted where they are finally to remain.

RUMEX, Dock; comprehending the *Acetosa*, or Sorrel, &c.

This genus furnishes herbaceous perennials for the kitchen-garden, and pleasure-ground, and a ligneous ever-green for the green-house; are garnished with simple, oblong-sagittated and roundish, heart-shaped leaves; and spikes of small tripetalous flowers of no beauty.

Class and order, *Hexandria Trigynia*.

Characters.] CALYX, three obtuse, reflexed, permanent leaves. COROLLA, three small oval, connivent, permanent petals, like the leaves of the calyx, but larger. STAMINA, six very short capillary filaments, having erect didymous antheræ. PISTILLUM, a turbinate triquetrous germen, three hair-like reflexed styles, and large lacinated stigmas. PERICARPIUM, none; a single triquetrous seed, lodged in the permanent corolla.

To this genus, *Rumex*, is added the *Acetosa* or Sorrel, formerly considered as a distinct genus, consisting of several species, but now all ranged as species of *Rumex*, which comprehends in the whole many herbaceous, and one woody species; eight or ten of the former grow wild in this country, and the others are of foreign growth; but there are not more than four or five that have merit for garden culture; consisting of four hardy herbaceous perennials, and one tender woody plant.

Hardy Herbaceous Kinds.

Under this head is comprised the common culinary Sorrels for the kitchen-garden; the Patience Dock, &c. and Bloody Dock, for medical purposes, and variety; all of which are hardy perennials.

The two first sorts are of the Sorrel kind.

1. RUMEX *Acetosa*.

(*Acetosa*)—or Common Arrow-pointed Meadow Sorrel.] Hath fibrated roots, crowned by a large tuft of oblong-sagittated leaves; and amongst them upright stems a foot or more

high, terminated by spikes of small herbaceous dioecous flowers succeeded by ripe seeds in autumn.

Varieties.] Common Meadow-sorrel—Barren Northern Sorrel, which rarely running to seed continues almost always in leaf for use—broad-leaved Mountain Sorrel.

The Common Sorrel is a natural resident of our meadows and pastures; but has been long admitted an inhabitant of the gardens as a soup-herb; and is the most commonly cultivated Sorrel for general use, both as a valuable acid culinary herb, and for medicinal purposes; its leaves being the useful part, which by garden culture obtain a fine large size.

The plants are easily raised from seed, and by parting the roots. See their *Propagation*, &c.

2. RUMEX *scutatus*.

Shield-shaped Rumex, Round-leaved, or French Sorrel.] Hath a creeping root crowned with a tuft of large roundish-heart-shaped, hastated leaves; rambling shoots, and the flower stems terminated by spikes of small hermaphrodite flowers, succeeded by seeds in autumn.

This species of Sorrel is by many preferred to the common *Acetosa*, or Meadow Sorrel; the leaves being larger, and thought to possess a more agreeable acid relish.

The above two species of Sorrel and varieties are all of the culinary kind; any or all of which may be raised for general use; and may, all but the Barren Sorrel, be propagated by seed: all the sorts also by parting the roots, planting them in any bed or border, ten or twelve inches asunder, and they will furnish leaves most part of the year.

3. RUMEX *Patientia*.

Patience Dock, or Monk's Rhubarb.] Hath a large, thick, divided, deeply-striking root, yellow within, crowned with large, oblong-heart-shaped leaves, a foot long, on very thick reddish foot-stalks; upright strong stems, dividing and branching three or four feet high; having the branches terminated by close erect spikes of whitish hermaphrodite flowers, and with entire valves, one being graniferous.

Variety.] Round-leaved Alpine Patience Dock; commonly called Monk's Rhubarb.

This species and variety are natives of Italy and the Alps; are retained in our gardens both as medical plants, and to effect variety, also formerly for culinary uses; they shoot up into stalks annually in the spring, flower in May, and ripen seeds in autumn.

4. RUMEX *sanguineus*.

Bloody Dock.] Hath long downright roots, erect red-stalks, two or three feet high; heart-formed lanceolate leaves, having blood-red

veins, and many red spots; the stalks terminated by spikes of hermaphrodite flowers, and with entire valves, one being graniferous.

This is retained in many gardens for the sake of variety.

Woody Kind for the Green-house.

5. RUMEX *lunaria*.

Tree-like Rumex, commonly called Tree Sorrel.] Rises with a woody, tree-like, smooth stem, branching eight or ten feet high; garnished with roundish - heart - shaped leaves; the branches terminated by loose panicles of greenish hermaphrodite flowers, and with smooth valves.

This is an exotic from the Canary Islands, and is retained in our gardens to increase the variety in the green-house collection.

The above five species are principally all the sorts of *Rumex* commonly cultivated in the English gardens; the four herbaceous kinds are perennial in root, and annual in stalks, and hardy enough to succeed in any open situation, and the woody kind is durable both in root and stem, &c. and is tender, requiring shelter of a green-house in winter. They flower generally in June or July; the flowers are small and tripetalous, generally terminating the stalks and branches in spikes, but are not ornamental; and are succeeded by ripe seeds in autumn.

Their merit as garden plants is—all the herbaceous Sorrel kinds are eminent soup-herbs for culture in the kitchen-garden, as aforesaid: the *Rumex Patientia*, as a medical plant; also, together with the *Rumex sanguineus*, is often employed for variety in the pleasure-ground; and the *Tree Sorrel* being tender, must be potted and placed among the green-house exotics.

Propagation and Culture.

Most of the herbaceous culinary Sorrels are raised from seed, and by parting the roots.

By Seed.—The common Sorrel, and round-leaved kind, may be raised abundantly by seed in the spring; but the common Sorrel in particular is occasionally more generally raised by this method, as the other propagates exceedingly by its repent roots, &c. However, both sorts may be sown in March, in any bed or border, broad-cast, and rake them in evenly, they will soon come up; observing, if the plants rise too thick, thin them moderately; and after being a little advanced in growth in summer, plant out a quantity of the stoutest in moist weather, in some bed or border in rows, the common sort and varieties about eight or nine inches asunder, and the other a foot at least, giving proper waterings, and they will grow freely, and be fit to cut for use the same

summer and autumn, &c. and continue several years.

Observe however, of the common Sorrel in particular, that as seedling plants of one or two years old generally produce larger leaves than older plants, it may be eligible to raise a fresh supply of seedlings annually, or every other year.

By parting the roots.—All the sorts may be propagated by this method, but the Round-leaved French Sorrel in particular increases exceedingly by running at the root; and the Barren Sorrel, rarely producing seed, is propagated principally only by parting the roots. However, any of the sorts may be easily increased by this method, which may be effected either in autumn or spring, though I should rather prefer the spring season, about the beginning or middle of March: either slipping off a quantity of off-sets from the old plants as they stand, by assistance of a knife or spade; or take some of them wholly up, and divide them into several slips, planting them in rows a foot distance, and give directly a good watering; they will expeditiously take root, assume a free growth, and furnish plenty of leaves for use all summer and autumn, &c.

As to the culture of these plants, very little is required more than the necessary care of keeping them clean from weeds; and in summer, when they run to stalk, it is proper to cut them down close to encourage a more plentiful supply of large leaves from the bottom; likewise, when the leaves have become very rank, cut them down occasionally towards the latter part of summer, that the roots may send up a good supply of fresh leaves for autumn, and winter service.

The *Patientia* and Bloody Dock are also raised by seed, and the former likewise by roots.

By Seed.—In autumn, or early in spring, sow the seed in a bed of light earth, and rake it in; and when the plants are come up three inches high, thin out a quantity, and plant them either in nursery-rows a foot distance, or at once where they are to remain.

By Roots.—The *Patientia* Dock, and variety, increase by off-sets from the root, which being slipped in autumn, and the slips directly planted, they will readily grow.

And the *Rumex lunaria*, or *Tree Sorrel*, is propagated easily by cuttings of the young shoots in spring and summer; if performed in spring, plant them in pots, and plunge them in a hot-bed, they will very soon emit roots; but in summer, they will succeed without aid of artificial heat, planted either in pots, or in a border of common earth, and occasionally

ally shaded and watered, many of them will strike and be well rooted by autumn.

RUSCUS, Butcher's Broom, and Alexandrian Laurel.

Consists of low shrubby and under-shrubby ever-greens, for the shrubbery and green-house collection; rising some three or four feet high, others scarcely a foot; garnished with smallish, oblong, and lanceolate leaves, some prickly, others smooth, from one to three inches long, and from half an inch to an inch broad, remaining all the year; and diœcious apetalous flowers, produced, in most sorts, on the surface and margin of the leaves, and in some at the ends of the branches.

Class and order, *Diœcia Syngnesia*.

Characters.] **CALYX**, diœcious, or male and female flowers, on two distinct plants; having spreading cups composed of six oval convex leaves.—**COROLLA**, no petals, but an oval erect nectarium, the size of the calyx, open at the mouth.—**STAMINA**, no filaments, but three united antheræ, in the males, sitting on the nectarium, and joining at the base. **PISTILLUM**, an oblong-oval germen, hid within the nectarium, a cylindric style, crowned by an obtuse stigma, standing above the mouth of the nectarium. **PERICARPIUM**, a round or globular trilocular berry, having two round seeds.

This genus consists of five species, three or four of which are hardy for any open plantations; and the others tender, requiring shelter of a green-house in winter.

Hardy Kinds.

Under this head is comprised the common Butcher's Broom—*Hypoglossum*, or Tongued Laurel—and Alexandrian, Laurel, &c. all of which are shrubby ever-greens, mostly of hardy growth for the shrubbery, &c. though the second, third, and fourth sorts, are also sometimes potted, to move under protection from severe frost; however, in a dry sheltered situation, they commonly stand out winter, in the open ground.—and the first sort is very hardy to stand all weathers.

1. *Ruscus aculeatus.*

Prickly Ruscus, Common Butcher's Broom, or Kne-Holly.] Hath a thick, fibrated, creeping, deeply-furking, white root; several erect, shrubby, tough, green stems, two or three feet high, closely garnished with small, oval, stiff, dark-green leaves, placed alternately, terminating in prickly points; and small, purplish flowers, situated on the upper surface of the leaves, succeeded in the female plants, by large red berries, ripening in winter.

This species grows abundantly in England, &c. in woods, and is introduced in many gar-

dens, in wilderness and shrubbery plantations, for variety.

Great quantities of the young bushy plants of this species are brought to London in winter, &c. for sale; they being collected in the neighbouring woods, by the herb people, taking them up with a little ball of earth about the roots, wrapping the ball up with moss, and in that manner hawk them about the streets; and the citizens buy them to plant in pots of sand, to adorn rooms, where they will remain green a long time. It is also in much request among the butchers, for scrubbing brooms; the branches being tied in tight bundles, forming a sort of broom, or besom; and with which they scrub and clean their chopping-blocks. Hence the name Butcher's Broom.

2. *Ruscus Hypophyllum.*

Under-leaf-flowering, Broad-leaved Ruscus, called Alexandrian Laurel.] Hath thick, knotty, long fibrated roots; many ligneous, pliable, tough, green stems, two or three feet high: oblong-oval, stiff, shining-green leaves, placed alternately, and bearing flowers on their under surface; succeeded, in the female plants, by small red berries, ripening in winter.

3. *Ruscus Hypoglossum.*

Under-tongue-flowering, long-leaved Ruscus, or Tongued-leaved Alexandrian Bay.] Hath thick fibry roots; many ligneous, slender, pliable, green stems, ten or twelve inches high; long spear-shaped leaves, each having a smaller leaf, like a tongue, issuing from its upper surface, and from the bottom of which are produced small yellowish flowers, succeeded by large red berries, ripening in winter.

It is a native of mountainous parts of Hungary and Italy.

4. *Ruscus racemosus.*

Racemose flowered Ruscus, or Alexandrian Bay.] Hath thick, long, fibry, whitish roots; many shrubby, smooth, very pliable, shining-green stems, four or five feet high, producing branches alternate ways; garnished with oblong-lanceolate, shining-green leaves; and yellowish hermaphrodite flowers, terminating the branches in racemous clusters, succeeded by large red berries, ripening in winter.

Variety.] With red flowers.

The above four hardy species grow freely in any of the shrubbery plantations; and multiply exceedingly by off-set suckers from the bottom.

The last three species, natives of Italy, Hungary, &c. having the name of Alexandrian Laurel or Bay, most of which being of a very pliant growth, and closely set with ever-green leaves, are supposed to be the plants used by the ancients in those parts, for composing

posing wreaths to crown their victors and eminent poets.

Tender Kind for the Green-house.

5. *Ruscus androgynus*.

Androgynous Canary Ruscus.] Rises with shrubby, pliant stems, five or six feet high, producing many side branches; garnished with oblong, stiff leaves; bearing small white flowers on their edges, succeeded by reddish berries.

All the above five species of *Ruscus* flower abundantly in June and July; four of which producing their flowers wholly upon the leaves, exhibit a curious singularity; and the *Ruscus androgynus* in particular, which having its flowers closely set all along the edges of the leaves, effect a singular and beautiful appearance; and the hardy sorts are often succeeded by ripe fruit in our gardens in winter.

All the hardy sorts are proper furniture for the verges of shrubberies, or any close plantations, as they thrive under the drip of trees, and will remain green the year round, and increase the variety of these compartments.

The tender sort requires shelter of a green-house in winter, so must be planted in pots and managed as other shrubby exotics of that department.

The propagation of all the sorts is very easy, as they increase very fast by the roots, which sending up numerous stalks or suckers, they may be taken up in autumn, winter, or spring, in open weather, and divided into many separate sets, each forming a proper plant; though they need not be divided too small, unless where a great increase is required, planting the largest at once where they are to remain, and the smallest in nursery-rows, &c. each plant will soon increase by off-sets, and assume a bushy growth.

They may also be raised from seeds, though not expeditiously, for the seed often remains in the ground till the second spring; sow that of the hardy sorts in any bed or border an inch deep; and the tender kind in pots, and placed under shelter, in cold weather; and when the plants are a year old, it is proper in March to prick them out, the hardy sorts in nursery-beds, for two or three years; and the tender sort in pots.

RUTA, Rue.

It consists principally of under-shrubby evergreens for the kitchen-garden and pleasure-ground; adorned with small decomposed and supra-decomposed, many lobed, and ternate leaves, and small tetrapetalous flowers, growing in bunches.

Class and order, *Decandria Monogynia*.

Characters.] CALYX is short, five-parted, and permanent. COROLLA, four oval spread-

ing petals. STAMINA, ten awl-shaped patent filaments, having short erect antheræ. PISTILLUM, a gibbous, cross-furrowed germen, having ten punctures, an erect style, and simple stigma. PERICARPIMUM, a gibbous, five-lobed, quinquelocular capsule, opening in five parts at top, having many reniform, angular, rough seeds.

There are three species, one of which only, a shrubby perennial, is common to the English gardens, comprehending some varieties, valued both as medical plants, and sometimes to diversify the shrubbery; and the other two species are also eligible for the same occasion.

The species is,

1. *RUTA graveolens*.

(Rank-scented) or common Garden Rue.] Rises with a shrubby, very branchy stem, four or five feet high, forming a bushy head; closely garnished with decomposed, many-lobed, strong-scented, grey leaves; and the branches terminated by bunches of yellow flowers, having torn petals, and the lateral flowers quadrifid, succeeded by ripe seeds in autumn.

Varieties.] Common broad-leaved garden Rue—narrow-leaved Rue—variegated-leaved Rue.

They all flower in June, and ripen plenty of seed in autumn, particularly the common sorts.

2. *RUTA chalepensis*.

Aleppo Broad-leaved Rue.] Grows three or four feet high, garnished with supra-decomposed leaves, and hairy flowers.

Varieties.] Broad-leaved—narrow-leaved.

3. *RUTA patavina*.

Patavian three-leaved Rue.] Having ternate or threed, close-fitting leaves.

All these species and varieties are hardy enough to succeed in the open ground, though the two Aleppo Rues should have a sheltered situation, and dry soil; and it is advisable to pot some of those two sorts, to move to shelter of a frame, or green-house, in winter: the variegated kind should likewise have a dry, poor soil, otherwise is apt to become vigorous, and lose its variegations.

As to their uses in gardening, the common broad and narrow-leaved Rues are esteemed principally as domestic medicinal plants; their virtue as such, resides in the leaves; being occasionally used in a simple medical way in a family; and for which a few plants merit culture in every garden, allowing them generally a dry soil, and may be raised both by seed, and by slips or cuttings: and afterwards planted out either singly about the borders; or a few plants together in the herbary; or where large quantities

quantities are wanted, plant them in rows two feet asunder, and a foot and half in the lines; all the species and varieties may also be employed in the shrubbery compartments, in a dry situation, where they will effect an agreeable diversity, both in foliage and flowers.

The propagation of all the varieties is by seed, and by slips and cuttings.

By Seed.—The common Rue in particular may be raised plentifully, by seed in the open ground; sown in March or April, on a bed of light earth, and rake it in; they will soon come up, which, when two or three inches high, should be planted out in nursery rows, and watered till fresh rooted.

From the scattered or self-sown seeds of the

common Rue, many young plants often rise in autumn and spring.

By Slips or Cuttings.—This is the most expeditious method of propagation for all the sorts; for every slip or cutting of the young wood will readily grow; and is the only method of propagation, by which we can continue the different varieties distinct; therefore in spring, any time in March or April, slip or cut off a quantity of the young shoots, six or eight inches long, and plant them in a shady border, in rows half a foot asunder, giving a good watering, and repeat it occasionally, they will soon emit roots below, and shoots at top, so as to form little bushy plants by autumn.

S.

S A C

SACCHARUM, Sugar-cane, or Sacchariferous Reed.

The plants of this genus are tall growing tender perennials, of the arundinaceous tribe, natives of the Indies, and retained here in our stoves for variety; one of which is a most valuable plant, in its native soil, as from the juice of its stalks is prepared the various sorts of sugar; they rising with erect, strong, juicy stems, eight or ten feet high, adorned with very long leaves, and terminated by large panicles, and spikes of numerous bivalvous flowers.

Class and order, *Triandria Digynia*.

Characters.] **CALYX**, none; but a woolly down incloses each flower. **COROLLA**, is bivalve; having two oblong-lanceolate, acuminate, concave valves. **STAMINA** three capillary filaments, as long as the valves, and oblongish antheræ. **PISTILLUM**, a subulate germen, two cirrhose styles, and simple stigmas. **PERICARPIUM**, none; one narrow sharp-pointed seed to each floret, invested by the valves.

The species are,

1. **SACCHARUM officinarum**.

Common Sugar Cane.] Hath a long thick-jointed, fibrated, succulent root; sending up several upright, round, jointed stems, from six or eight to ten feet high, or more; abounding with a pithy saccharine juice; having at

S A C

each joint large oblong leaves, three or four feet long, the base embracing the stalk a considerable way up; and the stalks terminated by very large panicles of numerous small flowers.

This species is the true Sacchariferous Cane, from which the sugary juice is expressed, which being boiled and refined, becomes that well-known useful substance called Sugar.

2. **SACCHARUM spicatum**.

Spiked Sugar Cane.] Hath a thick-jointed fibrated root; upright jointed stems, six or eight feet high; oblong, waved leaves, two or three feet long; and the stalks terminated by spikes of purplish flowers.

Both these species are perennial in root; the stalks rise several from each root; and in their growth resemble the *arundo*, or common reed of the marshes, but considerably larger, and instead of being hollow like those plants, are filled with a whitish pith, containing the sweet juice, or liquid, which renders these plants so very valuable; the stems are strong, but brittle, generally growing to perfection in from six or eight to twelve or fourteen months, becoming of a pale-yellowish colour; producing at top numerous small flowers, collected into very large panicles, &c. sometimes two or three feet long, each flower having only two small valves for the corolla; and is wrapped up in long down; succeeded by.

by oblong, narrow seeds included in the valves.

But it is the first sort, *Saccharum officinarum*, that is cultivated for sugar, and for which purpose prodigious quantities are raised in the West-Indies, and other hot countries; being propagated by suckers and cuttings, planting them in fields, in rows four or five feet asunder, which soon shoot up into stalks, becoming fit to cut for use sometimes in six or eight months, being then taken to a mill and squeezed between iron-cased rollers, to express the juice, which is then properly boiled and refined to form it into a due consistence to become Sugar.

From the skimmings of the Sugar in the different boilings, and melasses, being the last drainings of the Sugar, mixing therewith a quantity of water, and the whole fermented, is extracted that spirituous liquor called rum, abounding with a salutiferous oiliness, whence proceeds the excellence of that spirit, compared with brandy.

In this country however, this valuable plant cannot be cultivated without the aid of a hot-house all the year; so that only a few plants are raised by way of curiosity, being planted in pots of rich earth, and placed in the stove.

Method of Propagation, &c.

Their propagation is effected abundantly by slips or suckers from the root, and by cuttings of the main stalks.

In this country, however, they are more generally propagated by slips from the bottom; or any side-shoots arising from the stems near the root, having earth raised about the bottom part, will soon emit fibres, and be fit for separation; observing, these slips or off-sets may be taken off at any season, in which they appear fit for the purpose, being careful to detach them with some fibres to each, and plant them separately in pots of rich earth, and plunged in the bark-bed, watered, and occasionally shaded till they have got root; retaining them always in the bark-bed in the stove; and managed as other exotics of that repository.

But in the West-Indies, &c. these plants are most commonly propagated by cuttings of the tops of the old canes, or any part thereof, divided into lengths of from twelve to eighteen inches long, and placed horizontally in the ground three or four inches deep.

SALIX, Sallow, or Willow-tree.

The Sallow and Willow are principally of the tree kind of the deciduous tribe; mostly of the aquatic nature, delighting in moist situations, but will grow any where; valuable

both as timber trees for various light uses, and in underwood plantations, for all sorts of basket-work, poles, &c. some sorts also to diversify garden plantations, there being many species, of different degrees of growth, from twenty to thirty or forty feet high, or more, garnished with oval, spear-shaped, and oblong leaves, in different trees, and dioecious apetalous flowers, disposed in amentums.

Class and order, *Dioecia Diandria*.

Characters.] **CALYX**, male and female flowers on separate plants, disposed in oblong, scaly, imbricated katkins or amentums, each scale containing one floret. **COROLLA**, no petals, but cylindric nectareous glands in the centre. **STAMINA**, in the males, generally two filaments, crowned with didymous quadrilocular antheræ. **PISTILLUM**, in the females, an oval narrow germen, a scarcely distinguishable style, having two erect bifid stigmas. **PERICARPIUM**, an oval-subulate, unilocular, bivalved capsule, having many small seeds crowned with down.

There are above forty different-species of this genus, mostly of the tree kind, deciduous and of hardy growth, and some low under-shrubby and herbaceous-like plants; but the tree kinds only merit consideration for general culture, several of which grow to timber-trees; others are of great value to the basket-makers, being planted in marshy grounds, kept to low stools to produce a crop of shoots or twigs to cut annually, for all kinds of wicker-work; and others planted in similar situations being suffered to grow larger, to cut every three, or five, or six years for poles, useful for various purposes: and for garden culture, some particular sorts may be introduced thinly in large plantations for variety; and some sorts of the osier kinds should be planted in some moist place, to furnish twigs for tying various garden articles.

The principal tree kinds in England are,

1. **SALIX caprea**.

Common Sallow Tree.] Grows but to a moderate height, having smooth, dark-green, brittle branches; oval, waved, rough leaves, indented at top, and woolly underneath.

Varieties.] Oblong, acute-pointed-leaved—silver-striped-leaved.

It grows abundantly in this country, but more frequently in dry than moist situations; is of a brittle nature, so is unfit for the basket-makers; but will serve for poles, stakes, and to lop for fire-wood, and its timber is good for many purposes.

2. **SALIX alba**.

White, or silvery-leaved Willow.] Grows to a great height, and considerable bulk, having

ing smooth pale green shoots; long, spear-shaped, acuminate, sawed, silvery-white leaves, being downy on both sides, with glands below the ferratures.

This is the common White Willow, which grows abundantly about towns and villages, and by the sides of rivers and brooks, &c.

3. *SALIX vitellina*.

Yellow, or Golden Willow.] Grows but to a moderate height, having yellow, very pliant shoots, oval, acute, ferrated, very smooth leaves, with the ferratures cartilaginous, and with callous punctures on the foot-stalks.

4. *SALIX purpurea*.

Purple Norfolk, or Red Willow.] Grows to a large height, having long, reddish, very pliant shoots, and long, spear-shaped, ferrated, smooth leaves, the lower ones being opposite.

5. *SALIX viminalis*.

Osier Willow.] Grows but a moderate height, having slender rod-like branches, very long, pliant, greenish shoots, and very long, narrow, spear-shaped, acute, almost entire leaves, hoary and silky underneath.

6. *SALIX amygdalina*.

Almond-leaved Willow.] Grows to a middling height, with long, flexible, light-green branches and shoots; spear-shaped, ferrated, smooth, shining-green leaves, on short foot-stalks, having trapeza-shaped stipulæ.

7. *SALIX pentandria*.

Pentandrous, Broad-leaved, Sweet-scented Willow.] Grows to some considerable stature, having brownish-green branches; oblong, broad, ferrated, smooth, sweet-scented leaves, shining above; and pentandrous flowers.

8. *SALIX triandria*.

Triandrous Willow.] Grows to a large stature, having numerous, erect, greyish-green branches, and pliant shoots; oblong, acute-pointed, ferrated, smooth, shining-green leaves, eared at the base; and triandrous flowers.

9. *SALIX fragilis*.

Fragile, or Crack Willow.] Rises to a middling stature, with brownish, very fragile, or brittle branches, long, oval-lanceolate, sawed, smooth leaves of a shining-green on both sides, having dentated-glandular footstalks.

This sort in particular being exceedingly fragile, so that it easily cracks and breaks, is unfit for culture in other grounds.

10. *SALIX hastata*.

Hastated-leaved Willow.] Grows to a middling size, with long, green, pliant shoots; sub-oval, acute, ferrated, smooth, close-fitting leaves, having heart-shaped stipulæ.

11. *SALIX Helix*.

Dwarf Yellow Willow.] Grows but to a very moderate stature, having a yellow, rough-barked trunk, with brownish branches; and

narrow, lanceolate, ferrated, smooth, blueish-green leaves, the upper ones obliquely opposite.

12. *SALIX Babylonica*.

Babylonian pendulous Salix, commonly called Weeping Willow.] Grows to a largish size, having numerous, long, slender, flexible, pendulous branches, hanging down loosely all around in a curious manner, and long, narrow, spear-shaped, ferrated, smooth leaves.

This curious Willow is a native of the East, and is retained in our hardy plantations for ornament, and exhibits a most agreeable variety; particularly when disposed singly by the verges of any piece of water, or in spacious openings of grass ground.

Other principal Willows, distinguished by the following Names.—Sound-growing Norfolk Willow—Upland red Willow—Broad-leaved Flanders Willow—Swallow-tail Willow—Dutch Osier—Wire Osier, &c. with some other varieties, particularly of the Osier kinds, found principally in the osier-grounds for the basket-makers, distinguished by different names, in different places.

The mode of flowering of all the sorts of Willows is, in amentums, or katkins from the sides of the branches, being male and female in different katkins on separate trees; ripening in March and April.

All the above species and varieties of *Salix* are of the tree kind, very hardy, and remarkably fast growers, and several of them attain a considerable stature, when permitted to run up to standards, which frequently grow forty or fifty feet high, in twenty or thirty years, having proportionably large trunks; though some sorts are apt to decay on the sides, when large, and others will remain sound to a considerable age and bulk: but all the sorts may be easily raised from cuttings, both as standards for timber; or kept down to underwood, and dwarf stocks for producing rods and twigs; or formed into pollards, or half-standards for loppings.

Most of the sorts grow naturally in England, &c. in great abundance, except the Triandrous and Hastated Willows, which grow chiefly in Switzerland; and the Weeping Willow is a native of the East; but are all hardy enough to grow any where.

They are mostly of the aquatic tribe, as being generally the most abundant, and of most prosperous growth in watery or moist situations; they however will grow freely almost any where, in any common soil and exposure; but grow considerably the fastest and strongest in low moist land, particularly marshy situations, by the verges of rivers, brooks, and other waters; likewise along the sides of wa-

tery ditches, &c. which places often lying waste, may be employed to good advantage, in plantations of willows, for different purposes.—Some for standards to grow to timber, some to form Osier beds, and kept down to stools, a foot high, to furnish an annual cutting of rods or twigs, for the basket-makers; which, being cut every year, pay well for the ground and trouble; others disposed in under-wood plantations to furnish poles, for cutting every three, four, five, or six years, for various uses; and some planted also for pollards, forming stems, eight or nine feet high; which, branching out numerous above, at that height, furnish a lopping every four, five, or six years, both for poles, and for faggot wood to burn. For all of which purposes they may be raised expeditiously by cuttings either of the young shoots, one or two feet long, or large truncheons or poles, of from three or four to eight or ten feet in length, especially if planted in moist places; for the cuttings of these trees are remarkably free of growth, so as sometimes, when any are occasionally used for common hedge-stakes, they strike root freely and grow up to large trees.

For ornamental purposes in gardening, may introduce any of the sorts in large, hardy plantations for variety, as aforesaid; but more particularly the white Willow, yellow Willow, purple Willow, pentandrous sweet Willow, almond-leaved, and weeping Willow, being disposed thinly in large out-plantations, will effect an agreeable diversity: but the Babylonian, or weeping Willow, for its curious pendulous growth, demands culture in every pleasure garden of any tolerable extent; and which, for the general part, should be disposed singly or detached, both, by the side of water, and in spacious opens of grass ground; also near grottoes, cascades, caves, ruins, &c. in all of which, it will effect a most agreeable variety, with its numerous, slender, pendulous branches, bending arch-ways all around, terminated by very numerous, long, slender, flexible, hanging shoots; likewise plantations of all the sorts of Willow in assemblage with poplars, birch, and other aquatic trees, may be formed in any low, swampy, spongy, or watery situation, where other trees will not thrive, and they will diversify, and ornament the premises, or some to cut occasionally for profit, in smaller or larger growth, as may be required.

Likewise for garden-culture, should introduce some of the best Osier kinds, which are of great use for tying and binding particular articles; such as for tying the branches of espalier trees to the treillage; likewise in the

nurseries for binding bundles of trees for sending to a distance; and in the market-gardens for binding their ware in bunches for market, such as celery, turneps, cole-worts, leeks, horse-radish, &c. as practised by the London gardeners; also for tying up the leaves of early cabbages, &c. to facilitate their cabbaging and whitening in the heart; they are likewise useful for making and mending garden baskets occasionally; therefore it is proper, for all of those purposes, to plant a quantity of cuttings, of the best Osier kinds, in some moist situation, near water if possible, keeping them low, and they will furnish a crop of twigs annually; a quantity of which being cut in winter, and tied in bundles, may be preserved for use all the year, which, when become dry, they being thrown into water will supple them for use.

Method of Propagation and Culture.

All the sorts of Willows are propagated expeditiously by cuttings both of the young shoots of one or two years old, in lengths of half a yard or two or three feet; and those of several years growth in truncheons or poles, of from three or four, to eight or ten feet long, according to the purposes for which they are designed, as mentioned below; all of which will most readily strike root, especially in low moist soils: and the season for planting them is any time in open weather, from October until February; though February and March is a very eligible season: having generally a long iron-shod dibble for planting the smaller cuttings, and an iron crow for making holes for the larger sets, or make holes with a spade for very large long pole-cuttings; though some use no instrument in planting the smaller cuttings, but sharpen the ends of them, and thrust them into the ground, especially in soft land; but as this method is apt to force off the bark from the lower part of the cutting, it is therefore best to cut the bottom of each cutting even, and plant them with some instrument, as above.

They are planted for different purposes; as for timber trees—to form osier grounds—to cut for poles—pollards for lopping, &c. So the cuttings must be prepared and planted according as directed below, under their respective heads.

For timber trees.—The timber of Willows is esteemed for several purposes, it being very white, of a fine grain, smooth, and takes a good polish, which renders it proper for many light articles: and, to raise them for timber chuse the larger growing sorts, such as the white, yellow, and purple, or red willows, &c. taking cuttings of the strong young shoots,

shoots, which may be planted at once where they are to remain, in any low marshy situation, where they will grow amazingly fast.

Having, however, prepared the ground, by proper digging, or ploughing, as may be most convenient, and the situation admits; then provide a quantity of cuttings of strong young shoots, of one or two years growth, cut to half a yard, or two feet lengths, which plant in rows, only six feet asunder, and three or four distant in the rows, that they may draw each other up fast in growth, and allow for a gradual thinning, inserting each cutting two parts of three into the ground, by the method before observed; they will soon emit roots, and shoot strongly at top in spring and summer, observing that to have them run up with clean stems for full standards, clear all away but one of the strongest leading shoots for a stem, which suffer to run up always at full length in its future growth; remarking that in a few years, when the trees approach one another, they should be thinned, which thinnings will serve for poles for several uses, repeating the work of thinning in a few years more, according as the branches of the different trees interfere, leaving them at last about twelve or fifteen feet asunder, to attain full growth: thus they will draw each other up very expeditiously with straight handsome stems, forty or fifty feet high or more; and in twenty or thirty years, will be fit to fell for timber.

For Osier Grounds.—Osier grounds are plantations of osier Willows, in low stools, for producing twigs annually for the basket makers, being formed in any low, swampy, marshy or watery situation, planted with cuttings of the best osiers, and other most pliant sorts of Willows, in rows two or three feet asunder, and always kept to low stools a foot high, in order to force out a more plentiful annual crop of twigs and rods, proper for use in one summer's growth, of from three or four, to six or eight feet long, of a pliant tough nature, fit for working into all kinds of basket and wicker-work, which being cut annually in winter or spring, are worth from five or six, to eight or ten pounds an acre per annum: so that, osier plantations being thus formed in any low, watery, waste land, incapable of yielding other produce to perfection, will turn out to great advantage; and, if near any navigable river, for the convenience of water carriage, it will still be more advantageous: on which consideration, very large tracts of waste, boggy grounds and islands, along the river of Thames, are employed in osier grounds, for the London consumption.

Therefore, making choice of any convenient, low, moist situation, let it be dug or ploughed, for the reception of the osiers: then, in the proper season before-mentioned, gather a sufficient quantity of osier sets of different sorts, which must be cuttings of the one or two years old shoots, cut into two feet, or two feet and half lengths; these being provided, then draw lines for planting them, two feet and half distance, inserting each cutting ten or twelve to fifteen inches into the ground, leaving the rest out to form the stool, and let them be two feet and half distance in each row: having thus formed the plantation, the cuttings will root firmly in the spring, and shoot at top tolerably strong in summer, each stool generally throwing out several shoots, of an erect growth; observing, during this first summer, to keep down all large weeds, that the stools may have full scope to produce the first shoots as strong as possible, which, by the end of autumn, will probably be advanced some considerable length; and if much wanted, may be cut in the following winter or spring; though, for a full plantation, they should generally be suffered to continue their growth for two years, till the stools are firmly rooted and become strong; then cut down all the tops close to the head of the stools; they will serve for poles, &c. next year the stools will shoot out strong, a numerous crop of twigs and rods, fit for cutting for the basket-makers in winter following; and, the stools still remaining, furnish an annual crop, fit for cutting every winter, which should be cut down always to the head of the stool, as just above observed; sorting the twigs in sizes, tie them in bundles, and stack them up for use.

To cut for Poles.—Willow poles are useful for various husbandry purposes; such as for handles for implements, and for making hurdles, &c. and plantations of stools may be made in any waste, watery places, or along the sides of brooks, rivers, watery ditches, and other similar situations, as before observed, to cut every three, or four, or five, or six years, according to the purposes for which they may be required.

For this purpose, procure a quantity of sets, of two year old shoots, in cuttings about two feet and half long; plant them in rows, a yard asunder, introducing each cutting two parts of three into the ground; they will all readily grow, and each send out several erect shoots, which, in three or four years, will become large poles fit to cut for use.

Or large cuttings or truncheons, three or four feet long, thrust down along the sides of

rivers, brooks, ditches, &c. they will take root, and shoot out strongly at top for poles, as above.

To form pollard Standards.—Willow pollards are common almost every where, they being raised commonly from large sets or cuttings of poles, three yards long, or more, planted along the sides of rivulets or watery ditches, &c. and that being generally topped or divested of the leading shoot, they do not run up with tall stems, but branch out all around, at seven or eight feet height, into many erect branches, which, in four, five, or six years, being lopped down to the head of the stem, serve for poles, for hurdles, &c. also for fuel, as before observed; and the pollards shooting out again, they in this manner furnish a lopping every fifth, sixth, or seventh year, and thereby prove very profitable for many purposes.

The sets or cuttings for raising these pollards may be obtained in plenty from the loppings of any old pollard Willows, &c. choosing the large straight poles, cut about seven or eight to nine or ten feet lengths, according as they may occur, which must be planted either with an iron crow, or some similar implement, driven into the ground to make wide holes, two feet or two and a half deep, for their reception; or, if the ground is impliant and stubborn, must dig holes with a spade that depth, planting one set in each hole, placing them a foot and half at least, to two feet and half in the ground, leaving six, seven or eight above for a stem: thus, these sets, though to large and long, if planted in moist places, will readily strike root, and shoot out at top the following spring and summer, into many erect branches, which, after four or five years' growth, become fit to lop for poles, &c. and the trees will thus continue to afford a lopping every fifth, sixth, or seventh year; or may grow larger, according to the purposes for which the loppings may be wanted.

To form Hedges.—Sometimes Willow hedges are raised in some outward place, along ditch sides, or elsewhere, when designed to form either a fence, blind, or shelter expeditiously; which is easily effected by cuttings, either of strong young shoots, cut into two or three feet lengths, and planted in a row half a foot asunder, and twelve to fifteen or eighteen inches deep; or with larger truncheons of several years' growth, cut into sets, two, three, four, or five feet long or more; and in either case, that when the sets have made, the first years shoot, the shoots may be plashed together in winter, both to stiffen the hedge and give it a thicker form: afterwards

it may be kept regular by clipping it annually, or may be suffered to take its own natural growth, as occasion shall require.

Observe, however, that to form a Willow hedge, as soon as possible, you may use large straight sets, of five or six feet long, and plant them chequer-ways, placing each set half a yard in the ground, leaving three or four feet above; which, being arranged cross one another in the above-mentioned chequer manner, and ranged all an equal height, they will at once form a good firm fence, immediately fencible against cattle.

Or, where a speedy fence is wanted, by way of blind or shelter, may procure a quantity of loppings, five, six, or seven feet long, well furnished with lateral branches to the bottom, and planted in a deepish trench, pretty close together, they will grow and form a sort of fence directly.

To furnish Twigs for Garden Use.—Osier twigs being useful in many gardens for various tyings, as we before observed, it is eligible to cultivate a few of the best osiers in most gardens, to furnish a supply for the different purposes; choosing some moist situation, or near any watery ditch, or other water in any by place, or where most convenient: and, having procured a quantity of the most pliant kind of Osier sets, cuttings of young shoots, half a yard or two feet long, which plant in the place allotted in rows, planting or thrusting them two parts of three into the ground; they will grow freely, and furnish plenty of twigs every year. managing them as observed for those of the *Osier Ground*.

As to the culture of all the above different plantations of Willows, they require but little; which is principally the keeping down large weeds the first and second year after planting, which is more particularly requisite in the plantations of young low cuttings, till they are a little advanced in growth.

For Nursery Collections.—Collections of the different sorts of Willows should also be kept in all nursery grounds, both public nurseries for sale, and in private nurseries, to supply plantations occasionally, raising them generally from young cuttings, of a year or two old, in half yard or two feet lengths, and planted in rows, two or three feet asunder, to grow till wanted.

SALLAD HERBS.

Various sorts of esculent herbs of different genera are used for sallading, which by different sowings, plantings, &c. are obtained at all times of the year; but the most generally esteemed sorts may be comprised under the following three heads—*Large Principal Sallad*

Sallad Herbs—Small Sallad Herbs.—Occasional Sallad Herbs.

Large Principal Sallad Herbs.—These consist chiefly of three principal sorts, viz. lettuce, all the varieties estimable as the most generally useful of the large sallad plants,—endive, all the different sorts—and celery, all the varieties—which three principal sorts are all raised from seed, by different sowings and transplantings, and are in best perfection for use when arrived to full growth: either of which may be eaten as a Sallad alone, or all of these sorts mixed together, or any, or all of them mixed with a proper quantity of small sallading, or other Sallad Herbs occasionally: but with small sallading in particular is very eligible in winter and spring; as the small sallading, being of a warm nature, renders the Sallad more grateful and wholesome. Lettuce is generally esteemed as the most material Sallad Herb, for general use, at most times of the year, but particularly in summer, when full grown and firmly cabbaged; but by several sowings and transplantations at different times, from January and February, until September or October, in different situations, according to the season, the plants may be obtained in tolerable plenty almost the year round, but always more finely cabbaged in summer than in winter. And as to the endive and celery, they are excellent for autumn and winter Sallads; they being in full perfection in September, October, and November, when they will be full grown and finely blanched, and they often continue in tolerable perfection all winter and spring.—But for other particulars, together with the method of culture of these three, principal Sallad Herbs, see their respective genera, *LACTUCA*, *CICHORIUM*, and *APIUM*.

Small Sallad Herbs.—The principal sorts, denominated Small Sallad Herbs, are cresses, mustard, radish, rape, and turnep, also lap-cabbage-lettuce: in all of which herbs, considered as small sallading, the young leaves are the useful part for that purpose and are always in best perfection when quite young, or only a few days, or a week or two old at most, especially the first five of these sorts, whilst in their first leaves; cutting them up, stalks and top together, close to the ground, as when they are thus quite young they eat exceeding tender, with an agreeably warm relish, for they being mostly of so warm a nature, that if suffered to grow old for sallading, they would eat very hot and disagreeably strong-tasted, but being used when quite young, as above; whilst they remain of a palatably warm relish, they are highly proper

to mix in all winter and spring Sallads in particular, though many people are fond of them, at most times of the year, and many often use them alone, particularly in winter and spring; they, however, are preferable when mixed with lettuce and the other large sallading.

All these small Sallad Herbs are raised from seed, which, for the purpose of sallading, are sown at all times of the year, when they are required, in the open ground in the spring and summer, and in winter under frames and glasses, and occasionally in hot-beds; and where a constant supply is wanted, a repetition of sowings is requisite every week, ten days, or a fortnight, being sown generally in shallow flat drills, each sort separate, very thick, and only just covered with earth. But for the particular culture of these herbs for sallading, see the article *SMALL Sallad Herbs*.

Occasional Sallad Herbs.—This head comprehends several other plants that may come under the denomination of Sallad Herbs, but not being so estimable for general use as the former sorts, are only used occasionally, viz. Corn Sallad, or lamb's lettuce—purslane—spear-mint—water-cress—borage and borage-flowers—nasturtium-flowers and young leaves—chervil—burnet; and sometimes red-cabbage—radishes—red beet-root—fenchia, or Azorian fennel—sorrel—tarragon—young onions—cives—and sometimes horse-radish, incorporated with other herbs; most of which sorts are occasionally used both in composition with other Sallad Herbs, and some used alone as a Sallad, such as red-cabbage, water-cress, young borage, &c. they are mostly hardy plants raised in the full ground; and as each of which requires a particular mode of culture, we refer to their respective genera, where their peculiar uses as Sallad Herbs, &c. methods of propagation and culture, are fully explained.

SALSOLA, Glass-wort, and Stone-crop-tree.

This genus is composed of herbaceous annuals and perennials of but little merit as garden plants, and one shrubby ever-green, proper for the shrubbery.

Class and order, *Pentandria Digynia*.

Characters.] *CALYX*, five oval permanent leaves. *COROLLA*, no petals. *STAMINA*, five very short filaments inserted into the divisions of the calyx. *PISTILLUM*, a round germen, a double, or a tripartite style, and recurved stigma. *PERICARPIUM*, an oval unilocular capsule lodged in the calyx, having one large seed.

There are many herbaceous species, and some

some of shrubby growth; one of the latter being the only sort generally cultivated in the English gardens, viz.

SALSOLA fruticosa.

Shrubby Glass-wort, commonly called Stone-crop tree.] Rises with a shrubby erect stem, branching numerous and erectly, four or five feet high, closely garnished with very small obtuse fleshy leaves, like the common Stone-crop on the walls.

This species inhabits the sea-shores in England, France, and Spain, &c. but is retained in many curious gardens, in the ever-green collection, to adorn the shrubbery compartments, allowing it generally a sheltered situation.

The propagation of this ever-green is by suckers, layers, and cuttings; many stems generally rising from the root, which may be divided in autumn or winter, into so many separate plants; and layers or cuttings of the young branches in autumn or spring will be well rooted by autumn following.

SALVIA, Sage, Clary, &c.

It comprehends under-shrubby, herbaceous, and shrubby plants, both for the kitchen garden, pleasure-ground, and green-house, garnished mostly with spear-shaped, oval, and oblong leaves, and small, monopetalous, ringent flowers, generally terminating the branches in whorled spikes.

Class and order, *Diandria Monogynia.*

Characters.] *CALYX* is monophyllous, wide at the mouth, and bilabiate—*COROLLA* is monopetalous, tubulous below and ringent above, having the upper lip concave and indented, and the under one broad and trifid. *STAMINA*, two short filaments, split into two parts, one of which supports the antheræ. *PISTILLUM*, a quadrifid germen, a long slender style, and bifid stigma. *PERICARPIUM*, none; four roundish seeds lodged in the calyx.

To this genus *Salvia*, is now joined *Sclarea*, or common Garden Clary, and *Horminum*, or Wild Clary, &c. amounting in the whole to above thirty species, though not half so many that merit culture, as garden plants, consisting of hardy under-shrubby, and herbaceous perennials for the open ground, and shrubby evergreens for the green-house.

Hardy under-shrubby kinds.

Under this head is comprehended the common Sage of the kitchen garden, having many varieties; all under-shrubby perennials, originally exotics from the southern parts of Europe, but are all hardy enough to succeed here in the open air, the year round.

1. *SALVIA officinalis.*

Common officinal Sage.] Rises with short,

under-shrubby, hairy stems, branching numerous from the bottom, two feet high, or more, forming a very bushy head; spear-shaped-oval, entire, slightly crenated, rough leaves, and the branches terminated by spikes of blueish flowers, having acute cups.

Varieties.] Common culinary red Sage, being of a black-red colour—green broad-leaved balsamic Sage—Broad-leaved, hoary, balsamic Sage, having generally the broadest leaves of all the sorts, standing on long foot-stalks—Wormwood Sage.—Narrow-leaved hoary Sage, commonly called Sage of Virtue, having the base of the leaves sometimes auriculated, or indented in form of ears, and sometimes not eared—Lavender-leaved Sage—Variegated green Sage—Variegated red Sage.

They all flower in June and July, and are sometimes succeeded by ripe seed in autumn.

This species and varieties are all very hardy plants, perennial in root, stem, and branches, and retain their leaves the year round. They are plants of sovereign virtue, as the name imports, and the leaves are the only useful part, being proper for various culinary purposes, and for medical uses; are also often used in the manner of tea, by way of medicine, and eaten with bread and butter, and used for making sage-cheese, &c. these plants, therefore, demand culture in every family-garden; and any, or all the sorts may be cultivated for use, they possessing nearly all the same quality; but the red Sage is the most commonly cultivated for general kitchen purposes; and the broad-leaved hoary Sage, and the Sage of Virtue, is often preferred for tea and other medical uses, though it is probable any of the sorts may be equally eligible, as being all varieties of one species.

Hardy herbaceous kinds.

There are many herbaceous species of *Salvia*, some of which formerly composed different genera, such as *Sclarea*, or Garden Clary, and *Horminum*, or Wild Clary, &c. mostly originally of foreign growth, but grow freely in our gardens in the open ground; though they possess no great merit, except one for culinary and medical use; and the others principally as plants of variety, and consist of biennials, perennials, and annuals, garnished mostly with broad rough leaves.

The most noted species are,

2. *SALVIA Sclarea. (Biennial).*

(Sclarea)—or common Garden Clary.] Hath a fibrated biennial root, crowned with broad-oblong, heart-formed, serrated, wrinkled, rough, hairy leaves; upright, thick stems, two or three feet high, branching oppositely, having all the branches terminated by large, loose, whorled

whorled spikes of pale blue flowers, attended by concave, acuminate, bracteal leaves longer than the corolla and calyx.

Varieties.] Broad-leaved—Long-leaved—Most wrinkled-leaved.

This species and varieties are biennials, have all large, thick, woolly leaves, that impart a strong disagreeable odour, and are the useful part of the plants, which are cultivated in kitchen gardens, for some domestic uses, and medicinally by infusion, and decoctions both inwardly and outwardly; the plants being raised from seed annually, and planted out a foot and half asunder, they spread out into large leaves for use, till next summer; when they shoot up into stalk for flower and seed, then totally perish.

3. *SALVIA verbenaca.* (*Perennial.*)

Common Wild Clary.] Hath a fibrated perennial root, oblong, sinuated, serrated, wrinkled leaves, and declinated stems, a foot long, terminated by whorled spikes of small blue flowers, having the corolla narrower than the calyx.

It grows wild in England, &c. its virtues are supposed nearly the same as the garden clary; and the seed being of a viscous nature, is sometimes used for clearing the eye from any moat that happens to fall into it, putting one of the seeds into one corner, and moving it about, the dust sticking thereto, removes it out of the eye.

4. *SALVIA indica.* (*Perennial.*)

Indian Clary with a variegated Flower.] Hath a fibrated perennial root, upright four-cornered stems, three or four feet high, heart-shaped, acutely crenated leaves, the upper ones sessile, and half the upper part of the stalks adorned with blue variegated flowers, in remote whorls.

5. *SALVIA glutinosa.* (*Perennial.*)

Glutinous yellow Clary.] Hath a strong, fibrated, perennial root; heart-shaped, sagittate, acutely serrated, glutinous leaves, upright four-cornered, glutinous stems, three or four feet high, terminated by spikes of yellow flowers, in close whorls.

6. *SALVIA Horminum.* (*Annual.*)

Galeated Horminum—or Purple-topped annual Clary.] Rises with upright stalks, a foot and half high, obtuse crenated leaves, and the stalks terminated by whorled spikes of small purplish flowers, with coloured bracteal leaves at top.

Varieties.] With purple tops—with red tops.

All these herbaceous species flower mostly in June, and the seeds ripen in Autumn.

They are all hardy enough to grow in any common soil, the first of which being for the

kitchen-garden, and the others to increase the variety of the herbaceous collection.

Tender shrubby kinds for the Green-house.

Consists of four or five shrubby ever-green plants of the Sage kinds, natives of different warm countries, and retained here in our green-house collections for variety.

7. *SALVIA mexicana.*

Shrubby Mexican Sage.] Rises with a shrubby branchy stem, eight or ten feet high; having four-cornered, purplish branches; oval leaves, pointed at both ends, and serrated; and close spikes of blue flowers at the ends of the branches.

8. *SALVIA africana.*

Shrubby African Sage.] Rises with a shrubby branching stem, four or five feet high; roundish serrated grey leaves, truncated and indented at the base; and whorled spikes of blue flowers towards the ends of the branches.

9. *SALVIA aurea.*

Golden African Sage.] Rises with a shrubby branching stem, six or seven feet high; roundish entire leaves, truncated and indented at the base; and short spikes of golden-coloured flowers at the ends of the branches.

10. *SALVIA pomifera.*

Pomiferous or Apple-bearing Sage of Crete.] Rises with a shrubby branchy stem, four or five feet high, spear-shaped-oval, entire, slightly crenated, hoary leaves, and spikes of blue flowers, having obtuse cups.

The branches of this sort have sometimes glandular protuberances as big as apples; hence the name Pomiferous Sage.

11. *SALVIA canariensis.*

Canary Sage.] Rises with a shrubby branching downy stem, garnished with hastated-triangular, obtuse, crenated leaves; and whorled spikes of blue flowers at the ends of the branches.

All the above species of *Salvia*, both hardy and tender kinds, are principally of the verticillate tribe, or such as produce their flowers in a verticillus, or whorls round the stalks, some having the whorls standing almost close, others placed remote (see *VERTICILLATUS* and *VERTICILLUS*); and the flowers are all monopetalous and ringent, generally small, but numerous in each spike. See the *Characters*, &c.

All the under-shrubby and shrubby kinds, both hardy and tender sorts, are durable in root, stem, and branches, and remain in leaf the year round.

But the herbaceous kinds are furnished with stems only in summer.

The *Salvia Officinalis*, or common Sage and varieties, considered as culinary and medical

dical plants, merit culture in every kitchen-garden, allowing them a moderately dry soil, and sunny situation, to enable them to stand the winter more effectually; for if planted in moist or shady places, they are liable to suffer by severe frosts: they are easily raised from slips, as hereafter directed, and afterwards planted in rows a foot and half asunder; in which they will grow large bushy plants, and remain several years, furnishing leaves plentifully the year round; which are proper for use, both fresh gathered from the plants, and when dried; though for culinary purposes, they are best when fresh gathered, either gathering the leaves distinct, or taking the small young side-shoots or tops and leaves together, slipping or cutting them off: and towards the latter end of summer, about July or August, gather a quantity to dry, both for culinary use in winter, and to use for sage tea in the same season, where required: being careful in all the gatherings not to stump them too close, particularly in autumn and winter.

But the varieties of the common Sage may also be employed to diversify the fronts of small shrubbery clumps, &c. particularly the variegated kinds.

As to the merit of the herbaceous kinds, the *Garden Clary* being a culinary and medical herb, must be stationed in the kitchen garden; and all the others, being considered principally as plants of variety, as aforesaid, may be employed to diversify any of the compartments of the pleasure ground; all of which herbaceous kinds are easily raised from seed; and the seedlings, when two or three inches high, should be planted out. See their *Propagation, &c.*

And as to the tender shrubby kinds, they requiring shelter from frost, must be kept always in pots, in order for moving to a greenhouse in winter; and as being elegant evergreens, they will effect an agreeable variety among the exotics of that conservatory.

Propagation and general Culture of the common Sage kinds.

The propagation of all the varieties of common Sage is effected plentifully by slips or cuttings of the young shoots from the sides of the branches;—also sometimes by bottom, rooted off-sets, &c. and may also be raised from seed.

By slips or cuttings.—The slips both of the former and same year's growth, planted in April or May, will readily grow. Slips of the former year's shoot may be obtained plentifully any time in spring, but should not be planted earlier than April; which however, if planted any time in April or early in May, they will

root freely, and form good plants against winter: but young slips, shoots of the same year, are rarely fit for slipping before the middle of May, or beginning of June: these however are exceedingly eligible, will most readily strike root in a short time, and assume a free growth; in either case, taking opportunity of moist weather, and having recourse to some good bushy plants, slip off a proper quantity of the outward, robust side shoots, about five, six, or seven inches long; trim off all the lower leaves, then in some shady border proceed to plant them with a dibble in rows, half a foot asunder, planting them down almost to their tops; giving water directly, to settle the earth close, as well as to promote an early emission of fibres, repeating the waterings occasionally in dry weather; and the slips will soon emit fibres, and shoot freely at top: observing, if they should spindle up with slender shoots, or run up to flower, it is proper to top them short, in order to force out laterals below, to assume a bushy growth: thus they will form tolerable bushy plants by August or September; when, or in spring following, they may be removed, with balls of earth about their roots, and planted where they are finally to remain, either in four feet beds, or in continued rows, a foot and half asunder, if designed as a close plantation for use: and those designed for the pleasure ground should be disposed accordingly.

By rooted off-sets.—Sometimes Sage, as before observed, having grown into large bushy plants, with numerous branches rising near the ground, which touching the earth, have formed plenty of fibres at bottom; and that being slipped off separately with the fibres thereto, each immediately commences a proper rooted plant; they may either be slipped off as the plants stand in the ground, or the bunches of plants may be taken up and divided into as many separate slips as are furnished with roots: and as they thus directly form rooted plants, they may be planted at once where they are to remain.

However, those raised from young slips generally form the strongest bushy plants in the end.

By Seed.—The raising these plants from seed is hardly worth practising, since they may be propagated so easily by slips or cuttings. However, the season for sowing the seed, is any time in April, in a bed of light rich earth; sow it evenly, and rake it in; the plants will soon come up: and when about two or three inches high, prick out the strongest in nursery rows, half a foot asunder, to gain strength till September or spring following;

lowing; then transplanted with balls, where they are always to stand.

As to the culture of this species of Sage and varieties, all that is required is the keeping them clean from weeds in summer, cutting down the decayed flower-stalks in autumn, and slightly digging between the rows in the same season, to remain clean and decent during the winter, &c. and is also beneficial to the plants, so as if not done in autumn, it should not be omitted in the spring; and generally observing in gathering the Sage for use, it should be done with some care and regularity, not to cut the tops too close, to render the plants naked and stubby, especially late in autumn and winter; in which they would be more liable to suffer from severe frost than when the head is preserved somewhat full and regular; and in this state the plants will continue longer in a prosperous free growth accordingly, of several years' duration.

Likewise observing, that when in any old plantation, naked, stubby, or decayed parts casually occur, cut them out accordingly, and reduce to order any straggling irregular growth; which occasionally pruning being performed in spring or summer, the plants will more readily emit fresh shoots and form full heads.

Also observe, that when the general plants of any old plantation of Sage, of some considerable standing, appear to assume a declined state, not productive of plenty of young leafy shoots, &c. should, in proper time, propagate a fresh supply from slips or cuttings, as above, ready to succeed the said old plantation.

Or in continuing plantations of Sage, if the ground appears much impoverished, a little dry rotten dung pointed in lightly will add vigour to the plants.

Propagation, &c. of the herbaceous kinds.

All the herbaceous kinds of *Salvia* are easily raised from seed, sown in spring in the open ground; and the perennial sorts also by parting the roots.

By Seed.—The Garden Clary, being a biennial, must be raised every year from seed. Sow it in March, in any bed or border of common earth, and rake it in; and when the plants have got leaves of two or three inches growth, plant them out in showery weather, in rows eighteen inches distance, and the same distance in the rows; they will soon get root, and grow large, and furnish large leaves, fit for use in autumn, winter, and the following spring.

The perennial sorts are also raised from seed, sown in a bed of light earth in March, and raked in, and the seedlings planted out in

summer, in nursery-rows till autumn, then transplanted into the borders, &c.

And the annual sorts may be sown in spring, about the borders, in patches to remain.

By Parting the Roots.—The perennial kinds only can be increased by this method, which may be performed in autumn, or early in the spring.

Propagation, &c. of the tender shrubby kinds.

All the five tender shrubby kinds for the green-house are easily propagated by cuttings of the young shoots in spring and summer. If in spring, a quantity of cuttings planted in pots, and plunged in a hot-bed, will very soon emit roots at bottom, and shoots at top, when they should be gradually hardened to the full air. But cuttings planted in summer will often strike without the aid of a hot-bed, planted either in pots, or in a bed of natural earth, under frames and lights, or covered close with hand-glasses, shaded from the mid-day sun, and occasionally watered.

The plants must afterwards be potted off separately, and managed as other shrubby exotics of the green-house. See GREEN-HOUSE PLANTS.

SAMBUCUS, Elder-tree.

This genus consists of hardy deciduous trees and shrubs, and herbaceous perennials, of the berry-bearing tribe, proper for some useful purposes in gardening, and for diversifying hardy plantations; also in their production for some domestic uses: their buds, leaves, and flowers for medicinal occasions, and their berries, in some sorts, valuable for making elder wine; are mostly of strong, but not very lofty growth, producing large, long shoots, full of a fungous pith, and are all garnished with large winged leaves and numerous small rotaceous flowers, mostly in cymose umbels towards the ends of the branches, succeeded by large bunches of black and other coloured berries in autumn.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX is small, monophyllous, five-parted, and permanent. COROLLA is monopetalous, rotated and concave, and cut into five obtuse reflexed segments. STAMINA, five awl-shaped filaments, having roundish antheræ. PISTILLUM, an oval germen under the corolla: no style, but instead thereof, a swelling glandule and three obtuse stigmas. PERICARPIUM, a roundish unilocular berry including three angular seeds.

There are about four species in this genus, retained in our garden plantations, three of which are of the tree and shrub kind, and one is an herbaceous perennial: two of them are common in England, &c. namely, the Com-

mon Black Elder-tree, and the Herbaceous Dwarf Elder; the other two are foreigners, one being from the south of Europe, and the other of America; but are all hardy enough to grow here in any situation.

Tree and shrub kinds.

1. *SAMBUCUS nigra.*

Black-berried, or Common Elder-tree.] Rises with a tree-like stem, branching out numerous into a large spreading head, twenty feet high; pinnated leaves, of two or three pair of oval lobes and an odd one; and large, cymose, five-parted umbels of white flowers towards the ends of the branches, succeeded by large bunches of black, and other different coloured berries, in the varieties.

Varieties.] Common Black-berried Elder-tree.—White-berried Elder.—Green-berried Elder.—Lacinated or Parsley-leaved Elder, having the folioles much lacinated, so as to resemble parsley-leaves.—Gold-striped-leaved Elder.—Silver-striped Elder.—Silver-dusted Elder.

All these being varieties of *Sambucus nigra*, mostly of a tree-like growth, and have, for the general part, five or seven-lobed leaves, and quinquepartite umbels of flowers and fruit; the common Black-berried Elder, however, is the most generally known variety, and the most commonly cultivated: sometimes as standards in plantations of other common hardy trees, but more frequently in forming outward hedges expeditiously, as being a very fast grower; likewise often in detached standards in orchards and in hedge rows, &c. for the sake of their berries for making of Elder-wine; and all the varieties may also be employed for diversifying plantations: all the varieties make very strong shoots, full of a white pithy substance, but becomes woody as they advance in age, and the old wood becomes solid and very hard, fit for many purposes: all of which varieties will grow in any situation, and may be raised very expeditiously by cuttings of the year-old shoots. See the *Propagation*.

The bark, buds, leaves, and flowers are used in medicine, being sovereign in many disorders.

And the ripe berries make an excellent cordial wine.

2. *SAMBUCUS racemosa.*

Racemous-flowering, Red-berried Elder.] Rises with a tree-like stem, branching ten or twelve feet high, having reddish-brown branches and buds; pinnated leaves of six or seven oval deeply-sawed lobes, and compound, oval, racemous clusters of whitish-green flowers, succeeded by oval clusters of red berries.

This is a resident of the mountainous parts

of the south of Europe, and is retained in our gardens as a flowering shrub, having a peculiar singularity in its oval-clustered flowers and berries.

3. *SAMBUCUS canadensis.*

Canada Shrubby Elder.] Rises with a shrubby stem, branching eight or ten feet high, having reddish shoots; somewhat bipinnated leaves, often ternate below, composed of five, seven, or nine oval lobes; and towards the ends of the branches, cymose, quinquepartite umbels of flowers, succeeded by blackish red berries.

Herbaceous kinds.

4. *SAMBUCUS Ebulus.*

Herbaceous Elder, commonly called Dwarf Elder.] Hath a thick, creeping, tough, perennial root, spreading widely around; herbaceous, strong, pithy, green stems three or four feet high; large pinnated leaves, of from three or four to six or seven pair of long, acute-pointed, indented lobes, with leafy stipulæ, and large, cymose, three-parted umbels of white flowers, succeeded by black berries in autumn.

This is a perennial, and grows wild in England in hedges, banks, and fields, but is admitted in some gardens for variety and medical uses.

Variety.] Lacinated-leaved, having the folioles beautifully jagged into segments.

All the sorts of Elder are of the deciduous tribe, very hardy, and grow freely any where; are generally free shooters, but particularly the *Common Elder* and varieties, which make remarkably strong, jointed shoots, of several feet length, in one season; and they flower mostly in summer, except the *Racemose Elder*, which generally begins flowering in April; their modes of flowering being in cymose umbels, and racemose clusters, as in their respective descriptions; rising generally towards the termination of the preceding year's shoot, each bunch consisting of numerous small, wheel-shaped, concave, semi-quinquefid flowers; and the bunches being large, spreading, and very abundant, are exceeding conspicuous; but they emit a most disagreeable odour; are succeeded, in most of the sorts, by large bunches of ripe berries in autumn, which, although very unpalatable to eat, are in high estimation for making that well-known cordial liquor called Elder-wine, particularly the common Black-berried Elder; which ripen for that purpose in September and October, and should be gathered accordingly as soon as fully ripe.

The merit of Elders in gardening may be both for use and ornament, especially in large grounds.

With

With respect to the tree and shrub kinds, the common Elder may be introduced occasionally in forest-tree plantations, and as detached standards, in any by-place, for the sake of their berries, as before hinted; and all the sorts may be employed to diversify large ornamental plantations, disposed, however, but thinly, particularly the Common Elders, as their flowers send forth a strong disagreeable scent, so should be but sparingly introduced near much frequented places; however, the different varieties thereof may be dispersed in out-plantations so as to effect an agreeable diversity; but as to the *Sambucus racemosa* and Canada Elder, they may be disposed in any of the shrubbery compartments, more particularly the former, which will exhibit a conspicuous singularity in its mode of flowering and fruiting.

And the Common Elder, being a very fast grower, is often employed in forming outward hedges along ditch-sides, or the sides or tops of banks, where it is necessary to form a hedge-fence as cheap and expeditiously as possible, which may be raised from cuttings of the strong shoots of from one or two to five or six feet long, planted at once where the hedge is intended, a foot distance in the row; and from one to two feet deep in proportion to their length; but the short and middling cuttings generally form the closest hedge from the bottom: though long cuttings are sometimes used in order to form an immediate fence, which being arranged chequer-ways will render the fence stronger, and more immediately fencible against cattle. The hedges, raised by either method, if designed merely as a fence, should be trained only to a moderate height, and kept close and regular by an annual clipping: but some suffer these Elder hedges to grow up rough, in a natural growth, without any trimming, especially at top, permitting them to branch out on each side upward, in order to produce large crops of berries, either for private use or for sale.

As to the Dwarf Elder, it is sometimes admitted in gardens, by way of variety, in the herbaceous collection, and for medical use; observing, as this perennial multiplies exceedingly by its creeping root, it must be occasionally trimmed at bottom to confine it within moderate limits.

In most of the species of Elder, the leaves and flowers impart a strong, disagreeable, and almost nauseous smell; especially the common and dwarf Elder, in which the leaves and whole plant are so very bitter that few animals will browse upon them; and the dwarf Elder in particular exhales so

strong a disagreeable odour, they on that account are sometimes planted round granaries to drive away rats, and other vermin; and sometimes large spreading branches of Elder, of both these sorts in summer, when full of leaves, are drawn over fields of young turneps just come up, when thought in danger of being attacked by the fly, often so destructive to these crops, the elder leaves diffusing their rank odour on the ground and young turneps, and the bitter effluvia remaining, has sometimes a good effect, in proving noxious to those devouring insects, as in some degree to prevent, or greatly check their general attack and depredations on the above young plants.

The bark, buds, leaves, and flowers of the common Elder are used in medicine; the leaves are applied outwardly in fomentation to the piles, and swellings; the flowers infused in whey are beneficial in disorders of the skin; and from the berries are prepared a spirit, a wine, and an oil, which promote urine, perspiration and sweat; the juice of the dwarf Elder (*Sambucus Ebulus*) is recommended in dropical disorders; and the berries are a gentle purge.

Method of Propagation, &c.

All the tree and shrub Elders are propagated very expeditiously by cuttings of the young yearling shoots, and may also be easily raised from seed.

By Cuttings. — Cuttings of Elder shoots, in lengths of from one or two to five or six feet, very readily grow, and may be planted in autumn, or any time in open weather, from October till spring, though the spring, in February or March, is rather the more proper season for planting them; as when planted in autumn or winter, not having struck root, are liable to be killed by rigorous frost; choosing cuttings of the last year's shoots, not those that are green and succulent, but such as are become a little woody; and for general planting, cut them about fifteen or eighteen inches to two-feet lengths, or observing, that if they are designed for nursery rows to train occasionally for different purposes, cut them into short lengths of about three joints, planting them in rows two feet asunder, each cutting two parts of three in the ground: they will readily emit roots in the spring, and shoot strongly at top in summer, training them for the purposes wanted, some to run up with a single stem for standards, others to form bushy shrub-like plants, &c. and in a year or two they may be transplanted finally, if required.

Or if intended to form an Elder-hedge, cuttings of the Common Elder, of the above

mon Black Elder-tree, and the Herbaceous Dwarf Elder; the other two are foreigners, one being from the south of Europe, and the other of America; but are all hardy enough to grow here in any situation.

Tree and shrub kinds.

1. *SAMBUCUS nigra.*

Black-berried, or Common Elder-tree.] Rises with a tree-like stem, branching out numerous into a large spreading head, twenty feet high; pinnated leaves, of two or three pair of oval lobes and an odd one; and large, cymose, five-parted umbels of white flowers towards the ends of the branches, succeeded by large bunches of black, and other different coloured berries, in the varieties.

Varieties.] Common Black-berried Elder-tree.—White-berried Elder.—Green-berried Elder.—Lacinated or Parsley-leaved Elder, having the folioles much lacinated, so as to resemble parsley-leaves.—Gold-striped-leaved Elder.—Silver-striped Elder.—Silver-dusted Elder.

All these being varieties of *Sambucus nigra*, mostly of a tree-like growth, and have, for the general part, five or seven-lobed leaves, and quinquepartite umbels of flowers and fruit; the common Black-berried Elder, however, is the most generally known variety, and the most commonly cultivated: sometimes as standards in plantations of other common hardy trees, but more frequently in forming outward hedges expeditiously, as being a very fast grower; likewise often in detached standards in orchards and in hedge rows, &c. for the sake of their berries for making of Elder-wine; and all the varieties may also be employed for diversifying plantations: all the varieties make very strong shoots, full of a white pithy substance, but becomes woody as they advance in age, and the old wood becomes solid and very hard, fit for many purposes: all of which varieties will grow in any situation, and may be raised very expeditiously by cuttings of the year-old shoots. See the *Propagation*.

The bark, buds, leaves, and flowers are used in medicine, being sovereign in many disorders.

And the ripe berries make an excellent cordial wine.

2. *SAMBUCUS racemosa.*

Racemous-flowering, Red-berried Elder.] Rises with a tree-like stem, branching ten or twelve feet high, having reddish-brown branches and buds; pinnated leaves of six or seven oval deeply-sawed lobes, and compound, oval, racemous clusters of whitish-green flowers, succeeded by oval clusters of red berries.

This is a resident of the mountainous parts

of the south of Europe, and is retained in our gardens as a flowering shrub, having a peculiar singularity in its oval-clustered flowers and berries.

3. *SAMBUCUS canadensis.*

Canada Shrubby Elder.] Rises with a shrubby stem, branching eight or ten feet high, having reddish shoots; somewhat bipinnated leaves, often ternate below, composed of five, seven, or nine oval lobes; and towards the ends of the branches, cymose, quinquepartite umbels of flowers, succeeded by blackish red berries.

Herbaceous kinds.

4. *SAMBUCUS Ebulus.*

Herbaceous Elder, commonly called Dwarf Elder.] Hath a thick, creeping, tough, perennial root, spreading widely around; herbaceous, strong, pithy, green stems three or four feet high; large pinnated leaves, of from three or four to six or seven pair of long, acute-pointed, indented lobes, with leafy stipulæ, and large, cymose, three-parted umbels of white flowers, succeeded by black berries in autumn.

This is a perennial, and grows wild in England in hedges, banks, and fields, but is admitted in some gardens for variety and medical uses.

Variety.] Lacinated-leaved, having the folioles beautifully jagged into segments.

All the sorts of Elder are of the deciduous tribe, very hardy, and grow freely any where; are generally free shooters, but particularly the *Common Elder* and varieties, which make remarkably strong, jointed shoots, of several feet length, in one season; and they flower mostly in summer, except the *Racemose Elder*, which generally begins flowering in April; their modes of flowering being in cymose umbels, and racemose clusters, as in their respective descriptions; rising generally towards the termination of the preceding year's shoot, each bunch consisting of numerous small, wheel-shaped, concave, semi-quinquefid flowers; and the bunches being large, spreading, and very abundant, are exceeding conspicuous; but they emit a most disagreeable odour; are succeeded, in most of the sorts, by large bunches of ripe berries in autumn, which, although very unpalatable to eat, are in high estimation for making that well-known cordial liquor called Elder-wine, particularly the common Black-berried Elder; which ripen for that purpose in September and October, and should be gathered accordingly as soon as fully ripe.

The merit of Elders in gardening may be both for use and ornament, especially in large grounds.

With

With respect to the tree and shrub kinds, the common Elder may be introduced occasionally in forest-tree plantations; and as detached standards, in any by-place, for the sake of their berries; as before hinted; and all the sorts may be employed to diversify large ornamental plantations, disposed, however, but thinly, particularly the Common Elders, as their flowers send forth a strong disagreeable scent, so should be but sparingly introduced near much frequented places; however, the different varieties thereof may be dispersed in out-plantations so as to effect an agreeable diversity; but as to the *Sambucus racemosa* and Canada Elder, they may be disposed in any of the shrubbery compartments, more particularly the former, which will exhibit a conspicuous singularity in its mode of flowering and fruiting.

And the Common Elder, being a very fast grower, is often employed in forming outward hedges along ditch-sides, or the sides or tops of banks, where it is necessary to form a hedge-fence as cheap and expeditiously as possible, which may be raised from cuttings of the strong shoots of from one or two to five or six feet long, planted at once where the hedge is intended, a foot distance in the row; and from one to two feet deep in proportion to their length; but the short and middling cuttings generally form the closest hedge from the bottom: though long cuttings are sometimes used in order to form an immediate fence, which being arranged chequer-ways will render the fence stronger, and more immediately fencible against cattle. The hedges, raised by either method, if designed merely as a fence, should be trained only to a moderate height, and kept close and regular by an annual clipping: but some suffer these Elder hedges to grow up rough, in a natural growth, without any trimming, especially at top, permitting them to branch out on each side upward, in order to produce large crops of berries, either for private use or for sale.

As to the Dwarf Elder, it is sometimes admitted in gardens, by way of variety, in the herbaceous collection, and for medical use; observing, as this perennial multiplies exceedingly by its creeping root, it must be occasionally trimmed at bottom to confine it within moderate limits.

In most of the species of Elder, the leaves and flowers impart a strong, disagreeable, and almost nauseous smell; especially the common and dwarf Elder, in which the leaves and whole plant are so very bitter that few animals will browse upon them; and the dwarf Elder in particular exhales so

strong a disagreeable odour, they on that account are sometimes planted round granaries to drive away rats, and other vermin; and sometimes large spreading branches of Elder, of both these sorts in summer, when full of leaves, are drawn over fields of young turneps just come up, when thought in danger of being attacked by the fly, often so destructive to these crops, the elder leaves diffusing their rank odour on the ground and young turneps, and the bitter effluvia remaining, has sometimes a good effect, in proving noxious to those devouring insects, as in some degree to prevent, or greatly check their general attack and depredations on the above young plants.

The bark, buds, leaves, and flowers of the common Elder are used in medicine; the leaves are applied outwardly in fomentation to the piles, and swellings; the flowers infused in whey are beneficial in disorders of the skin; and from the berries are prepared a spirit, a wine, and an oil, which promote urine, perspiration and sweat; the juice of the dwarf Elder (*Sambucus Ebulus*) is recommended in dropical disorders; and the berries are a gentle purge.

Method of Propagation, &c.

All the tree and shrub Elders are propagated very expeditiously by cuttings of the young yearling shoots, and may also be easily raised from seed.

By Cuttings. — Cuttings of Elder shoots, in lengths of from one or two to five or six feet, very readily grow, and may be planted in autumn, or any time in open weather, from October till spring, though the spring, in February or March, is rather the more proper season for planting them; as when planted in autumn or winter, not having struck root, are liable to be killed by rigorous frost; choosing cuttings of the last year's shoots, not those that are green and succulent, but such as are become a little woody; and for general planting, cut them about fifteen or eighteen inches to two-foot lengths, or observing, that if they are designed for nursery rows to train occasionally for different purposes, cut them into short lengths of about three joints, planting them in rows two feet asunder, each cutting two parts of three in the ground: they will readily emit roots in the spring, and shoot strongly at top in summer, training them for the purposes wanted, some to run up with a single stem for standards, others to form bushy shrub-like plants, &c. and in a year or two they may be transplanted finally, if required.

Or if intended to form an Elder-hedge, cuttings of the Common Elder, of the above
6 L 2 length,

length, may be planted at once, where the hedge is intended, either in a single or double row, about a foot asunder.

But in some particular cases, large cuttings of from a yard to five or six feet long, or more, particularly of the Common Elder, may be planted in any moist situation, or along ditch-sides, either to form spreading standards, as soon as possible, for producing plenty of berries, or to form a growing hedge immediately fencible, as it were; in either case, planting the cuttings of this length half a yard deep, and ten or fifteen feet asunder, for the standards, and one foot apart for the hedge, arranged either flanking or chequerways, as before observed.

The planting of all these cuttings may be performed either with a long iron-shod dibble, or, for the larger long sets, make holes with an iron crow, or a large stake driven into the ground: or, sometimes, in moist, soft, deep soils, the ends of the cuttings being sharpened, they may be thrust into the ground a proper depth, especially the moderate-sized cuttings.

By Seed.—This mode of propagating Elders is not generally practised, they being much more expeditiously raised from cuttings as above; however, they may also be easily raised in abundance from the seed or berries, sown in autumn, in beds of common earth, half an inch deep, and managed as other nursery seedling trees.

The scattered or self-sown seeds of these trees, falling any where accidentally, either on the ground, in the crevices of old walls, or hollow trees, grow without care or trouble, and produce young plants.

The fourth sort, *Sambucus Ebulus*, is propagated very plenteously by parting the roots in autumn.

SAND, See COMPOSTS, EARTH, LOAM, &c.

SANGUINARIA, Puccoon.

This genus affords, for our purpose, one low, herbaceous, flowering perennial for the flower borders, rising with a low stalk, crowned with octa-petalous flowers.

Class and order, *Polyandria Monogynia*.

Characters.] CALYX, two oval concave leaves that fall away. COROLLA, eight oblong, obtuse, spreading petals. STAMINA, many short filaments, having single antheræ. PISTILLUM, an oblong compressed germen, no style, but a thick, two-furrowed, permanent stigma. PERICARPIMUM, an oblong-bellied bivalvular capsule, having many roundish acute seeds.

There is but one species, viz.

SANGUINARIA *canadensis*.

Canada Sanguinaria, or Puccoon.] Hath a tuberous fibrated root, crowned with large, roundish, indented leaves, and low, slender, leafless stalks, terminated each with one large, octa-petalous, pure-white flower.

Varieties.] Single-flowered—Semi-double-flowered—Full-double-flowered.

They are all perennial in root, but annual in stalk and leaves; the stalks rising in the spring, and flower in April, very ornamentally.

All the varieties are hardy, and proper to intermix with other low spring flowers in the fronts of the borders and other compartments; should be planted in autumn, when the stalks and leaves are decayed, any time from August till October, planting them about a foot, or fifteen or eighteen inches from the edge of the border, and about two or three inches deep, and they will all flower in spring following.

They are all easily propagated by parting the roots in autumn, when the leaves and stalks decay.

The roots of all the varieties of these plants, when broken asunder, pour forth a bright-red or orange-coloured juice, with which, it is said, the Canada Indians paint themselves of those colours.

SANTOLINA, Lavender Cotton.

This genus furnishes low, under-shrubby ever-greens, and herbaceous perennials, for ornamenting the pleasure ground, and for medical use, garnished with very small hoary leaves, simple and pinnated, in different species, and compound rayless flowers terminating the branches.

Class and order, *Syngenesia Polygamia Æqualis*.

Characters.] CALYX, a hemispherical, imbricated, general cup. COROLLA, a compound uniform flower, consisting of numerous hermaphrodite, tubulous, funnel-shaped florets. STAMINA, five fine hair-like filaments, and cylindric tubulous antheræ. PISTILLUM, an oblong tetragonous germen, filiform style, and two oblong, depressed, truncated stigmas. PERICARPIMUM none; each floret is succeeded by one four-cornered seed, resting on the common receptacle.

There are four species; two of them are shrubby and two are herbaceous; all originally exotics from the south of Europe, but hardy enough to prosper here in the open ground, all the year.

Shrubby Kinds.

Consist of two low, shrubby, bushy perennials,

ennials, comprising some varieties, all durable in root, stem, and branches, and retain their leaves the year round, mostly assuming a hoary-whitish appearance.

1. *SANTOLINA Chamæ Cyparissus*.

Dwarf Cypress, or Common Lavender Cotton.] Rises with a low, shrubby stem, very branchy and bushy, two or three feet high, very closely garnished with minutely small, indented, hoary leaves, quadrifarious or ranged four ways; and the branches terminated by long peduncles, each supporting one compound yellow flower.

2. *SANTOLINA rosmarinifolia*.

Rosemary-leaved Lavender Cotton.] Rises with a shrubby stem, branching numerously from one or two feet to a yard high, in different varieties, closely garnished with small linear hoary leaves; with tuberculated margins, and the branches terminated by long pedunculi, each sustaining one compound pale-yellow flower.

Varieties of this.] Greater Rosemary-leaved Lavender Cotton, growing about a yard high—Minor Rosemary-leaved Lavender Cotton, with blunt leaves growing in clusters—Dark-green-leaved—Villose hoary-leaved, with a large flower.

The above two shrubby Lavender Cottons, and varieties are retained in our gardens both as plants of ornament and for medicinal use, the leaves, flowers, and seeds being proper, particularly the first species.

Herbaceous Kinds.

3. *SANTOLINA anthemoides*.

Anthemis-leaved Lavender Cotton.] Hath fibrous perennial roots, herbaceous, very branchy, hairy stalks, eight or ten inches high; bipinnated, many-parted downy leaves like those of chamomile, and the branches terminated by long pedunculi, each sustaining one compound yellow flower.

4. *SANTOLINA alpina*.

Alpine Lavender Cotton.] Hath fibry perennial roots, herbaceous unbranching stalks eight or ten inches high, bipinnated grey leaves, and pedunculi terminated by one yellow flower.

The two shrubby species and varieties, being hardy, low, bushy evergreens, are proper ornamental plants for adorning borders, and the fronts of small shrubbery compartments, where, with their hoary, and lighter and darker-green leaves, in different varieties, they will exhibit an agreeable variety. Some may also be potted, to move occasionally, to embellish any particular compartment in assemblage.

The herbaceous kinds being also hardy, are

likewise employed occasionally to cause variety in the pleasure ground.

Method of Propagation.

The shrubby kinds are propagated the most expeditiously by slips or cuttings of the young shoots, and may also be raised from seeds.

By Slips or Cuttings.—In spring, or early in summer, slip or cut off a quantity of the last year's shoots, five or six inches long, clear away all the lower leaves, then plant them in any shady border in rows half a foot asunder, water them directly, and repeat it in dry weather, and they will root freely and form tolerable plants by autumn, when, or in the following spring, they may be transplanted with balls, in wider nursery-rows, &c. or some of the largest where they are finally to remain.

By Seed.—Sow it in the spring, in a bed of light earth, either in shallow drills or all over the surface, covering it a moderate depth; they will grow the same year, and towards autumn, or in the next spring, prick them out half a foot asunder, and after having a year's growth they must be transplanted to wider distances.

The two herbaceous kinds are propagated by parting the roots in autumn, and by seed in the spring, sown in any common earth, and raked in; and when the seedlings are a little advanced in growth plant them out.

SAPINDUS, Soap-berry Tree.

It consists of tree-like, shrubby, and other tender exotics of the East and West Indies, retained here in our stove collections, adorned with winged and trifoliate leaves, and spikes of small, quadripetalous flowers.

Class and order, Octandria Trigynia.

Characters.] *CALYX*, a four-leaved spreading cup, each leaf is ovate, plane, spreading, and coloured. *COROLLA*, four ovate unguiculate petals, with four oblong, concave, erect leaves for the nectarium, inserted in the base of the petals. *STAMINA*, eight filaments with cordate, erect antheræ. *PISTILLUM*, a trilobate germen, with three short styles, and blunt, simple stigmas. *PERICARPIMUM*, three fleshy, ventricose, variated capsules, joined together, containing one, two, or three nuts.

The species are,

1. *SAPINDUS Saponaria*.

Common Indian Soap-berry tree.] Rises with a woody stem, where it is a native, to the height of twenty or thirty feet, sending out many branches, garnished with winged lanceolate leaves: the flowers which are small and white, come out in loose spikes at the ends of the branches, and are succeeded by round saponaceous berries.

2. *SAPINDUS rigidus*.

Rigid

Rigid Ash-leaved Soap-berry Tree.] Rises about twenty feet high with strong woody branches, garnished with ovate-oblong winged leaves; the flowers come out in spikes from the ends of the branches, and are succeeded by smooth berries.

3. *SAPINDUS trifolius*.

Trifoliate Malabar Sapindus.] With leaves composed of three folioles.

4. *SAPINDUS chinense*.

Chinese jagged-leaved Sapindus.] With pinnated leaves, having the folioles jagged.

The propagation of these plants is by seeds sown in pots, and plunged in a hot-bed early in the spring; the young plants soon arise, and may be transplanted into single pots, and replunged into the hot-bed, and by degrees inured to the open air; and towards autumn, plunged in the bark-bed in the stove, and managed as other plants of the woody kind.

SAPONARIA, Soap-wort.

The plants are herbaceous perennials and annuals, of hardy temperature, some of the former being cultivated as flowering plants for variety, &c. producing annual stalks two or three feet high, terminated by bunches of pentapetalous flowers.

Class and order, *Decandria Digynia*.

Characters.] *CALYX* is monophyllous, tubular, quinque-dentate and permanent. *COROLLA*, five petals, narrow and angular below, and broad, obtuse, and plane above. *STAMINA*, ten awl-shaped filaments, inserted alternately into the ungues or tails of the petals, having long incumbent antheræ. *PISTILLUM*, a cylindric germen, two parallel styles crowned with acute stigmas. *PERICARPIUM*, a cylindric, covered, unilocular capsule, having many small seeds.

There are several species, one of which only is common to the English gardens, viz.

SAPONARIA officinalis.

Common Soap-wort.] Hath a creeping, very spreading, perennial root, upright jointed stalks, two feet high or more, garnished with oval-lanceolate opposite leaves, and the stalks terminated by umbel-like bunches of purplish flowers.

Varieties.] Common single-flowered Soap-wort—Double-flowered—Hybrid Soap-wort with concave leaves.

This species grows wild in England, but is sometimes retained in gardens for variety, particularly the Double-flowered and Hybrid concave-leaved sort; they all succeed in any common soil, are durable in root, which send up stalks annually in the spring, and flower in July, continuing in succession till September.

The root and leaves are used in medicine; and the leaves were formerly used instead of Soap, and by being boiled in water afford a soap-like froth, proper for washing cloaths; hence the name Soap-wort.

These plants are easily propagated by parting the roots, any time in open weather, from autumn till spring.

SARRACENA, Side-saddle Flower.

A genus consisting principally of herbaceous perennials, admired for the singularity of their leaves and flowers; they rising with numerous large leaves of a singular construction, pitcher-shaped, and hollow, and upright stalks, decorated at top with large pentapetalous, inflexed, purple and yellow flowers, placed singly.

Class and order, *Polyandria Monogynia*.

Characters.] *CALYX*, a double perianthium, the lower one composed of three small oval deciduous leaves, and the upper one of five large coloured leaves, which also fade away and fall off. *COROLLA*, five oval inflexed petals, having oval-oblong claws. *STAMINA*, numerous small filaments, topped with simple antheræ. *PISTILLUM*, a roundish germen, very short cylindric style, crowned with a clavated, peltated, pentangular stigma, covering the stamina. *PERICARPIUM*, a roundish quincloocular capsule containing many roundish, pointed seeds.

The species for our purpose are,

1. *SARRACENA purpurea*.

Purple Sarracena.] Hath a fibrous, deep-striking root, sending up many pitcher-shaped, firm leaves, rising from a small base, widening gradually in an erect position, so as to contain a quantity of water; and from the root an upright, round, naked flower-stem, half a yard high, adorned at top with singly-placed, large fine purple flowers, hanging in a drooping posture; appearing in June, and sometimes succeeded by ripe seeds in autumn.

2. *SARRACENA flava*.

Yellow Sarracena.] Hath a fibrous root as the former, sending up numerous hollow leaves, standing on a slender base widening to the top, a yard high, and upright naked stalks, terminated by singly-placed, yellow flowers, appearing in June or July.

Variety.] With greenish flowers.

Both these species of *Sarracena* are natives of North America, residents of moist boggy places; and in this country should have a somewhat similar situation, either in a bed, border, or pots; but should be guarded against severe frost for their protection.

They are propagated by seed, and by offsets of the roots, though with no great certainty

tainty of success in this country, so that the plants are occasionally procured from America; and are kept in most of the principal nursery grounds.

SATUREIA, Savory.

This genus is composed of low, under-shrubby, and herbaceous aromatic perennials and annuals, for the kitchen-garden, pleasure ground, and green-house, ornamented with small narrow leaves, and small monopetalous ringent flowers at the sides and termination of the branches.

Class and order, *Didynamia Gymnospermia*.

Characters.] CALYX is monophyllous, erect, tubulous, striated, five-parted at top, and permanent. COROLLA is monopetalous and ringent, with a cylindric tube, and labiated, having the upper lip acutely emarginated, and the under lip three-parted. STAMINA, two long and two short filaments, crowned with connivent antheræ. PISTILLUM, a quadrifid germen, a bristly style, having two bristly stigmas. PERICARPIUM, none: four roundish naked seeds lodged in the permanent calyx.

There are eight or nine species; the following six of which are the sorts principally known in our gardens, being all exotics from different countries; three of which are hardy, and the others tender, requiring shelter of a green-house in winter.

Hardy Kinds.

Consist of three species; two low, under-shrubby, and herbaceous perennials, and one annual; all of the aromatic tribe; two of which, Winter Savory and Summer Savory, are eminent pot herbs for the kitchen-garden, and for medical use.

1. SATUREIA montana. (Perennial.)

Mountain, or common Winter Savory.] Rises with a low, under-shrubby stem, branching numerously about a foot high; closely garnished with small linear-lanceolate leaves, many together at the joints; and at the sides of the branches, short, forked peduncles, supporting small whitish-red flowers.

This is a fine aromatic perennial, durable in root, stem, and branches, and continues in leaf the year round.

2. SATUREIA virginiana. (Perennial.)

Virginian Savory.] Rises with upright, stiff, angular stalks, branching a foot and half high; small spear-shaped, pointed, stiff leaves, scented like penny-royal; and the branches terminated by white flowers in round heads.

3. SATUREIA hortensis. (Annual.)

Garden, or Summer Savory.] Rises with upright slender stalks, branching by pairs a foot or more high; narrow, spear-shaped, stiff, odoriferous leaves, and from the sides of the branches

pale-red flowers, two on each peduncle.

This is a choice aromatic annual pot-herb for the kitchen-garden.

Green-house Kinds.

They consist of three low, under-shrubby, ever-green, aromatic perennials, exotics from warm countries, and require shelter in winter.

4. SATUREIA Juliana.

St. Julian's whorled Savory.] Rises with erect, slender, ligneous stalks, branching moderately nine or ten inches high; narrow, spear-shaped, finely-scented leaves, and small white flowers, in whorled bunches, round the branches.

5. SATUREIA Thymbra.

(Legitimate Thymbra)—or Hispid-whorled Savory.] Rises with shrubby stems, branching about two feet high; oblong, acute, odoriferous leaves, and reddish flowers, in thick hispid whorls round the branches.

6. SATUREIA capitata.

Capitated Savory.] Rises with shrubby, slender stalks, branching eight or nine inches high; narrow, carinated, punctated, ciliated leaves; and the branches terminated by capitated spikes of white flowers.

All these six species of Savory are of low, bushy growth; mostly evergreen except the hortensis; and flower in June and July; the flowers are small, and each formed of one ringent petal, and in some sorts are succeeded by seeds in our gardens, particularly the Winter and Summer Savory.

With respect to the three hardy species, the two first are perennial, and the third is annual; are all hardy enough to succeed in the open ground; the first and third sort merit culture in every kitchen-garden, as aromatic pot-herbs and as medical plants; and all the three sorts may also be employed to diversify the compartments of the pleasure garden, &c. allowing them generally a dry soil.

And the tender kinds, requiring shelter from frost, must be kept in pots, and placed among the green-house exotics, where they will increase the variety, managing them as other shrubby exotics of that collection.

Method of Propagation for all the Sorts.

The three hardy sorts are propagated, some by seed, and the two perennials also by slips or cuttings of the branches, and by parting the roots.

By Seed.—The Winter and Summer Savory furnish plenty of seed annually in autumn, by which they may be raised in abundance, sown in the open ground in spring; for which, in the latter end of March, or in April, dig a bed or border of light rich earth, and sow the seed

seed thereon moderately thick, and rake them in evenly, they will soon come up; being then careful to give occasional weeding, and if the plants are any where too much crowded, thin them moderately, and they may either remain where sown, thinning them to small distances, or may be transplanted.

Observe, however, of the Winter Savory, that when the seedlings are about two or three inches high, it is eligible to plant out a quantity of the strongest, in moist weather, in nursery-rows six inches asunder, to remain till September or spring following, then to be transplanted with balls where they are finally to remain, in rows a foot asunder.

But the annual or Summer Savory may either be sown in small drills, six inches asunder to remain, or broad-cast and raked in lightly, and thinning the plants six inches distance; or when two inches high, a quantity may be pricked out in beds, in rows the above distance; in either case the plants will become useful in June or July until winter, when they will totally perish.

Or, when designed to have the Winter or Summer Savory remain where sown, the seeds may be sown in shallow drills, either in beds or along the edge of any bed or border by way of an edging.

By Slips, &c.—In the spring or early part of summer, the common Winter Savory may be increased plentifully by slips or cuttings of the young shoots or branches, which very freely take root; therefore, slip or cut off a quantity of young shoots five or six inches long, plant them with a dibble in any shady border in rows six inches asunder, giving occasional waterings, and they will be well rooted by September, when they may be transplanted with balls where wanted; those for the kitchen-garden plant in rows a foot asunder, or may be planted in rows along the edge of any border, or other compartment, by way of an edging, as before observed of the seedlings.

By parting the Roots.—The above, and the Virginian Savory, in particular, may be propagated in plenty by parting the roots in autumn or spring.

The three tender kinds are very easily propagated by slips or cuttings in May, June, or July, choosing some of the most robust young side-shoots, slipping or cutting them off, and plant them in pots, several in each, which, if plunged in a hot-bed, will greatly facilitate their rooting, or, in default thereof, place them under a frame and lights, or hand-glasses, shading them from the sun, and give water, they will soon show signs of growth, when let them enjoy the free air, and, when well rooted, to-

wards autumn, transplant them in separate pots.

As these kinds are apt to dwindle off in three or four years, it is therefore proper to continue raising a fresh supply of new plants accordingly.

SATYRIUM, Satyrion, or Lizard Flower.

A genus of bulbous-rooted, hardy flowering perennials, sending up annually leaves and flower-stems, which are terminated by spikes of pentapetalous, nectariferous flowers.

Class and order, *Gynandria Diandria*.

Characters.] **CALYX**, a vague spathe, protruding a simple spadix of flowers, without perianthiums. **COROLLA**, five ovate-oblong petals, three of them exterior, and two interior, rise upward and meet, and a monophyllous nectarium, between the divisions of the petals, having a short upper lip, the under plane, pendulous, and scrotiform. **STAMINA**, two short gynandrous filaments, and obovate antheræ. **PISTILLUM**, an oblong contorted germen below the flower, the style is connected with the upper lip of the nectarium, and compressed obtuse stigmata. **PERICARPIUM**, an oblong, three-keeled, trivalvate, one-celled capsule, containing many small scobiform seeds.

This genus hath a great affinity to the *Orchis*. See *ORCHIS*.

The species for our purpose are,

1. **SATYRIUM hircinum**.

Stinking Lizard Satyrion.] Hath a solid undivided root, the stem rises eighteen inches high, garnished with lanceolate leaves, five inches long; the flowers which come out in a spike on the upper part of the stalk, are of a dirty white, with linear streaks, and spots of a brown colour, with the lip of the nectarium trifid, and the middle segment linear and end-bitten.

2. **SATYRIUM viride**.

Green, Frog Satyrion, or Orchis.] Hath a palmate, bulbous root, the stem rises about a foot high, the lower part of which is garnished with oblong obtuse leaves, about three inches long; the flowers which terminate the stems come out in a long slender spike, and are large yellowish-green, with some purple, and the lip of the nectarium divided into three linear parts, the middle one being obsolete.

This species grows on dry pastures and chalk hills in several parts of England.

3. **SATYRIUM albidum**.

White Satyrion.] Hath numerous cylindric roots joined together, with a stalk rising eight inches high, with the lower part garnished with spear-shaped leaves, three inches long; the stalk is terminated by a thick spike of a whitish colour, with the lip of the nectarium trifid-acute, the middle segment being the largest.

All

All the Satyrions are hardy, perennial, durable roots, but annual in leaves and flowers; they grow spontaneously in many parts of this kingdom, and are kept in curious gardens for variety.

They are propagated by seeds and off-sets from their roots, in like manner to the Orchis. See ORCHIS.

SAXIFRAGA, *Saxifrage*.

This genus comprehends many low, and moderate-growing, hardy, herbaceous perennials, principally for ornament and variety; several of which producing ornamental flowers, are proper for the decoration of the pleasure-ground, rising mostly with annual stalks, some a foot high or more, others not so much, adorned with small lobated and entire leaves, and terminated with small pentapetalous flowers.

Class and order, *Decandria Digynia*.

Characters.] CALYX is short, monophyllous, five-parted, and permanent. COROLLA, five patent petals. STAMINA, ten awl-shaped filaments, with roundish antheræ. PISTILLUM, a roundish acuminate germen, two short styles, and obtuse stigmas. PERICARPIUM, an oval, birostrated, or two-beaked, unilocular capsule, containing numerous small seeds.

There are upwards of thirty species of this genus, but not more than seven or eight that are esteemed for general culture, which are considered generally as flowery plants, for variety in the pleasure-ground, as aforesaid.

The principal species are,

1. SAXIFRAGA *granulata*.

Granulous-rooted, or Common White Saxifrage.] Hath a granulous perennial root, being composed of numerous small tuberos parts like grains of corn, crowned with many small, kidney-shaped, lobated leaves, upright branchy stalks, a foot high; garnished also with kidney-shaped leaves, and terminated by tufted bunches of numerous white flowers.

Varieties.] Common Single-flowered of the meadows—Double-flowered of the gardens, being very ornamental.

They flower in April and May, which, when in large tufts, as many stalks rise close together, they make a very ornamental appearance, particularly the Double-flowered variety, and may be disposed both in patches towards the fronts of borders, and in pots.

2. SAXIFRAGA *Cotyledon*.

Cotyledon Saxifrage, with a paniculated and pyramidally branching stalk.] Hath a thick, fibrated, perennial root, crowned with tongue-shaped, cartilaginous-sawed leaves, in an aggregate cluster like house-leek, an upright pa-

niculated branching stalk; a foot or more high, having all the branches terminated by panicles of white flowers.

Varieties.] Common Paniculated Cotyledon Saxifrage—Pyramidal Saxifrage, branching almost from the bottom a foot and half high, with the branches diminishing gradually in length upward, and all of them terminated by spreading white flowers; the whole forming a beautiful pyramid.

3. SAXIFRAGA *crassifolia*.

Thick large-leaved, Purple Saxifrage.] Hath a fibrated perennial root, crowned with a tuft of large, oblong-oval leaves, slightly crenated, and upright stalks, rising a foot high; terminated by a large panicle of purple flowers, very ornamental in April and May.

4. SAXIFRAGA *umbrosa*.

Umbrose Saxifrage, commonly called London Pride, or None-so-pretty.] Hath a fibrated perennial root, crowned with ob-oval nearly retused leaves in circular heads, having cartilaginous crenated margins; and upright, slender, naked, paniculated stalks a foot or more high, terminated by panicles of whitish flowers spotted with red, having also red pistils.

This is an old inhabitant of our gardens, and was formerly planted for edgings, though it is rather improper for that purpose; but being disposed in tufts about the borders, it will effect a proper variety.

5. SAXIFRAGA *hypnoides*.

Cushion Saxifrage, commonly called Lady's Cushion.] Hath a fibrated perennial root, crowned with narrow trifid leaves, many trailing spreading shoots, garnished with entire and trifid leaves, and upright, almost naked stalks, but a few inches high, terminated by small bunches of whitish flowers.

The trailing shoots and leaves of this plant forming a close roundish bunch like the shape of a cushion or pillow, hence it is commonly called Lady's Cushion.

6. SAXIFRAGA *punctata*.

Spotted Saxifrage.] Hath a fibrous perennial root, crowned with roundish indented leaves, in a circular cluster, on long foot-stalks, and upright, slender, naked stalks, a foot high, terminated by panicles of white flowers spotted with red punctures.

7. SAXIFRAGA *hirsuta*.

Hairy Saxifrage.] Hath a fibrous perennial root, crowned with heart-shaped-oval retuse leaves, with cartilaginous crenated edges, and hairy leafless stalks, near a foot high, terminated by panicles of white flowers, having a few red spots.

8. SAXIFRAGA *sarmentosa*.

Sarmentous, or Shoot-bearing, Strawberry Saxifrage.] Hath a fibrous, perennial root, sending forth runners, as the strawberry; the leaves arise from the root upon red foot-stalks, they are roundish, slightly crenated, and pleasantly variegated, the stalk rises about a foot high, furnished with distant pedicles, sustaining each a nectarious flower with five petals; the three upper ones are small and spotted with red, the two lower ones are very long, spear-shaped, and of a pale flesh colour.

This species being a native of China, requires some protection in winter.

The first seven species are all hardy perennials, generally considered as flowery plants; but the first three or four sorts are the most commonly cultivated, and have the greatest merit as plants of ornament; however, all the sorts may be employed for variety, and disposed in patches towards the fronts of flower-borders, &c. and the first and second sort are also often planted in pots to move to any place occasionally, more particularly the Granulous Double White Saxifrage, and the Cotyledon Pyramidal Saxifrage, both of which demand singular attention for their ornamental flowers.

They are all durable in root, and some sorts also retain their leaves all the year; the Granulous Saxifrage, however, is deciduous, and all the sorts produce flower-stalks annually in the spring, flowering, in the different sorts, from April till June; the first species and variety generally flower in April and May, and the others in May and June.

All the sorts are very easily propagated by off-sets of the roots and heads, which they furnish abundantly.

The first sort multiplies exceedingly by its granulous roots, which, towards autumn, when their stalks and leaves decay, may be divided, not too small, but in little bunches, and let them be planted again directly, some in the open borders, &c. and some in pots, forming a small hollow in the earth an inch deep, in which deposit the bunch of roots, covering them the same depth with earth; and being thus planted in bunches, they will send up several stalks in a cluster together, and exhibit a large tuft of flowers.

The second, third, and fourth species multiply very fast by side off-sets from the root and head, or crown of the plant, each furnished with roots, which may be parted or separated in autumn, or early in the spring, and planted where they are finally to remain, observing to plant some of the Cotyledon pyramidal sort in pots, and the others in patches towards the middle and front of the borders.

The other hardy sorts are also propagated by off-sets, and parting the roots, in autumn or spring, and the eighth is easily propagated by its runners.

SCABIOSA, Scabious.

This genus of plants consists of herbaceous annuals, biennials, and perennials, for ornament and variety in the pleasure-ground, and shrubby perennials for the green-house, garnished with leaves of different forms in the different species, and terminated with numerous round aggregate heads of flowers, each head composed of many small florets contained in one general calyx.

Class and order, *Tetrandria Monogynia*.

Characters.] CALYX, a spreading, many-leaved, general cup, containing many florets, each floret having a double calyx. COROLLA, the general flower a round aggregate of many florets; each floret of the aggregate is monopetalous, tubulous, and cut into four or five parts at top. STAMINA, four awl-shaped filaments in each floret, having oblong incumbent antheræ. PISTILLUM, a germen under each floret, and a slender style, crowned with an obtuse, obliquely emarginated stigma. PERICARPIMUM, none; a single, oblong-oval seed to each floret, crowned with its partial calyx, and resting on the elevated general receptacle.

There are many different species of Scabiosa; a few only are in esteem for general culture, principally as plants of ornament and variety, consisting of ten hardy herbaceous annuals, biennials, and perennials; and four shrubby exotics for the green-house.

Hardy herbaceous Kinds.

This head comprehends some remarkably flowery annuals and biennials, and several perennials, rising with upright branchy stems, two or three feet high or more, garnished with leaves below; and numerous flowers at top; observing, the first two are annuals, the rest perennial; but the annual kinds are the most generally known, and cultivated as ornamental plants.

1. SCABIOSA *atropurpurea*. (*Annual-Biennial*.)

Dark-Purple Indian Scabious.] Hath a fibrous annual-biennial root, crowned with a large tuft of oblong leaves, variously jagged and cut on the edges, and often into segments, and upright stems, branching numerously on every side, three feet high or more; and from the sides and ends of the branches, numerous dark-purple, and other coloured flowers, in the varieties, having all quinquefid florets and awl-shaped receptacles.

Varieties.] Common Dark-purple Scabious — Pale

— Pale - purple - flowered — Red-flowered — White-flowered — Black-flowered — Hen and Chicken-flowered, having several small flowers arising from the sides of the main one — Striped flowered, &c.

They all flower in June, continuing in plentiful succession till September, forming a very ornamental appearance, and are succeeded by abundance of ripe seeds in autumn.

All the varieties of this species are very hardy, and may be considered both as annuals and biennials; for, being raised from seed forward in the spring, they will run up to stalk and flower the same year, and generally perish the following winter; but if not sown till summer, they produce only leaves that year, increase in strength, and remain vigorous till spring following, when they will shoot up vigorously into very strong branchy stems, and produce an amazing quantity of flowers from June till autumn, and furnish plenty of seeds, then totally perish root and stem towards winter, so that a fresh supply must be annually raised from seed both as annuals and biennials.

2. *SCABIOSA stellata.* (Annual-Biennial.)

Starry Spanish Scabious.] Hath a fibrous annual-biennial root, crowned with oblong leaves, variously cut on the edges, and upright stems branching numerously about a yard high, garnished with oblong, finely cut leaves, and the upper part supporting numerous purple flowers composed of quinquefid star-shaped florets with roundish receptacles, flowering in July.

Varieties.] Greater jagged-leaved—Minor jagged-leaved—Red-purple-flowered—White flowered.

This species and varieties may also be treated both as annuals and biennials, as observed of the former sort.

3. *SCABIOSA integrifolia.* (Annual-Biennial.)

Entire-leaved Montpellier Scabious.] Having the radical leaves ovate, sawed, the branch ones spear-shaped; branches spreading; and all the florets quadrid:—purple.

4. *SCABIOSA arvensis.* (Perennial.)

Common Field Scabious.] Hath fibrous perennial roots, upright hispid stems, branching three feet high, garnished with pinnatifid leaves, with the lobes at a distance, and blue flowers, having radiated florets.

Varieties.] With reddish flowers,—Purple-flowered, &c.

It grows wild in the fields and meadows in England, but is sometimes cultivated for variety.

5. *SCABIOSA succisa.* (Perennial.)

Devil's Bit (Morsus Diaboli), or Root-bitten Scabious.] Hath a thick, short, downright root, terminated abruptly as if bit off, crowned with oval-spear-shaped, entire leaves; upright single stalks two feet high, with the branches growing near, and terminated by blue flowers with equal quadrid florets.

This grows naturally in England, &c. in pastures and woods.

6. *SCABIOSA alpina.* (Perennial.)

Alpine Blue Scabious.] Hath a strong, fibrous, perennial root, sending up several strong stems, branching four or five feet high, garnished with pinnated leaves of four or five pair of spear-shaped sawed lobes; and from the upper parts, whitish-yellow drooping flowers, having quadrid equal florets.

7. *SCABIOSA argentea.* (Perennial.)

Silvery Oriental Scabious.] Rises with low slender stems, dividing into spreading branches, pinnated silvery-white leaves, with spear-shaped lobes, and the branches terminated by long, naked, smooth peduncles, sustaining small pale flowers with quinquefid florets.

8. *SCABIOSA graminifolia.* (Perennial.)

Grass-leaved Silvery Scabious of the Helvetic Mountains.] Hath a fibrous perennial root, sending up herbaceous stalks half a yard high, garnished below with very narrow, lanceolate, entire, silvery leaves; and the upper part supporting pale-blue flowers, having quadrid florets.

9. *SCABIOSA gramontia.* (Perennial.)

Gramontian Cut-leaved Scabious.] Having the stem leaves bipinnated, cut thread form, short calyx, and the florets five-cleft.

10. *SCABIOSA leucantha.* (Perennial.)

White-flowered Narbonne Scabious.] Having pinnatifid leaves; calyx scales ovate-obtuse, imbricated; and the florets four-cleft equal.

All these herbaceous kinds are very hardy plants, that succeed in any common soil of a garden, and in almost any situation.

But the two annual sorts are the most generally known and cultivated, and have the greatest merit as ornamental flowery plants.

Tender Shrubby kinds for the Green-house.

Comprises four shrubby species, exotics from warm countries, as mentioned in their titles, and require shelter here in winter, so must be kept in pots and placed among the green-house plants.

11. *SCABIOSA crotica.*

Cretan Shrubby Scabious.] Rises with a shrubby stem, branching two or three feet high; long, spear-shaped, whitish, entire leaves, numerously in clusters, and the

branches terminated by fine blue flowers, having quinquefid florets.

Variety.] Auricula-leaved.

12. *SCABIOSA africana*.

African Shrubby Scabious.] Rises with a shrubby stem, branching four or five feet high; oval-spear-shaped cut leaves, and the branches terminated by flesh-coloured flowers, leaving quinquefid florets.

Varieties.] Rough crenated-leaved—Finely cut-leaved—Woolly-leaved.

13. *SCABIOSA rigida*.

Stiff-leaved Shrubby Ethiopian Scabious.] Rises with a shrubby stem, branching two or three feet high; spear-shaped, serrated, stiff, shining leaves, and the branches terminated by whitish flowers, having quadrifid, nearly-radiated florets, and obtuse calycinal scales.

14. *SCABIOSA attenuata*.

Narrow-leaved Scabious.] Rises with a shrubby stem, branching three or four feet high; linear, smooth, entire leaves, winged at their base, and the branches terminated by flowers, having equal quadrifid florets.

All the above fourteen species of *Scabiosa* flower commonly in June, July, and August, and some continue in succession till autumn, generally producing the flowers upon long foot-stalks singly, each flower being an aggregate of several small quadrifid or quinquefid florets, placed all within one common calyx, forming together a moderately large flower, which, in some species, are exceedingly numerous, and very ornamental, and which in most of the sorts are succeeded by plenty of seeds in autumn.

The merit of these plants is, some for ornament, others for variety.

The three annual-biennial kinds, in particular, producing abundance of ornamental flowers, very conspicuously, two or three months in summer, are choice furniture for all the common flower compartments, and merit culture in every garden; being raised annually from seed in spring and summer, in the open ground, and thence planted out to remain to flower, which, in those of the spring sowing, will be effected the same year; but those raised in summer do not flower till the summer following.

The herbaceous perennial kinds may be introduced as flowering plants, in any large borders and other compartments of the pleasure ground, in which they will effect a very distinguished variety.

And the shrubby kinds being potted and placed among the green-house exotics, they will effect a good variety, and flower ornamentally in summer.

Propagation and Culture of all the Sorts.

First, the Annual and Biennial Sorts.—

The first three species, being hardy annuals and biennials, may be raised plentifully from seed annually, in a bed or border of common earth, and, as formerly noticed, may be considered both as annuals and biennials, and may be treated accordingly, more particularly the *Scabiosa atropurpurea* and varieties; observing, that if intended to raise any of the sorts as annuals, for flowering the same year, they should be sown in the spring, about February or March or beginning of April, on a warm border, or, to bring them as forward as possible, may sow them in a hot-bed; and being planted out about the borders, in May or beginning of June, they flower the same year in July or August, though not near so strong as plants raised the year before as biennials: therefore, in order to have strong flowering plants, it is most eligible to sow a principal share in June, July, or beginning of August; to increase in growth all the latter part of summer till the end of autumn, without running up to stalks, and stand the winter, for flowering early next summer, in which they will produce much stronger stems, branching more numerous and strong, and produce a greater number of flowers: however, it may be proper to sow both in spring for flowering the same year, and in June or July, &c. for next year's flowering; but it is more particularly proper to sow some of the Starry Scabious in spring as annuals.

Observe, in sowing these sorts, the first in particular should be sown for transplantation; also both the other annual-biennial kinds: choosing a bed or border of light earth, and either sow them in small shallow drills, five or six inches asunder, or sown on the surface and raked in evenly: and when the plants are two or three inches high, prick out some of the strongest, in moist weather, where they are to remain to flower, especially the spring-sown plants; but those designed for next year's flowering should be planted in nursery-beds, in rows six or eight inches asunder, giving necessary waterings and weeding, and they will grow fine large plants by autumn, when, or in the following spring, transplant them with balls of earth to the places where they are to flower.

But the Starry Scabious may also either be sown in spring for transplantation, or in patches about the borders, to remain where sown, to flower.

Perennial Sorts.—The hardy, herbaceous, perennial Scabiouses, are all very easily propagated, both by seeds sown in any bed or border

border of common earth in the spring, and the seedlings planted out where they are to remain, and by parting the roots in autumn.

Shrubby kinds.—All the shrubby sorts are expeditiously propagated by planting slips or cuttings of the branches in spring or summer; if in spring, plant them in pots, and place them either in a hot-bed or under shelter of glasses; but in summer they may be planted in the full ground, shaded and watered; and in either method they will root tolerably well the same year, and towards autumn may be potted off separately, and managed as other shrubby exotics of the green-house.

SCANDIX, Shepherd's Needle, Garden Chervil, &c.

This genus furnishes a hardy, herbaceous, aromatic annual for the kitchen-garden, and a perennial for variety, rising with finely divided leaves, and erect stalks from one to four or five feet, in the different species, terminated by umbels of small pentapetalous flowers.

Class and order, *Pentandria Digynia*.

Characters.] CALYX, umbellate flower; the general umbel long, and composed of a few rays, and the partial umbels of many, and the smaller umbellæ only have a five-leaved involucre. COROLLA, a deformed, radiated, general umbel, having both hermaphrodite and female florets, composed of five heart-shaped petals. STAMINA, five slender filaments with roundish antheræ. PISTILLUM, an oblong germen, two permanent styles and obtuse stigmas. PERICARPIUM, none; a long two-parted fruit, having two awl-shaped furrowed seeds.

There are seven, eight, or more species, one of which only is common to the English gardens, known by the name of the Garden Chervil, a fine aromatic, esteemed as a salad and soup herb. There is also a perennial sort sometimes cultivated for variety.

1. SCANDIX *Cerifolium*. (*Annual*.)

Garden Chervil.] Hath a fibrated annual root, crowned with many finely divided leaves, of an aromatic flavour, and upright stalks, one or two feet high, terminated by umbels of white flowers, with lateral umbels sitting close, succeeded by oval-awl-shaped, shining seeds.

This is an annual plant, but remains in leaf all winter, and is cultivated as a culinary herb for winter and spring service; it may also be continued for use the year round, by sowing several times from February till September, because the spring and summer sown plants run up to seed the same year, but the autumn sowing will remain green until spring before it runs.

2. SCANDIX *odorata*. (*Perennial*.)

Odoriferous, Great Perennial Chervil, or Sweet-fern.] Hath a thick, fibrated, perennial root, of a sweet aromatic taste, crowned with large divided leaves resembling fern, and upright hollow stalks, four or five feet high, terminated by large umbels of white, very fragrant flowers, succeeded by long, angular, furrowed seeds.

These plants are both very hardy; the first is an annual, and the other a perennial. The annual sort is in estimation both for salads and soups, as before observed, and the leaves are the useful part; the young leaves of the second were also sometimes used formerly, but rarely now, so is only retained in some gardens to increase the variety in the pleasure-ground, and the annual sort for the kitchen-garden only, which will grow in any soil and situation.

They run up to stalk in spring, flower in May or June, and the seeds ripen in July.

As to the culture of the Garden Chervil, it is by seed annually, observing, if it is required most part of the year, the sowing should be continued every month from February or March till August or September, as before hinted; but if required only for winter and early spring use, an autumn sowing in August, or beginning of September, will be sufficient, and the plants coming up soon after, remain useful from October till March or April. The seed may be sown any where, either broad-cast and raked in, or in shallow drills six or eight inches asunder; and in either case the plants are to remain where sown; being careful to give occasional weeding, which is all the culture they require, and they will soon be fit to cut for use.

The second may also be raised from seed; and plant out some of the plants about the large compartments; and when once thus raised, they will remain several years, and from its scattered seeds many young plants will rise in the adjacent ground.

SCHINUS, Indian Mastic-tree.

It consists of two shrubby evergreen exotics for the green-house and stove, rising eight or ten feet high, adorned with pinnated many-lobed leaves, and the branches terminated by bunches of pentapetalous flowers.

Class and order, *Diaecia Decandria*.

Characters.] CALYX, dioecious flowers, having monophyllous, acutely five-parted cups, that of the females being permanent. COROLLA, five oval petals in the males, and five oblong ones in the female flowers; those in both sexes being petiolated. STAMINA, ten uniform spreading segments, having roundish antheræ. PISTILLUM, a roundish germen,

no style, but three oval stigmas. **PERICARP-
FIUM**, a globular trilocular capsule, having
three seeds.

There are only two species, which being
natives of Peru, and other parts of America,
require shelter of a good green-house here in
winter, so must always be kept in pots.

1. *SCHINUS Molle*.

(*Molle*)—or *Peruvian Mastic-tree*.] Rises
with a woody stem, branching numerously
eight or ten feet high, with pinnated leaves of
ten or twelve pair of sawed lobes and an odd
one, which is much the longest; and the
branches terminated by loose bunches of whit-
ish flowers.

2. *SCHINUS Arcira*.

Brazilian Mastic-tree.] Hath a woody stem,
branching eight or ten feet high, with pin-
nated leaves of ten or twelve pair of entire
lobes, and an odd one, all of equal length;
and at the sides and ends of the branches
small clusters of whitish flowers.

Both these species are shrubby, durable in
root, and top, and retain their leaves the year
round; and being natives of hot countries, re-
quire shelter here of a good green-house in
winter; or, if sheltered in a stove, two or
three winters whilst young, it will be an ad-
vantage to the plants; however, they both suc-
ceed tolerably with the culture of common
green-house exotics. They being pretty ever-
greens, with finely pinnated leaves, merit a
place in the collection of our tender exotics,
in which they will effect a good variety; let
them, therefore, be cultivated in pots of rich
earth, and placed among the plants of the a-
bove department.

They are propagated by seed obtained from
abroad, also by layers and cuttings.

Sow the seeds, as soon as obtained, in
spring or summer, in pots of rich earth, and
plunge them in a hot-bed, managing them as
other tender seedling exotics.

Layers of the young branches in the spring
will be well rooted in one year.

And cuttings of the young shoots, planted
in the spring or summer, in pots, and plunged
in a hot-bed, will readily emit roots in six or
eight weeks.

SCHOTIA.

This genus furnishes the green-house with
an evergreen shrub, garnished with blunt-
pointed leaves, and quinquepetalous flowers.

Class and order, *Decandria Monogynia*.

Characters.] **CALYX**, a monophyllous co-
loured cup, the tube turbinate, and border
cut in five parts. **COROLLA**, five obtuse, e-
rect, concave petals, inserted in the tube of the
cup. **STAMINA**, ten awl-shaped, erect fila-

ments, with oblong incumbent antheræ. **PIS-
TILLUM**, an oblong compressed germen, style
slender and simple, obtuse stigma. **PERICAR-
PIUM**, a pedicillated legumen, containing two
seeds.

There is but one species, viz.

SCHOTIA speciosa.

Lentiscus-leaved Schotia.] Rises with a
branchy stem, furnished with pinnated leaves,
composed of three or four pair of spear-shaped,
blunt lobes, and flowers with blunt concave
petals.

This plant is an evergreen, and must be
kept in the winter in the green-house.

It is propagated by laying down the young
branches in summer.

SCILLA, Squill, or Sea-Onion, Starry
Hyacinth, &c.

This genus comprehends a fine collection of
hardy, bulbous-rooted, flowery perennials,
for adorning the flower borders, having most-
ly very large tunicated and solid bulbous roots,
crowned with long narrow leaves, and erect
flower-stalks, annually; in some sorts two or
three feet high, in others but a foot, and some
but six or eight inches, ornamented at top with
pyramidal and conic clusters of hexapetalous
starry flowers.

Class and order, *Hexandria Monogynia*.

Characters.] **CALYX**, no cup. **COROLLA**,
six oval petals, spreading out like the figure of
a star. **STAMINA**, six awl-shaped filaments,
crowned with oblong, incumbent antheræ.
PISTILLUM, a roundish germen, simple style,
and single stigma. **PERICARPIMUM**, a nearly
oval, three furrowed, trilocular, trivalved cap-
sule, containing many roundish seeds.

There are about eight species in our garden
collections, all of the bulbous-rooted tribe,
most of which are originally from distant coun-
tries, as Spain, Portugal, France, &c. except
one or two, which grow wild in some parts
of England, and all the sorts are hardy enough
to succeed in our gardens in the full ground.

1. *SCILLA maritima*.

Maritime Squill, or Common Sea Onion.] Hath a large, oval, tunicated, onion-like, bul-
bous root, sending up long narrow leaves,
near half a yard in length, and an upright
naked stalk, two or three feet high, having
the upper half adorned with a pyramidal thyrtle
of white starry flowers appearing early in
summer.

Varieties.] Red-rooted—White-rooted.

This species is a maritime plant, inhabit-
ing the sandy sea shores of Spain and other
warm countries, but the bulbs are sent here
annually for medical use, and are planted in
many gardens as flowery plants for curiosity.

2. *SCIL-*

2. *SCILLA Lilio-hyacinthus*.

Lily Hyacinth.] Hath a squamous, or scaly, bulbous, lily-like, yellow root, crowned with oblong lily-like leaves, half a foot long or more, and an upright slender stalk, about a foot high, terminated by many star-shaped blue flowers, appearing in June.

3. *SCILLA peruviana*.

Peruvian Starry Hyacinth, or Hyacinth of Peru.] Hath a large, oblongish, bulbous, brown root, sending up several carinated spreading leaves, six or eight inches long, broad at the base, decreasing to a point at top, and upright, thick, succulent stalks, six or eight inches high, terminated by a conical corymbose cluster of deep-blue starry flowers, appearing in May.

Variety.] With white flowers.

4. *SCILLA italica*.

Italian, Starry Hyacinth.] Hath a roundish, white, bulbous root; longish leaves with obtuse points, and erect stalks, eight or ten inches high, terminated by a hemispherical corymbus of pale-blue flowers, appearing in April.

5. *SCILLA amœna*.

Bright, Starry Hyacinth of Byzantium.] Hath a large, roundish, bulbous, purplish root, sending up several narrow, carinated, spreading leaves a foot long, and upright purplish stalks eight or ten inches high, ornamented upward with fine sky-blue, somewhat drooping flowers, rising laterally in alternate order, appearing in March or April.

6. *SCILLA bifolia*.

Two-leaved Early Star Hyacinth.] Hath a small, roundish, solid, bulbous root, sending up only two narrow leaves, about six inches long, and a slender stalk half a foot high, terminated by a few, nearly-erect, blue, starry flowers, appearing early in March.

Variety.] With white flowers.

7. *SCILLA autumnalis*.

Autumnal Squill, or English Starry Hyacinth.] Hath a round, white, bulbous root, very slender linear leaves, six inches long, and upright slender stalks, half a foot high, adorned at top with a corymbus of small, blue, starry flowers, having naked peduncles, rising over one another, the length of the flower, appearing early in September. This grows naturally in many parts of England, &c.

8. *SCILLA campanulata*.

Campanulate, or Bell-flowered, Starry Hyacinth.] Hath a roundish, solid, bulbous root, sending up slender, spear-shaped leaves, six or seven inches long, and a slender stalk, terminated by several erect, bell-shaped, spread-

ing, whitish flowers, with purple bottoms; appearing in May and June.

All these species of *Scilla* are bulbous perennials, durable in root, but annual in leaves and stalks, which rise immediately from the root: in some sorts the leaves spring up in autumn, and remain green all winter, and decay in spring, particularly the first, third, and last sort, and some others: and in some the leaves and flower-stalks appear at the same time. The stalks are generally naked or leafless, and terminated by the flowers, which consist each of six oval petals, spreading open, in a star-like manner, with great uniformity and beauty, exhibiting a good ornamental appearance; and in most of the sorts are succeeded by ripe seeds in autumn, by which all the sorts may be raised; but more expeditiously by off-sets of the roots annually, when the leaves and stalks decay.

They being all of hardy temperature, may be employed as flowery plants to adorn the pleasure ground, disposed either in patches about the borders, &c. or deposited in beds by themselves.

Observe, they should generally be removed for transplantation when their leaves and flower-stalks are decayed, when the roots may be taken up, and either planted again directly where wanted, or kept till autumn, &c. though the autumnal sort should be planted early, in order that it may blow the same year in autumn; planting all the sorts about three or four inches deep, or in proportion to the size of the bulb. See BULBUS.

The bulbs of all the sorts may be had, moderately cheap, at most of the nursery-grounds and seed-shops.

Method of Propagation, &c.

The propagation of all the sorts is by off-sets of the roots; the first species, however, being a native of sandy sea-shores, it increases but sparingly in gardens, but is obtained plentifully from abroad. All the others furnish plenty of off-sets, which may be separated every other year, if required, when their leaves, &c. decay, as practised for other bulbous roots.

They may all be propagated also by seed, though this is a tedious method, as the seedlings are several years before they blow: they should be sown in autumn, in light earth, an inch deep, observing the same method of sowing and culture practised for the Common Hyacinths. &c. See HYACINTHUS.

SCORPIURUS, Caterpillar.

The plants of this genus are hardy, herbaceous, trailing annuals, cultivated in the pleasure ground, more as plants of singularity than

than beauty, for the oddity of their caterpillar-like seed-pods; they rising with procumbent stalks, garnished with oblong simple leaves, and papilionaceous flowers, succeeded by contorted pods resembling green caterpillars.

Class and order, *Diadelphia Decandria*.

Characters.] CALYX is monophyllous, inflated, and cut into five acute segments.—COROLLA is papilionaceous; the standard roundish, emarginated, spreading, and reflexed; the wings are loose and nearly oval, and a semi-lunulated, pointed, erect keel, two-parted below. STAMINA, ten diadelphous filaments, with small antheræ. PISTILLUM, an oblong taper germen, a rising inflexed style, terminated by a punctura or point. PERICARPIUM, an oblong, coriaceous, revolute, rough pod, of many transverse cells, each containing one seed.

There are four species, natives mostly of the south of Europe, but grow freely here, in our gardens, in the open borders.

The species are,

1. *SCORPIURUS vermiculatus*.

Vermiculated, or Common Uniflorous Caterpillar.] Rises with trailing herbaceous stalks, a foot or more long, garnished with oblong spatula-shaped leaves; and at the axillas long pedunculi, each supporting one papilionaceous yellow flower, succeeded by oblong twisted pods, covered on every side with obtuse scales.

2. *SCORPIURUS muricatus*.

Muricated Biflorous Caterpillar.] Rises with thick-trailing, herbaceous stalks, a foot and half long, garnished with oblong, broad, obtuse leaves, and at their axillas long pedunculi, each sustaining two papilionaceous yellow flowers, succeeded by oblong, very twisted, rough murexed pods, having the outside armed with obtuse aculei.

3. *SCORPIURUS sulcatus*.

Sulcated Triflorous Caterpillar.] Rises with slender, trailing, herbaceous stalks, a foot long, oblong obtuse leaves, and each peduncle supporting three yellow flowers, succeeded by slender moderately-twisted pods, armed on the outside with acute distinct spines.

4. *SCORPIURUS subvillosus*.

Subvillos Quadriflorous Caterpillar.] Rises with trailing herbaceous stalks, a foot and half long, oblong, obtuse leaves, and long pedunculi, each sustaining four yellow flowers, succeeded by oblong, slender, very contorted pods, armed on the outside with sharp spines in clusters.

All these four species of *Scorpiurus* are hardy herbaceous annuals, that rise from seed annually in the spring; are all of trailing

growth, extending their stalks along upon the ground, having one leaf at each joint; and at the wings of the leaves arise the flowers, being universally papilionaceous, appearing in June and July, and are succeeded by oblong pods, variously contorted and stained, so as to bear a very great resemblance to large caterpillars, apparently feeding on the plants, effecting a curious singularity, those of the first sort in particular, which are the largest, most conspicuous, and caterpillar-like; however, all the sorts form an agreeable variety, and they all furnish plenty of ripe seeds in autumn.

These plants, therefore, merit a place in the collection of hardy annuals, principally for the singularity of their caterpillar-like seed-pods; and being disposed in patches about the borders, they will exhibit an eligible variety.

They are propagated by seed in the spring, which succeeds in the full ground, and should generally be sown in patches about the borders, where the plants are designed to remain, as they do not succeed so well by transplantation; therefore form small patches in the different compartments, sowing several seeds in each patch, half an inch deep; and when the plants are come up an inch or two high, thin them to two or three in each place, and clear out weeds, which is all the culture they require, and they will flower in June, and exhibit their pods abundantly all the latter part of summer.

SCORZONERA, Viper's Grass, but commonly called *Scorzonera*.

The plants are herbaceous perennials, biennials, and annuals, mostly of the carrot-rooted kind, one of which, in particular, producing large eatable roots, is cultivated as a kitchen-garden esculent: they rise mostly with long, narrow, grassy leaves from the root, and erect tall stalks, surmounted by large compound flowers.

Class and order, *Syngenesia Polygamia Æqualis*.

Characters.] CALYX, a long, imbricated, nearly-cylindric, general cup, containing many florets. COROLLA, a compound flower, having many tongue-shaped, quinque-dentate, imbricated, hermaphrodite florets, the outer ones being the longest. STAMINA, five short filaments, having cylindric antheræ. PISTILLUM, an oblong germen, filiform style, and two reflexed stigmas. PERICARPIUM, none, a single oblong seed in each floret, sitting on the receptacle within the connivent calyx.

There are several species, but of which there is only one cultivated for use, as an esculent and

and medical plant; the others having but little merit, their culture is not attended to, except in some botanic gardens merely for variety.

The cultivated sort therefore is,

SCORZONERA hispanica.

*Spanish Viper's Grass, or Common Scorzone-
ra.*] Hath a long, downright, carrot-shaped, eatable root, covered with a brown skin, but white and milky within, crowned with several long, narrow, entire, slightly-sawed leaves, terminating in a long acute point; and when it shoots for seed, runs up with an erect, robust, branchy stem, a yard or more high, garnished with amplexicaulous leaves, like the lower ones, and all the branches terminated by large, compound, bright-yellow flowers.

The root is the useful part, being in perfection in autumn and winter, and is boiled and eaten like carrots, &c. and is by many greatly esteemed.

This species, though of a perennial nature in the root, yet, for general use, it should be commonly treated as an annual or biennial; for, being raised from seed in the spring, the roots will be fit for use in the following autumn, and remain in perfection till next spring, when they will shoot up stalks for flower and seed, and become hard, sticky, and unfit for use, so should be thrown away, and a fresh supply raised from seed.

The general propagation of this plant is by seed annually, in any open light spot of ground, sown the latter end of March or beginning of April, not earlier, lest the plants fly up to seed the same year, before the roots acquire perfection: having, therefore, made choice of an open spot of ground in the kitchen-garden, and at the proper season digged it one good spade deep at least, then let the seed be sown, either broad-cast, all over the surface, thinly, and raked in, or may draw shallow drills, ten or twelve inches asunder, and sow the seeds therein, and rake the mould evenly over them half an inch thick; in either method the plants will rise in two or three weeks; observing, when they are a little advanced in growth, let them be thinned and cleaned from weeds, by small-hoeing them in dry weather, cutting out the plants to eight or ten inches distance, and cut down all weeds between them; thus they will grow freely, and their roots continue increasing in size till September, when they will have acquired their full size, discoverable by their leaves beginning to decay; at which token of maturity, may begin to draw them for use.

The roots may either remain in the ground, and drawn as they are wanted, or may be taken wholly up in autumn, when their leaves decay, and preserved in sand all winter, that

they may be ready at all times, especially in frosty weather, when they cannot be dug out of the ground.

To save seed of this species, let some of the plants remain where sown, when they will shoot up in the spring, and produce plenty of seed in autumn.

SCROPHULARIA, Fig-wort.

This genus comprehends perennial, fibrous-rooted, herbaceous, and shrubby plants, some of which are retained in our gardens for ornamental flowering, and variety, in the pleasure-ground and green-house; growing three or four to five or six feet high, garnished with trifoliate, pinnated, and spear-shaped leaves, in different species; and monopetalous, tubular, inflated, red flowers, axillary and terminal.

Class and order, *Didynamia Angiospermia.*

Characters.] **CALYX**, a monophyllous, quinquefid, permanent cup. **COROLLA**, monopetalous, and unequal; the tube round, large, and inflated; the border is five-parted and small, the two superior segments, erect, and larger, the two lateral spreading, and the lower reflexed. **STAMINA**, two longer, and two short, linear, declining filaments, topped with twin antheræ. **PISTILLUM**, an oval germen, with a simple style and stigma. **PERICARPIUM**, a roundish-pointed, two-celled capsule, containing many small seeds.

There are many species: those for our purpose are,

1. *SCROPHULARIA trifoliata.*

Trifoliate African Figwort.] Hath a perennial root, smooth leaves, the lower ones irregularly cut, trifoliate-pinnated, upright stalks, four feet high; garnished with simple, oval, or trilobate leaves, and axillary peduncles, sustaining bright red flowers with greenish bottoms.

2. *SCROPHULARIA sambucifolia.*

Sambucus-leaved Spanish Figwort.] Hath a perennial root, upright stalks, five or six feet high, garnished with interruptedly pinnated leaves, of five or seven cordate, unequal folioles, and axillary and terminal red and greenish flowers.

3. *SCROPHULARIA frutescens.*

Undershrubby Lusitanian Figwort.] Hath ligneous, undershrubby stalks and branches, lanceolate, obtusely-dentated, serrated leaves, and bifid peduncles, with greenish flowers.

4. *SCROPHULARIA lucida.*

Lucid, or Shining-leaved Figwort.

5. *SCROPHULARIA aquatica.*

Aquatic, Striped-leaved Figwort.

The above five are the principal species of *Scrophularia* retained in our gardens, introduced for ornament and variety; are mostly exotics, originally from warm countries, A-

frica, Spain, and Portugal, &c. they, however, being tolerably hardy, to stand our ordinary or moderate winters, are cultivated in the borders of the pleasure-garden; and some also in pots, in order for removing under the protection of a green-house in winter, to defend them from severe frost, by which they are liable to suffer in the full ground.

They are propagated by seeds sown in the spring, and also by parting their roots in the same season, or in autumn; the shrubby sorts likewise by cuttings or slips in the spring or summer months.

SCUTELLARIA, Skull-cap.

A genus of hardy, perennial, herbaceous plants, garnished for the most part with cordate leaves and ringent flowers.

Class and order, *Didynamia Gymnospermia*.

Characters.] CALYX, a very short, tubulated, one-leaved cup, with the mouth entire. COROLLA, monopetalous, and ringent; the tube is very short and bent backward, the throat is long, and compressed, the upper lip concave, and trifid, and the lower broad and emarginated. STAMINA, four filaments, two of which are longer, with small antheræ. PISTILLUM, a four-parted germen, style slender, and crowned with a pointed incurved stigma. PERICARPIUM, none; but the cup becomes a helmet-shaped fruit, containing four roundish seeds.

There are several species of this genus, but not more than three are commonly cultivated for variety and ornament.

1. *SCUTELLARIA altissima*.

Tall Skull-cap.] Hath a perennial root, the stalks rise three or four feet high, with a few slender branches, garnished with oblong, heart-shaped, serrated, pointed leaves. The flowers are purple, and come out at the top of the stalks, in naked spikes.

2. *SCUTELLARIA peregrina*.

Florentine Skull-cap.] Hath a perennial root, the stalk is four-cornered, hairy, rising two feet high, and garnished with heart-shaped, serrated leaves; the flowers come out in a long spike at the top of the stalks, and are either of a purple or white colour.

3. *SCUTELLARIA integrifolia*.

Entire-leaved Skull-cap.] Hath a perennial root, from which rises several four-cornered stalks, two feet high, with side branches; the lower leaves are heart-shaped, sawed on their edges, and the upper ones are oval and entire; the flowers are of a blue colour, and come out from the ends of the branches in long loose spikes.

The propagation of these plants is by seeds, sown either in autumn or spring, in the com-

mon ground where they are to remain, or may afterwards be transplanted into the borders of the pleasure-garden.

SEDUM, Lesser House-leek, Orpine, and Stone-crop.

This genus is composed principally of hardy herbaceous succulents for variety, rising with annual flower-stalks, some erect, a foot or two high, some but a few inches, and some are of trailing growth; adorned with fleshy leaves, and terminated with bunches of pentapetalous flowers.

Class and order, *Decandria Pentagynia*.

Characters.] CALYX is erect, acute, five-parted, and permanent. COROLLA, five spear-shaped, plane, spreading petals, and five nectariums, formed each of one emarginated scale, inserted in the outside of the germen. STAMINA, ten awl-shaped filaments, having roundish antheræ. PISTILLUM, five oblong germens, terminating in slender styles, crowned by obtuse stigmas. PERICARPIUM, five acuminate spreading capsules, opening longitudinally, and are filled with many small seeds.

There are many species of *Sedum*, consisting of herbaceous perennials and annuals, inhabitants mostly of dry sterile places, as hills, rocks, and tops of walls and buildings; and of which several of the perennials are retained in gardens for variety, and some as medical plants, most of which are succulent both in stalks and leaves, some rising with erect stalks half a yard high, others not six inches, and some trail along the ground, as above hinted, and consists both of deciduous and evergreen plants.

The most noted species are,

1. *SEDUM Telephium*.

Common Greater Orpine, or Livelong.]

Hath a perennial root, composed of many knobbed tubercles, sending up erect, round, succulent stalks, branching half a yard or two feet high, garnished with oblong, plane, serrated, succulent leaves, and the stalks terminated by a leafy corymbus of flowers, of different colours in the varieties.

Varieties.] Purple-flowered Orpine—White-flowered—Broad-leaved—Greater Sedum Orpine.

This species is an inhabitant of woods and dry places in England, &c. but has been long a resident of gardens for variety and medical use: considered as a medicinal plant, it has great virtue in easing pains both of green wounds and old sores, the leaves being peeled or bruised, and applied to the part affected; and it is said they will also cure corns.

There is a singularity in this plant, that the stalks being cut in summer, and fastened upright

right in a room, they, by their succulency, will continue shooting a long time, only by sprinkling them with water once a week.

2. *SEDUM Anacampseros*.

(*Anacampseros minor*)—*Lesser Orpine*, or *Ever-green Lesser House-leek*.] Hath a fibrous perennial root, decumbent or trailing stalks, roundish-wedge-shaped entire leaves, and the stalks terminated by a corymbus of purple flowers.

3. *SEDUM rupestre*.

Rock Sedum, or *Stone-crop of St. Vincent's Rock*.] Hath slender, trailing, purple stalks; short, thick, awl-shaped, succulent, glaucous leaves in clusters, quinquenariouly imbricated round the stalks, and the stalks terminated by roundish, cymose bunches of bright-yellow flowers.

It grows naturally on St. Vincent's Rock near Bristol, and other rocky places in Europe.

4. *SEDUM Aizoon*.

Aizoon, or *Siberian Yellow Orpine*.] Hath a tuberculated, fibrous, perennial root; many upright, round, succulent stalks, a foot high; lanceolate, plane, serrated, thickish leaves; and the stalks terminated by a close-fitting, cymose cluster of bright-yellow flowers.

5. *SEDUM reflexum*.

Reflexed, Small Yellow Sedum, or *Wall Orpine*.] Hath a slender, fibrous, perennial root; small, trailing, succulent stalks, garnished with thick, awl-shaped, succulent leaves sparsely, the lower ones recurved, and the stalks terminated by reflexed spikes of bright-yellow flowers.

It grows naturally on old walls and buildings in England, &c.

6. *SEDUM acre*.

Acrid, Minute Sedum, *Common Stone-crop of the Wall*, or *Wall Pepper*.] Hath a small fibry root, very slender succulent shoots, of very low spreading tufty growth, very small, sub-oval, gibbous, erect, alternate leaves, close together; and the stalks terminated by trifid cymose bunches of small yellow flowers.

This sort grows abundantly on rocks, old walls, and tops of low buildings, almost everywhere, which often appear covered with the flowers in summer: it merits culture in pots of rubbishy earth, and in patches in dry borders, stony banks, and in rock-work, or on tops of walls, sheds, &c. where it will increase into large tufts, and exhibit a pretty variety both in its green tufty growth, and when in flower.

Its leaves, &c. are of an acrid biting quality.

7. *SEDUM sexangulare*.

Sexangular Stone-crop.] Hath a fibry per-

ennial root; thick, short, succulent stalks; small, sub-oval, gibbous, erect leaves, close together, arranged six ways imbricatum, and the stalks terminated by bunches of yellow flowers.

It grows on rocky and other dry places in England, &c.

8. *SEDUM album*.

White Stone-crop.] Hath fibry perennial roots; trailing slender stalks, six or eight inches long; oblong, obtuse, sessile, spreading leaves; and the stalks terminated by branchy cymose bunches of white flowers.

This grows on old walls, rocks, and buildings in England, &c.

9. *SEDUM hispanicum*.

Spanish Sedum.] Hath fibrous perennial roots, crowned with clusters of cylindric, acute, succulent leaves; slender succulent stalks, four or five inches high, garnished also with cylindric leaves, and terminated by downy cymose clusters of white flowers.

10. *SEDUM stellatum*.

Starry Italian White Sedum.] Hath succulent leaves, planish-angled, and lateral sessile, white flowers, placed solitary.

11. *SEDUM libanoticum*.

Libanotic Sedum of Palestine.] Grows with bundled radical leaves, which are spatulate-lance-shaped; and with a naked stem, terminated at top by the flowers.

12. *SEDUM populifolium*.

Poplar-leaved Siberian Stone-crop.] Hath a shrubby stalk rising a foot high, garnished with plane, heart-shaped, dentated leaves on petioles, changing with the stalks to a reddish colour, placed alternately, and deciduous; the flowers are of a pale red, and come out at the ends of the branches in a corymbus. This is a native of Siberia and hardy.

Of the above twelve species of *Sedum*, the first eight or ten sorts are the most noted and generally known in our gardens; though all the sorts are occasionally cultivated in general collections to increase the variety: there are also some annual species occasionally cultivated; the most material of which are known by the following names.

13. *SEDUM annuum*. — Annual, Northern White Sedum.

14. *SEDUM dasphyllum*. — Dense-leaved Sedum.

15. *SEDUM rubens*. — Reddish or Blushing Sedum.

16. *SEDUM Cypæa*. — Purslane-leaved, White Sedum.

Of the above collection of *Sedums*, all the perennial kinds particularly have the greatest claim to admittance in our garden compartments

ments for variety and diversity, in their various different modes and sizes of growth, and various foliage, and different orders of flowering; and are eligible to introduce as flowering perennials for ornament in assemblage, in borders, beds, pots, &c. and some also as medicinal plants, such as the orpines, &c.

The first twelve species, being the principal sorts for our garden collections, are all herbaceous succulent perennials, mostly of hardy growth; all durable in root, but mostly annual in stalk, &c. which rising in spring and summer, advance to flowering in June, July, and August, in the different sorts; the flowers, consisting each of five small petals, crown the stalks numerously in corymbose and cymose bunches and spikes, very conspicuously; and are succeeded by plenty of seeds in autumn, by which they may be propagated; also abundantly by parting the roots, and by slips or cuttings of the shoots in spring and summer; in all of which methods they readily grow, and spread into tufted bunches.

They being all of succulent growth, are consequently most inclinable to affect a more prosperous durable growth on dry soils.

For most of these plants, in their native state, are residents of dry barren situations, sides and bottoms of mountains, rocks, &c. in different parts of Europe and Asia; and some grow spontaneously and abundant upon old walls, and the roofs of low old buildings in England, &c. particularly the common Stone-crops; so that all the sorts of these plants, in their culture in gardens, should generally have a dry light soil; in which they are always the most durable, both in the full ground, in borders, sides of banks, and in pots; and will also grow durably in any dry rubbishy earth; and some sorts also upon walls, and rock-work, and other similar situations.

Considered as garden plants, they merit estimation principally for variety and ornamental flowering, in which they will have an agreeable effect, in their different dimensions and orders of growth, some upright a foot or two high in their flower-stems, some procumbent, and trailing, and others curiously diminutive, spreading in a tufted growth; and with larger, smaller, and minute foliage in the different species; and their flowers, although separately small, some very minute, being produced numerously in their different modes of inflorescence, before observed, they appear conspicuous and very pretty in the summer from May or June till August or September, in the different species, purple, white, yellow, &c.

Most of the perennial sorts may be obtained at the nurseries in full plants, for planting as

required, in borders, pots, &c. either in the spring, for flowering the same year, or in autumn to flower the year following.

They may be planted in any of the spring and early summer months, March, April, May, and in autumn, August, September, October.

They may be planted in any dryish, light soil, in borders, beds, and other compartments, and in the sides of dry banks, or in any elevated rubbishy soil; and some in pots to move to different parts occasionally, or also some of the evergreen kinds, to introduce in their said pots among winter plants under shelter in that season, to increase the variety: and in all of which they may be planted either in full plants, or tolerably full off-set slips of the root and head together, in spring or autumn aforesaid, or most of them by cuttings of the young shoots in spring or summer, they will all readily grow, and increase plentifully according to their respective growths.

They, in most sorts, may also be introduced as rock plants, to embellish artificial rock-work, ruins, and other similar places in pleasure-grounds; planting either the rooted plants, slips thereof, or cuttings of the shoots, in any stiff, moist soil, a little to each plant or set, at first, and thus placed in the crevices, &c. in different parts; the plants will soon root therein, fix themselves, and advance in a spreading growth very agreeably; and the Stone-crops and other low trailing kinds may also be made to occupy the tops of any low walls, pent-house, shed, or other low building, planting them as above, in a little moist soil, or clumps of stiff mud, previously placed on the wall, &c. they will most readily root, establish themselves, and branch out thickly-spreading in their peculiar close, low, tufty growth, without further trouble.

Likewise the Stone-crops, *Sedum acre*, and *Sedum sexangulare*, being diminute tufty plants, may be disposed in patches towards the fronts of borders, &c. they will spread thick and tufty close to the ground, and flower abundantly; and these sorts being planted in pots, as is much practised about London, are proper to place in the outside of windows, copings of low walls, and in balconies, and court yards, in assemblage with other low fancy plants; they will closely overspread the surface, and flower profusely as far as they extend.

Method of Propagation for all the Sorts.

All the sorts are easily propagated by slipping the roots, at almost any time of the year; likewise by slips or cuttings of their shoots in spring and summer, particularly the stalky and running kinds; but slips and cuttings of all the
sorts

sorts will very readily grow; and as to the Stone-crop kinds, shoots of them may be easily slipped in spring and summer with roots to their bottom; the same may also be often practised to most of the other species: observing, in all the methods of propagation, the slips and cuttings may either be planted in the nursery way till well rooted, or planted at once where they are to remain, in the places and manner before mentioned.

They may also be propagated by seeds sown in any dry soil, or in the crevices of buildings, &c.

The annual sorts are also propagated by seeds in the spring, March or April, in beds or borders of dry light earth.

SELAGO. (*Selago*.)

For the green-house, this genus furnishes three species of ligneous, under-shrubby and shrubby, African exotics; rising with slender stems and branches, three or four to six or seven feet high; garnished with slender, thread-form, and narrow linear leaves in radiated bunches, and verticillate circles; and quinquefid spreading flowers, in terminal corymbose clusters and spikes: having quadrifid permanent calyxes, monopetalous corolla, five-parted above, and spreading; two long and two shorter stamina; a roundish germen, and single stigma, succeeded by a single seed involved in the corolla.

Class and order, *Didynamia Angiospermia*.

The species are,

1. SELAGO *corymbosa*.

Corymbous-flowering Selago.] Rises with ligneous under-shrubby stalks, and spreading branches; filiform or thread-shaped leaves in radiated bunches from the same point; and multipart corymbose clusters of pure-white flowers.

2. SELAGO *pinastra*.

Pinastr-leaved Selago.] Rises with shrubby stalks, and alternate erect branches, garnished with long linear leaves in whorls, and hairy corymbose spikes of flowers.

3. SELAGO *spuria*.

Spurious Selago.] Rises with shrubby stalks, garnished with linear denticulated leaves; and corymbose spikes of flowers.

These three species of *Selago* are the principal sorts known in our gardens, but more generally the first and second: though all the sorts effect a curious variety in assemblage among the other green-house exotics, in which they must be admitted, and have the same general culture summer and winter.

They are propagated by layers of the young wood in spring or summer; also by cuttings of the young shoots in the same seasons, in a hot-bed, or covered down close with a hand-glass.

SEMEN, the Seed, being the essence of the fruit of every vegetable, containing the future plant in miniature, and consists of the following essential parts.

Corculum, or Punctum Vitæ. The little heart, the point of life, or embryo of the future vegetable, being the small point or speck, placed in the centre of the Seed, between the cotyledons or lobes, and attached thereto, and is distinctly visible in the bean and most other leguminous seeds: consists of two parts, the *rostellum* and *plumula*, the former being the radical or descending part that strikes downwards, and becomes the root; the other is the ascending part, that shoots upward, and become the stem and branches, &c.

Cotyledon or Side Lobes. Being the side perishable lobes of the seed, which involve, and for some time nourish the *corculum* or embryo plant: these lobes are generally two in number, very conspicuous in the bean and other seeds of the leguminous tribe, particularly if they have been previously laid in earth or water.

After the seeds have been committed to the earth, the *corculum* or *punctum vitæ* begins to germinate, and the cotyledons expand, burst open the outer cover, and rise gradually out of the earth in form of leaves, commonly called the Seed-leaves, exhibiting the first visible formation of the infant plant, accompanying it for some time after its eruption from the earth, till the first proper leaves are formed in the centre of the vegetable, and advanced a little in growth; then the lobes or seminal leaves becoming useless, wither and decay.

Most plants have two cotyledons or Seed-leaves (*Dicotyledones*), particularly almost all the tribe of fibrous-rooted herbaceous plants, and all trees and shrubs; but some have only one cotyledon (*Monocotyledones*), as in most of the bulbous plants of the liliaceous tribe, rising out of the ground like a sheath; and some seeds have no cotyledon at all (*Acotyledones*), such as the ferns, mosses, flags, and funguses.

Other parts of the Seed are,

Ala or Wing. Many Seeds are winged, or furnished with a thin membrane or film, and, by its flying, helps to disperse them, as in fir, birch, maple, ash, elm, hops, and numerous other sorts.

Coronilla or Little Crown. Many Seeds are crowned, and some surrounded with a pappus, i. e. a feathery or hairy down, particularly many of the compound tribe and others, for the purpose of dissemination; being framed for flying like a shuttlecock, so as to be easily transported by the wind to very considerable distances.

distances from the parent plant ; hawk-weed, groundsel, and dandelion, furnish examples.

But numerous sorts of Seeds are simple, i. e. have neither wing nor pappus.

The number, form, size, and substance of Seeds are extremely various in different plants.

In point of number, it consists of from one to several hundred, or even thousands, in each seed vessel ; for some plants have only one, some two, three, four, or many Seeds, and some are of amazing fertility, amounting to many hundreds ; as for instance, a single Seed-vessel of tobacco often contains about one thousand Seeds ; that of white poppy, eight thousand : and the whole produce of one tobacco plant is upwards of forty thousand, though some have computed the number above three hundred thousand ; and the produce of a single stalk of spleen-wort is estimated at upwards of a million of Seeds.

As to form, Seeds are either round, oval, kidney-shaped, heart-shaped, angular, &c.

With respect to size, Seeds are of numerous sizes in different plants, from the large size of cocoa nuts down to the minute seeds of cresses, mosses, and others much smaller.

And as to substance, some Seeds are soft or fleshy, some membranous, and some are of a hard bony nature, as in all the nuciferous tribe, and the stones of many sorts of berries, and other stone fruit.

Seeds are covered or naked. Covered Seeds (*Angiospermia*) are such as are contained in some vessel, either of the capsule, pod, berry, apple, or cherry kind : and naked Seeds (*Gymnospermia*) are those that are not contained in any vessel, but lodged in the receptacle, or in the bottom of the calyx.

The vast variety of ways nature has provided for the dissemination of seeds is truly wonderful ; in most plants, the fruit or vessels containing the seed are raised above the ground either by erect firm stems, or often by climbing stalks, so that the fruit being elevated from the ground, it may be more easily shaken by the wind, which often blows Seeds to a great distance ; for the same reason that species of seed-vessel called a capsule opens at the top, that the Seeds may be more easily disseminated. Many Seeds being winged, as before observed, are by that means spread far and near by the winds ; these wings consisting either of a thin membrane or film, as in the fir, birch, maple, elm, ash, hops, &c. as formerly hinted ; or of a fine feather-like or hairy down, beard, or tail, as in most of the compound plants, also in the scabious, valerian, and many others, whereby they are easily waisted to a great distance to different

soils and territories. Some seed-vessels are endued with a remarkable elasticity, by which means they dart their Seed, with an elastic force, to some considerable distance, such as touch-me-not, and spiriting cucumber, &c. Many Seeds and seed-vessels being armed with hooks, hairs, &c. by which they attach themselves to animals, and are thereby dispersed, such as in carrot, hemp agrimony, burdock, &c. Likewise Seeds of many sorts being devoured by birds, they void them entire, often in different parts at a distance, and they grow. Berries, and other pulpy fruit, being eaten as food, the Seeds or kernels of many sorts often pass through unhurt, and falling to the ground often grow. Seeds are also often disseminated by rivers, torrents and all running waters and tides, hence often conveyed many hundred leagues from their native soil, and cast upon a very different climate, to which, however, they sometimes, by degrees, render themselves familiar.

The duration of Seeds, in respect to the retention of their germinative property, is very considerable ; for instance, the cucumber, melon, and gourd, often retain their vegetative power eight, ten, or twelve years ; and it is said, the *mimosa* or sensitive plant will retain the principle of life thirty or forty years ; on the other hand, the greater number of seeds will not keep good above one or two years, and many, or the greater part will not grow well if more than one year old ; and some Seeds require to be sown soon after they are ripe, or they will not grow till the second year ; others, unless sown soon after they are gathered, will not grow at all, as is often the case with the coffee-berries. It is however observable, of almost all sorts of Seeds, that being sown the first year, they generally rise sooner and stronger than older Seeds ; for which reason it is advisable to chuse principally new Seeds, not more than one year old, if possible, of all sorts of plants and trees, only a few excepted, such as cucumbers and melons in particular, of which, Seeds of two or three years old, or more, are often preferable, because plants raised from new Seed are apt to run vigorously to stem without either becoming tolerably soon fruitful, or producing much fruit.

All Seeds produced in dry capsules, pods, and other dry Seed-vessels, keep much longer in their said vessels than if taken out ; though it is probable that most Seeds will retain their germinative faculty longest in the bowels of the earth, when they have been accidentally buried a considerable depth out of the reach of the influence of the sun and

and air. And it has been observed of corn-fallad in particular, which by accident have been buried three feet deep in the ground thirty years, and the soil being turned up that depth to the top, they have grown freely; the same has also been observed of many other Seeds, which by chance have been immersed in the ground several feet deep; and in the bottom of wells, vaults, ponds, and ditches, that have not been stirred for many years, as may be judged from circumstances; for when occasion required the soil to be thrown to the top, and exposed to the sun and air, many plants have risen that had not been remembered to have been seen thereabouts before, or at least for many years past.

Likewise most sorts of Seeds, if sown too deep, remain inactive, and some never grow at all; others, nevertheless, preserve their growing property; and when the ground is again fresh stirred, such of the Seeds as happen to be moved nearer the surface will often come up; which shows the power of the sun and free air in promoting vegetation in Seeds and plants.

Seeds, therefore, should never be sown too deep, and always in proportion to their size; from about a quarter, or half an inch deep, for the smaller Seeds, to about one or two inches for the middling and large kinds of Seeds. See SOWING OF SEEDS.

The germination or growth of Seeds, after being regularly sown or committed to the earth a proper depth, is in some sorts very quick, and others slow; as for instance, cresses, mustard, turnep, and many others, come up in a few days; some other sorts in one, two, or three weeks, as in most of the esculents of the kitchen-garden, and numerous others of the herbaceous tribe; though parsley, and some others, often remain inactive a month or six weeks, and some sorts lie a year or two in the ground before they germinate. As to the tree and shrub Seeds, some will rise in a month or six weeks, or less time, others require two or three months to vegetate, and some sorts lie a whole year at least before they begin to grow, such as the hawthorn, holly, and most others of the very hard bony-seeded kinds; all of which, both in the herbaceous and woody tribe, is generally hinted in the culture of the respective sorts under their proper genera. See also GERMINATION.

For particulars in regard to the various methods of sowing of Seeds, see SOWING OF SEEDS.

SEMPERVIVUM, (Ever-living) Live-ever, or Common House-leek, &c.

The plants are of the succulent tribe, herbaceous and shrubby, consisting of low, hardy, herbaceous, evergreen perennials, for variety in the pleasure ground, &c. and medical uses, and shrubby ever-green succulents for the green-house collection, adorned with roundish and oblong, thick, fleshy, succulent leaves all the year, and the stalks terminated by bunches of polypetalous flowers.

Class and order, *Dodecandria Dodecagynia*.

Characters.] CALYX is concave, cut into many acute segments, and permanent. COROLLA, from six to ten or twelve oblong, spear-shaped, acute, concave petals. STAMINA, twelve awl-shaped filaments, with roundish antheræ. PISTILLUM, twelve germina, placed circularly, terminating in the like number of spreading styles, crowned with acute stigmas. PERICARPIUM, about twelve oblong, compressed, circularly-placed capsules, pointed outward and opening on the inside, filled with many small roundish seeds.

There are about six species retained in our gardens for variety and ornament; four of which are hardy herbaceous plants, and two are shrubby succulent exotics for the green-house.

Hardy Herbaceous kinds.

They are low herbaceous ever-greens, with succulent leafy heads close to the crown of the root, sending up flower-stalks annually, in some a foot high, others not half so much; one sort (*Common House-leek*) grows naturally in England, &c. on buildings, or barren hills, the others in mountainous parts on the continent of Europe, but are all hardy enough to grow here, any where either in the full ground or in pots, or on tops of walls, buildings, or rock-work, &c.

I. *SEMPERVIVUM tetlorum*.

Common House-leek.] Hath a fibrous perennial root, crowned with many ovalish, pointed, ciliated, succulent leaves, in roundish heads, close to the earth, having many spreading off-sets; and upright, round, succulent, reddish stalks a foot high, terminated by reflexed spikes of spreading red flowers, in July and August.

This is the Common House-leek, which grows naturally on barren hills, and tops of old buildings, walls, &c. in England, and most countries in Europe; and we may see it growing in tufts on the tops of sheds, and other low buildings, almost every where, with hardly any soil in which to root; for the off-sets being planted at first

in a little lump of any soil, and placed on the tiles or thatch of any building, or on the coping of a wall, they will readily strike, and multiply into large bunches without any culture.

This species, being of a very cooling quality, is used against the St. Anthony's fire, shingles, burns, scalds, and inflammations, &c.

2. *SEMPERVIVUM globiferum.*

Globiferous Siberian House-leek.] Hath a fibrous root, crowned with numerous oblong-oval, succulent, ciliated leaves in compact globular heads, producing many globular off-sets; and erect, round, succulent stalks, six or eight inches high, terminated by yellowish flowers.

Variety.] With red flowers.

This species produce numerous small globular off-sets, which being thrust off by the larger heads, and falling on the ground, &c. take root freely of themselves, and become proper plants.

3. *SEMPERVIVUM arachnoideum.*

Cob-web, Smaller House-leek, commonly called Cob-web Sedum.] Hath fibrous roots, crowned with short, narrow, succulent leaves in small heads, having many hair-like threads, intersecting one another, from leaf to leaf, resembling a spider's web; and erect, round, succulent stalks, six inches high, terminated by spikes of bright red flowers ranged mostly along one side.

4. *SEMPERVIVUM montanum.*

Mountain Helvetican House-leek.] Hath fibrous roots, crowned with oblongish, pointed, ciliated, succulent, smooth leaves, in expanded open heads, producing very spreading off-sets; and erect succulent stalks, eight or ten inches high, terminated by spikes of deep-red flowers.

All these herbaceous *Sempervivums* are very hardy evergreen perennials, formed of roundish clusters of succulent leaves close to the ground, &c. remaining green all the year, and from the centre of the heads of leaves arise the flower-stalks annually, flowering mostly in July and August, succeeded by ripe seeds in Autumn.

They are all hardy enough to grow any where in dry light ground, rubbishy banks, or in pots, and the tops of buildings, rock-work, &c. as before intimated.

The smallest off-set, being planted in a small portion of any soil, will grow and increase exceedingly.

Tender shrubby kinds.

These consist of two shrubby succulent exotics, with strong erect stems, terminated by heads of numerous succulent leaves, and

large spikes of flowers; and being natives of hot countries, require shelter of a green-house here in winter.

5. *SEMPERVIVUM arboreum.*

Tree House-leek, or Tree Sedum.] Rises with an upright, thick, fleshy, tree-like, smooth, branching stem, six or eight feet high, with the branches terminated by large clustering heads of spear-shaped, bright-green leaves; and, from the centre of the heads, large pyramidal spikes of bright-yellow flowers, in autumn and winter.

Varieties.] Variegated-leaved Tree House-leek, which is a very curious variety of a fine ornamental appearance — White-flowered. Both the varieties flower very ornamentally, and the flowers continue long in beauty.

It is a native of Portugal, Crete, and the Cape of Good Hope.

6. *SEMPERVIVUM canariense.*

Canary Shrubby House-leek.] Rises with an upright, succulent, rough stalk, half a yard or more high, appearing rugged with the rudiments of past foliage, having the top crowned by large globular heads of retuse succulent leaves; and from the centre of the head a long pyramidal spike of greenish flowers, in June and July.

All the above six species of *Sempervivum* retain their leaves the year round, which, in all the sorts, are thick, fleshy, and succulent, and generally collected many together into round heads; and from the centre of the head arises the peduncle or flower-stalk, terminated by the flowers in summer and autumn, each flower composed of from about eight or ten to twelve petals, spreading out every way in a star-like manner, exhibiting a good ornamental appearance, and are succeeded by ripe seeds in autumn.

All the sorts being of a very succulent nature, are the most prosperous and durable in the driest light soils; and the hardy sorts, in particular, will also grow on walls, tops of low buildings, and rock work; being planted in a little clump of stiff mud or earth placed on walls, &c. they will readily grow; but the two shrubby kinds being tender, must be always kept in pots, to place in a green-house in winter: it is also proper to pot some of the smaller curious sorts of House-leeks occasionally, both as being of diminutive growth, not conspicuous when planted in the borders, &c. and to preserve them in a green-house or frame in winter, to continue them of a more lively state in that season, than those fully exposed.

However, the first four species are mostly hardy plants, all of herbaceous perennial growth, and will succeed almost any where in

in the full air all the year, in any dry raised borders, banks, or pots; or most of them upon walls and the roofs of any low building, shed, or hovel, &c. all of which, in their general growth, spread close to the earth, increasing in many collected heads of succulent fleshy leaves larger and of the most spreading growth in the first sort, Common House-leek; smaller in the second species, but curious in its globular propagina or off-set heads, emitted abundantly on every side; but the third is a diminutive plant, of curious singularity in its arachnoideous resemblance, formed by the interwoven hairs of the leaves; and being of minimous growth, some plants are generally kept in small pots as a peculiar curiosity; and the fourth sort, a plant of larger dimensions, although less known than most of the others, is equally deserving of admittance in the collection, as it forms a good variety in its expanded heads, spreading off-sets, and spikes of red flowers; the whole propagating freely by the abundant off-set heads, which being detached and planted, will most readily grow of several years continuance, remaining always green, and most of them will flower annually.

Of the above species, the common House-leeks are noted almost every where, for their remarkable singularity, in growing on the roofs of low cottages, barns, sheds, pent-houses, &c. and tops of walls, with scarcely any soil to grow in, but supported apparently by their own natural succulency: being retained both in situations as above, as occasional medical plants, and in gardens, for variety. But all the sorts are eligible to introduce for variety, and as flowering plants: some larger kinds disposed towards the front of dry raised borders, and others, of the different sorts, in pots, &c. but as being succulent replete with humidity, they should generally have a dry light soil in any raised borders, sloping banks, &c. and in pots of light, dry, sandy, or rubbishy earth, as they will succeed in any kind of dry rubbishy soil; and any of the larger sorts may also be placed upon walls or low buildings, in small clumps of any stiff soil for them to strike into at first, or also upon any kind of rock-work, &c. in all of which situations, they will succeed in a free growth; for as they increase exceedingly by their off-set heads, and these being detached or slipped at almost any time in spring, summer, or autumn, and planted as above, they will soon strike root, grow and multiply into clustered heads, as may be observed of the common House-leeks, continue for years, and flower in summer very agreeably.

However, it is also proper to plant some of

the different sorts in pots, for moving to any compartments occasionally; or more particularly the *globiferum* and *arachnoideum*; the former for the curiosity of its numerous surrounding progeny of globular off-sets, hence is frequently called Hen-and-chicken House-leek; and the latter, Cob-web Sedum, or smaller House-leek, as being curious in its diminutive growth, and interwoven hairs, as before observed; planting each sort separate, in middling, smallish, or small pots, according to the size of the different species; filling the pots with dry light compost, and set one plant in each pot, giving a little water just to settle the earth about the root; and being thus potted, they are ready to remove to any place required for variety; and the smaller sorts under shelter of a garden frame, or green-house in winter, both to preserve them more effectually in a lively state, and to effect a variety in that season among other sheltered small evergreen plants.

The two tender shrubby sorts, requiring constant shelter in winter, must be kept in pots of light sandy earth, or any dry rubbishy soil, and placed among the green-house plants, where they will exhibit a conspicuous variety at all times of the year; but more eminently the *Sempervivum arborcum* and variety, managing them as other succulents of the green-house collection, being particularly careful to water them but sparingly in the winter, as too much moisture is destructive of tender succulents in that season. See GREEN-HOUSE PLANTS.

Method of Propagation, &c.

All the four herbaceous *Sempervivums* are very expeditiously propagated by their off-set heads, which may be readily slipped off with roots, or even if without immediate root fibres, they will succeed; planting them in any light dry soil, or rubbish, as before observed; and if on buildings or rock-work, &c. lay a little mud or stiff soil thereon in patches, in which plant the slips, and they will grow and flourish without farther trouble.

The two green-house kinds are propagated by cuttings of the branches and by seed.

By Cuttings.—The first of these two sorts in particular is easily propagated by cuttings of the smaller branches, any time from April or May till July, either with or without the aid of hot-beds, though, if planted early, they may be greatly forwarded by the assistance of artificial heat; however, in any of the summer months they will readily take root in a bed, or pots of natural earth, in the open air; observing in taking off the cuttings, if they appear very succulent in the cut part, it is eligible to lay them in the dry a few days to skin over, previous to planting; then

either plant them in pots of dry light soil, or in a bed of common light earth till rooted; in either method allow them occasional shade from the sun, and sometimes moderately watered in very dry weather, especially those in pots; they will thus be well rooted in two or three months, and may then be potted separately in the middling pots, and placed among the other green-house exotics.

By Seed.—The Canary House-leek, in particular, producing seed in tolerable plenty in our gardens, may also be propagated by sowing the seed in autumn, or early in spring, in pots of light earth, placing them in a frame to have shelter from frost, but exposed in mild weather; and as the warm season advances the plants will begin to appear, which, when an inch or two high, prick them in separate small pots, and manage them afterwards as other succulents of the green-house.

SENECIO, Groundsel.

This genus comprehends several herbaceous perennials, and annual plants, garnished for the most part with pinnate leaves, and compound radiated flowers.

Class and order, *Syngenesia Polygamia Superflua*.

Characters.] CALYX, a common cup, conic and truncated. COROLLA, the compound flower is higher than the cup, the hermaphrodite florets are tubulous and numerous in the disk, the female ones, in the radius, are oblong, and slightly tridentated. STAMINA, five very small capillary filaments, topped with cylindric and tubulous antheræ. PISTILLUM, an ovate germen, slender style, crowned with two oblong, revolute stigmata; there is no pericarpium; the seed which is single, oval, and crowned with a long down, is contained in the cup.

Of this genus there are reckoned between thirty and forty species, several of which are common weeds; the following are therefore only cultivated in gardens.

1. SENECIO *hastatus*.

Hastated, or Spleenwort-leaved Groundsel.] Hath a perennial herbaceous stalk, rising between two and three feet high, garnished with sinuated winged leaves. The flowers are yellow and radiated, standing on very long foot-stalks, which divide at the upper part of the stalk.

2. SENECIO *purpureus*.

Purple Groundsel.] Hath a perennial stalk, rising two feet high, garnished with hairy lyrate lower leaves, and upper ones spear-shaped and dentated, the flowers come out at the ends of the stalks, are steculous, and of a purple colour.

3. SENECIO *elegans*.

Elegant Purple Groundsel.] Hath a fibrous

root, with erect stalks, a foot or eighteen inches high; garnished with equal spreading pinnatifid leaves; the flowers come out from the ends of the stalks, are radiated, the florets of the disk are of a bright yellow, and those of the radius, a rich purple colour.

Varieties.] With white flowers—with double purple flowers.

Their propagation is easily effected by cuttings of the branches planted in pots in the summer, and shaded till they have taken root, and when winter approaches, should be removed to the green-house till May, when they may be transplanted into the borders of the pleasure-garden, where they will be very ornamental during the summer: they may also be raised from seeds sown in the spring.

4. SENECIO *Pseudo-China*.

False or Bastard China-Root from Madagascar.] Hath a thick root formed of fleshy tubers, crowned with large, rough, cut leaves; and slender flower-stalks, half a yard high, terminated by compound yellow flowers, of many tubulous florets.

This is an herbaceous perennial of Africa, retained here in curious stove collections for variety, and is propagated by off-sets planted in pots plunged in the bark-bed; continuing the plants always in the hot-house or stove.

SERRATULA, Saw-wort.

It consists principally of tall, hardy, herbaceous, flowery perennials, for ornamenting the pleasure-garden; rising with annual stalks from two to seven or eight feet high, adorned with pinnatifid and entire leaves in the different species, and the stalks terminated by scaly heads of compound flowers.

Class and order, *Syngenesia Polygamia Æqualis*.

Characters.] CALYX, an oblong, imbricated, general cup, composed of many spear-shaped, acute, smooth scales.—COROLLA, a uniform compound flower, composed of many hermaphrodite funnel-shaped florets, with an inflexed tube and ventricose limb, cut into five parts. STAMINA, five short hair-like filaments, with cylindric antheræ. PISTILLUM, an oval germen, filiform style, and two oblong reflexed stigmas. PERICARPIUM, none; each floret succeeded by one oval seed crowned with down.

The principal species, in the English gardens, are the following, the first of which is a native of England, the others of different parts of America, but are all of hardy growth, consisting both of fibrous and tuberous-rooted perennials.

1. SERRATULA *tinctoria*.

Dying, or Common Saw-wort.] Hath a fibrous perennial root, upright annual stems,

two feet high, lyre-shaped pinnatifid leaves, having the terminal lobe the largest, and the stalks terminated by scaly heads of purple and white flowers in the different varieties.

This grows naturally in woods and meadows in England, &c. and is sometimes cultivated for variety.

2. *SERRATULA noveboracensis.*

New-York Saw-wort.] Hath a fibrated perennial root, upright channeled stalks, seven or eight feet high, oblong-lanceolate, ferrated, pendulous leaves, downy underneath, and the stalks terminated by heads of purple flowers.

3. *SERRATULA glauca.*

Glaucous Maryland Saw-wort.] Hath a fibrous perennial root, upright, channeled, purple stalks, six or seven feet high, oblong-oval, acuminate, sawed, glaucous, coloured leaves, and the stalks terminated by corymbus bunches of purple flowers, having roundish cups.

4. *SERRATULA scariosa.*

Scariose-flowered Virginia Saw-wort, or Tuberous Knap-weed.] Hath a tuberous perennial root; upright, strong channeled stalks, three or four feet high; spear-shaped entire leaves; and the stalks adorned upward with many purple flowers, rising laterally on obtuse peduncles, having also rough scaly calyxes.

5. *SERRATULA squarrosa.*

Squarrose Virginia Saw-wort, or Tuberous Melancholy Thistle.] Hath a tuberous perennial root, an upright stalk, near a yard high, linear, or very narrow stiff leaves, and the stalks adorned upward with purple flowers, rising laterally and sitting almost close in squarrose, or rough, scaly, acuminate cups.

6. *SERRATULA spicata.*

Spiked Virginia Saw-wort.] Hath a tuberous perennial root, upright single stalks, two or three feet high; linear leaves, ciliated at the base; and the stalks terminated by long spikes of close-sitting purple flowers, rising laterally.

7. *SERRATULA præalta.*

Tall Peached-leaved Virginia Saw-wort.] Hath a fibrous root, upright branching stalks, four or five feet high, oblong-spear-shaped, ferrated, spreading leaves, hairy underneath, and the branches terminated by loose bunches of purple flowers.

All these species of *Serratula* are perennial in root but annual in stalk, which, rising in spring, flower in June, July, and August, in the different sorts; the flowers are all compound, consisting of many tubular florets in large scaly calyxes, and in most of the sorts

are conspicuous and ornamental; but those of the American kinds are not always succeeded by good seeds in our gardens; they, however, multiply fast enough by the root.

These plants being mostly of erect tall growth, are proper ornaments for the compartments of large gardens, and to intersperse in shrubberies, and along the verges of woodwalks, &c.

Method of Propagation.

They are propagated by parting the roots, and by seeds.

By Parting the Roots.—All the sorts send out off-sets from the root, but the fibrous-rooted kinds the most abundantly, and the roots may be slipped or divided, either in autumn, when the stalks decay, or in spring before new ones begin to shoot up, though if done early in autumn they will flower much stronger in the following year.

By Seed.—All the sorts may also be raised from seeds, but the tuberous sorts, in particular, not increasing very plentifully by roots, they must be often raised from seeds, sown in autumn or early in spring, in an east border, in shallow drills; and when the seedlings are two or three inches high, prick out some of the longest in nursery-rows till autumn, then transplant the whole finally to remain.

SEXUS Plantarum, Sexes of Plants.

The different Sexes of plants, with regard to their being male, female, or hermaphrodite, is determinable by their flowers and fruit only.

All plants, from the largest tree down to the smallest mosses and fungi, and other the most minute vegetables, are furnished with flowers either visible or invisible, or concealed; but in the greater number visible and conspicuous: and in either case the flowers are the generative organs of all vegetables, being furnished with male, female, and hermaphrodite fructifications, sometimes on different plants of the same genus, and sometimes both male and female on different parts of the same plant; but the greater part of the vegetable kingdom is of the hermaphrodite kind, having both male and female organs (*stamina* and *pistillum*) all within the same flower: all which genital parts, or fructifications in the above different sexes, being essentially necessary for the purpose of generation, as serving the important office of fecundation to impregnate the embryo fruit, and fertilise the seed. See GENUS, and FLOS; also FEMINEUS FLOS, MASCULUS FLOS, HERMAPHRODITUS FLOS, &c.

Every flower, however large or minute, is furnished with generative parts, *i. e.* *stamina*

and *pistillum*, either in the same or in different plants and flowers, &c.

For example :

Male plants are such as produce male-flowers only, which male-flowers are those that are furnished only with the *stamina*, consisting of the filaments and antheræ, being the male genitals, but want the *pistillum*, or female organs.

Female plants being productive of female flowers only, such as are furnished with the *pistillum*, consisting of the germen, style, and stigma, the female fructifications, but want the *stamina*, or males.

And hermaphrodite plants are those which produce only hermaphrodite flowers, being such as contain both *stamina* and *pistillum*, the male and female organs, all within the same calyx and corolla, as prevail in the greater number of the vegetable creation.

Likewise observe,

Monœcious or androgynous plants are such as produce both male and female flowers distinct, situated on different parts of the same vegetable, as in the cucumber, melon, and many others. See the Class MONŒCIA.

Dicœcious plants, such as produce male and female flowers distinct, in separate habitations : one plant producing the males and another the female flowers. See the Class DICŒCIA.

Polygamous plants, such that bear the several sexes of flowers, as hermaphrodite and male and female flowers together. See the Class POLYGAMIA.

The existence of the Sexes of plants was greatly disputed by many of the ancient botanists and others ; but whoever is still doubtful in that point, will but examine the curious structure of flowers, and make some experiments, will soon be convinced, that the flowers of all plants are furnished with proper generative organs ; and that the male parts, the filaments, and antheræ, being furnished with a certain subtle powder, impregnate therewith the *pistillum* of the females, and fertilise the embryo fruit and seed in the germen, or ovary ; so that when the flower fades, the fruit swells, and the seeds become fertile, as may be experienced in early cucumbers in frames by carrying the antheræ of the male blossom and touch the stigma of the female flower therewith, so as to leave some of its golden powder on the stigma, or female organ, which infallibly impregnates the germen, or miniature fruit, and it will soon visibly swell and increase fast in magnitude, furnished also with fertile seed, which, without being previously fecundated by the male dust, generally prove sterile,

or barren, and if sown they would not germinate.

So that if we were to remove all the male flowers of cucumbers, or melons, before they blow, we render the females or fruit blossoms abortive.

Likewise, if flowers of any sort were castrated, or deprived of the male organs, the filaments and antheræ, before they ripen their impregnating powder of the antheræ, the female parts would become sterile, or, at least, the fruit would either not swell at all, or but very imperfectly, and the seeds would remain unfertilised, and if sown they would not grow.

For although some sorts of plants may probably by chance produce a sort of imperfect fruit and seeds, without the immediate vicinity of male flowers, the same as a hen may lay eggs without the congress of a cock, yet for want of being fertilised with the male sperm, neither will the seeds grow, nor the eggs bring forth chickens.

Linnaeus, in his definitions of the Sexes of plants, says, the calyx is the marriage-bed in which the male and female organs consummate the nuptials of plants, and in which these tender organs are cherished and defended from external injuries ; and the corolla, or petals, are the curtains closely surrounding the generative organs, in order to resist storm, rain, or cold ; but when the sun shines bright they expand freely, both to give access to the fecundating dust and to the sun's rays, to promote the fecundating faculty of the said powder, in acting with due effect on the stigma and style : for the filaments are the spermatic vessels of the males, by which the juice secreted from the plant is carried up to the antheræ in form of a fine powder, which is the pollen, or male dust, answering to the male sperm of animals, or the roe of fishes ; for although it is dry, it is more easily conveyed by the winds, or air, to the stigma, or female organ, where it is moistened, thence proceeds to the style, which is the vagina, or tube through which the effluvia, or male dust, passes to the germen, or ovary, and there impregnates the fruit or seed which immediately becomes fertile, and then the petals of the flower withers, and the fruit and seed grow fast to perfection.

Thus we need not wonder, that in the vegetable kingdom such numbers of plants are of the hermaphrodite race, *i. e.* the flowers having both male and female organs within the same calyx and corolla ; though in the animal kingdom there are very few of the hermaphrodite kind, for here one sex can easily go to another, whereas plants are fixed to one spot

spot and cannot go from it, so that the male and female parts of fructification being within the same cover, the fecundation is more easily effected by nature.

Other plants again having the male and female parts in different flowers, have their situation on the plants and their fructifications so wonderfully disposed by nature that the fecundation is effected by the winds and certain insects conveying the male dust from the antheræ to the female organs.

Most plants appear the most beautiful when in flower; but when the generative parts of the flower have performed their natural function, the flower soon after fades, and many plants gradually lose much of their former splendor, and numerous sorts, after flowering and ripening seeds, either decay wholly, as in all the annual and most of the biennial tribe, and some only die down to the root, as in numerous herbaceous perennials; likewise some plants and trees, after obtaining a great age and bulk, totally decay, after having once flowered; such as often occurs in the *agave*, or great American aloe, which in this country in particular, after fifty or an hundred years' growth before they attain a flowering state, they then expanding in the centre and shoot up rapidly, into a stalk of prodigious height, for flowering, which continuing in bloom two or three months, and the plants generally decay soon after, never surviving to flower again: the same also happens in the *musa paradisiaca*, or plantain-tree, which having been in some European gardens many years, and after having once flowered, no art can prevent its lofty stem from perishing the year after; and the like also often occurs in the *lavatera arborea*, or tree-mallow.

SHADING PLANTS, of young or tender growth, seed-beds, &c. from the sun occasionally.

This is often a necessary work in many particular occasions, in warm, dry, sunny weather in spring and summer, &c. in pricking out various sorts of small young plants from seed-beds into nursery-beds, pots, &c. all small cuttings, slips, above-ground off-sets, pipings, &c. as likewise in occasionally transplanting any kind of more advanced plants, flowers, &c. into beds, or pots, in a hot, dry season; and sometimes to seed-beds of particular sorts of small or curious seeds in hot sunny days; also often to plants in hot-beds, under frames and glasses, both of young and advanced growth.

The work of Shading is the most commodiously and effectually performed with garden mats in a sort of awning over the beds, to plants in the full ground, or also to plants

in pots placed close together, under a similar awning, or sometimes to seed-beds, either in an awning, or the mats spread on the surface, and if, in the latter method, occasionally watered over the mats, it proves very beneficial; or sometimes, in hot dry weather, in default of mats, some loose straw litter strewed over seed-beds, will be greatly serviceable in screening the surface from the parching sun, and preserving the moisture in the earth, to promote a more quick, regular, and free germination in the seed; and when the plants are come up, the covering is soon drawn off with a wooden or other rake lightly; and to plants under glasses in frames, &c. the occasional Shading is effected either with mats spread thinly over the glasses, or sometimes with a little loose, long litter, shaken lightly over them, just during the fierce heat of the sun: observing, that in the different occasional Shading, it should always be slight, only one mat thick, and the straw Shading in proportion, just sufficient to afford a moderate shade to intercept the approach of the sun beams, without darkening the plants, &c. too much.

The above Shading is only principally necessary in hot, dry, sunny weather, occasionally to many sorts of newly-set small plants, &c. in beds, pots, frames, as above, to defend them from the scorching rays of the sun till they have struck fresh root, and to screen some particular seed-beds similarly, till the seeds therein germinate, and the plants are come up in some advancing state; in all of which, the Shading is essentially beneficial, in case of dry hot weather succeeding the planting or sowing, as it insures more effectually a successful and expeditious free growth, which, without that aid, in the above young plants and sets, when a hot sun, would in many sorts fail considerably, or be greatly retarded; and to plants under glasses in hot-beds, when the fierce sun through the glasses occasions their leaves to flag, as in cucumbers and melons, &c. and sometimes apt to scorch the leaves, the Shading is particularly necessary for a few hours in the middle of the day.

But those occasional Shadings, it is necessary to observe, are only proposed as generally practicable to some particular sorts of plants, cuttings, &c. both of the kitchen-garden, pleasure-garden, and nursery, green-house and hot-house kinds, that are of small or moderate growth, and contained many together within a small compass, either in pricked-out beds, or in pots, frames, or under hand-glasses, so as the Shading can be readily and soon performed as occasion may require, in warm sunny weather to protect them from the scorching

ing sun till they strike root, and commence a fresh growth; and to seed-beds, &c. till the plants are come up; or sometimes, some particular sorts of small tender plants, both such as are pricked out, and others that are in seed-beds or pots, may require a continuation of occasional Shading till they are increased in some degree of strength to stand the full sun; but in plants transplanted finally into their respective different compartments in various parts of the garden, &c. the Shading would be impracticable in any general manner.

Likewise observe, in the work of occasional shading, that it is only to be continued principally in the warmest time of sunny days, generally longer to plants, cuttings, &c. not struck root, than those as are in a growing state; and generally in all plants in the full ground, or others designed for placing in the open air, having occasional shading as above, should be discontinued on evenings, mornings, and nights, that they may enjoy the benefit of the full fresh air at these times; as also tender sorts striking, or advancing in growth under glasses, having occasional shading when the sun is powerful, in the warmer part of the day, should remain unshaded before and after that time, that they may receive the necessary beneficial influence of light and air in a proper degree.

But in plants, cuttings, slips, &c. that have had occasional shading till struck good root, and begin to advance a little in a renewed growth, the shading should be mostly discontinued gradually, especially those in beds, pots, &c. in the open ground, or others designed for transplantation therein, or placing in pots, in the full air, for the summer, or as required, according to their kinds; or in some small tender plants of slender growth, the occasional shading will probably be necessary in longer continuation till they acquire more strength; and to plants remaining all summer in hot-beds, or under frames and glasses, the continuance of occasional moderate shading, in hot sunny days will be eligible; but most young plants, cuttings, &c. pricked out or planted as above, and designed for the full ground or open air, not continued under glasses, having the benefit of occasional shade till well struck, is all they require on that consideration.

Respecting the sorts of plants to which occasional shading at particular periods of their growth and culture would either be indispensably necessary, or beneficially assistant, are very numerous, both in herbaceous, shrubby and succulent kinds, hardy and tender, and as they are generally intimated in their respective genera, under the article of *Propagation*, &c.

it is unnecessary to enumerate them here: so shall only just mention that it is of utility occasionally in most departments of gardening, such as in the kitchen-garden is useful in pricking out many sorts of small young plants, and in some small seed-beds; and in the flower and pleasure-garden, in pricking out and potting many sorts of tender annuals, numerous sorts of perennials, and many shrubby plants; and in the nursery is useful in numerous sorts of small young plants, cuttings, slips, seed-beds, hot-beds; as also in the green-house and hot-house, in the propagation of the various plants by seeds, cuttings, slips, off-sets, &c.

SHIFTING PLANTS in Pots, from smaller into larger, &c. and into fresh earth.

This is a necessary occasional culture to all plants in pots, both with design to assist them with larger pots according as the advanced growth of the particular sorts renders it eligible, and at the same time to have the opportunity of supplying an additional portion of fresh earth about the radical fibres, beneficially to the prosperity of the plants, and sometimes is requisite principally for the application of fresh compost, either part or wholly, and either in consideration of the plants having remained long unremoved, and the old earth in the pots much decayed, or on account of some defect of growth in particular plants; and in all of which cases the occasional shifting into larger or new pots, and some addition of fresh earth, less or more, always proves very beneficial culture to plants in pots in general, both hardy and tender kinds of every order and nature of growth.

In regard to the requisite occasion for shifting, it, in some degree, is according to the advancing growth of the different sorts of plants: some sorts of a strong free growth may require shifting once every year or two, in their principal advancing state; others, more moderate growers, or of settled growth, once in two or three years; and some large-growing kinds, advanced to some considerable size, having been occasionally shifted, in their increasing growth, from smaller into larger pots of different proportionable sizes, and some probably from large pots into tubs, of larger dimensions, such as in large plants of *Agave* or American *Aloe*, orange and lemon trees, &c. they in that advanced state, in large pots, or tubs in proportion, will sometimes only need occasional shifting once in three or several years, especially when the pots or tubs are capacious, containing a large supply of earth, and are occasionally refreshed with some new compost at top, and a little way down round the

the sides about the extreme roots: for in such plants of considerable growth, in the larger or full-sized pots or tubs, it would, in some sorts, be attended with much trouble to shift them often; and some small slow-growing plants, as in many of the succulent tribe, the shifting them once in two or three years may be sufficient; other sorts want shifting annually into larger pots, accordingly as they advance considerably in a free growth, both of hardy and tender kinds, herbaceous and shrubby plants, &c. and in some of the tender annual flower-plants, cultivated in pots, and forwarded in hot-beds, they being planted first in small pots, will want shifting, in their increased growth, into larger sizes, once or twice the same season, from April to May, or beginning of June, when being shifted finally into the requisite full-sized pots, they remain therein during their existence, terminating in September or October following.

So that agreeable to the above intimations, in regard to the nature of the different growth of the various sorts of plants, generally or occasionally cultivated in pots, the necessary shifting may be ordered accordingly; some annually, others once in two years, and some only once in three years, or more; regulating the whole on this occasion as it may seem necessary, according to the different growths of the respective plants, sizes of their present pots, the time they have remained therein, and according as a supply of fresh earth may appear more or less requisite, as this is always a principal consideration not to be omitted in the work of Shifting.

Though it should be observed, that as plants in pots, &c. are limited therein to the small compass of earth about the roots, the Shifting is thereby necessary in most sorts, in their principal advancing growth, once in a year or two, or some three years at farthest, either wholly into larger pots where requisite, otherwise some replanted with fresh earth, in the same, or others nearly of similar size, where larger pots are not so materially wanted as a supply of fresh earth; and in the whole, in every case of Shifting, removing and replanting in pots or tubs, some addition of fresh earth, more or less, must always be applied at the same time, as hereby the shifting is rendered essentially effectual for the prosperity of the plants in their future growth.

And it may likewise be observed, that although large-grown plants, either of the shrub or tree kind, American aloes before mentioned, and other plants of large growth, now finally stationed as it were in the fullest sized large pots and tubs, will succeed several years therein,

without shifting, they, in this case, should in the interval have the top earth loosened, and down round the sides to some little depth, removing the loosened old soil, and fill up fully with fresh earth, settling it close by a moderate watering.

The general season for occasional Shifting such plants as may require it, is principally the spring and autumn: March and April, or early part of May for the spring Shifting; and August and September for that of autumn; though in plants that can be removed with the full ball of earth about the roots, they may be occasionally shifted almost any time; however, for any general Shifting, the spring and autumn are the most successful seasons, as the plants will then sooner strike fresh root; and many sorts preferably in the spring, by having the benefit of the same advancing growing season, and that of summer.

In the business of Shifting, it is generally advisable to remove the plants from the smaller to the larger pots, mostly with the ball of earth about the roots entire, either wholly, or some of the outward old earth, and the dry or matted radicle fibres trimmed away carefully, not to disturb the principal roots in the body of the ball of earth, which being preserved, more or less, the plants receive but little check in growth accordingly, by the removal; or sometimes when any particular plant, shrub or tree, &c. in their respective pots, discover by their top, or above-ground growth, symptoms of a declining state, as probably the defect may be either in the root, or the old ball of earth, it is proper, in Shifting, to shake all the said earth entirely away, in order to examine the root, and to trim and dress it accordingly, as the case may seem to require, and to replant it in entire fresh compost.

In preparing for the occasional Shiftings, when necessary to give larger pots, &c. provide them of proper sizes in some regular gradation larger than the present ones, in a smaller or greater degree, according to the nature and growth of the respective plants; the whole placed ready, together with a proper quantity of fresh compost earth in proportion to the number and size of the plants intended to be shifted.

Then, in proceeding to the Shifting, let those plants intended to be transplanted with balls, be removed out of their present pots one at a time, with the whole ball or clump of earth about the roots as entire as possible; and if a large, tolerably full ball, may, with your knife trim off some of the outward loosest earth, and the extreme fibres of the root; but if

If a small ball of earth, adhering together compactly, may commonly preserve the whole entire; observing, in either case, that where very matted dry or decayed fibres surrounding the ball occur, trim them as it may seem necessary: otherwise in those of a fresh lively growth, cut only any loose straggling parts thereof: likewise give any requisite pruning, trimming or dressing in the head or top, where it may seem proper, according to its state of growth, and that of the natural habit of the different plants; many sorts may probably require very little or none; others as may casually have very naked, or irregular, uncomely, or decayed heads, especially of the shrubby tribe, it may probably be proper either to prune them down, less or more, or to prune any very disorderly or weakly bad growth, or decayed shoots, &c. and in some others of different growths, they may require some little trimming or dressing conformably to their natural order, either to detach any bad or straggling growth, or sometimes very infirm and casual decayed parts, and dead leaves, &c. however, in all plants having tops of a fresh lively state, and regular good growth, according to their respective kinds, no pruning or trimming will be required, and similarly in plants not furnished with immediate tops, at the time of Shifting.

So thus far proceeding agreeable to the above intimations, then having prepared the intended pots for the reception of the plants, by placing some pieces of tile or oyster-shell, &c. loosely over the holes at bottom, and laid in a little fresh earth two, three, or four inches deep or more, according to the size of the pot: set the plant therein with its ball of earth, as above, filling up around with more fresh mould, raising it an inch or two over the top of the ball; and directly give a moderate watering to settle the earth close about the ball and roots regularly in every part, in a proper effectual manner: and thus proceed in Shifting the whole in as many as intended.

As probably, in the above Shifting with the entire ball of earth about the roots, the ball sometimes, in particular plants, may appear very compactly hard and binding, in which case it would be proper to loosen it a little, by thrusting a sharp-pointed stick down into the earth in different parts, giving it a gentle wrench, to open the earth moderately; or sometimes it may also be proper to trim away some of the old earth at top and sides; so plant it as above, and fill up round and over the ball with fresh earth, and watered.

In the course of Shifting different sorts of

plants in pots occasionally, hardy or tender, either shrubby, succulent, or herbaceous, if any appear of a sickly, very weak, or unprosperous growth, it would be advisable to clear off some considerable part of the outward old earth from the ball about the roots, or, in some cases, shake it wholly away therefrom, that, as we formerly intimated, if the defect in growth is occasioned either by some fault in the roots, or in the earth, you may have the opportunity of remedying it in some degree, both by pruning out any decayed or bad parts of the said roots, and by replanting them wholly in entire fresh earth; and, at the same time, it may in some be proper to prune or trim any very infirm, or unprosperous and decayed shoots, or other similar bad and unseemly parts of the head, according to the nature of growth of the particular plants, ordering them conformably as it shall seem expedient, consistent with their general habit.

Sometimes, particular sorts of plants in pots need Shifting, more for the advantage of having some supply of fresh earth, than for want of new or larger pots; and as probably, in this case, some of the same or present pots, may be still of eligible size in which to re-pot them, these pots, thus intended, should be well cleaned from all adhering parts of the old earth, and replenished with entire new at the time of re-potting the plants; which being now removed out of their said pots, either with the entire ball about the roots, and part of the old mould cleared off all round, to admit of a larger portion of fresh earth in the pot at replanting; or in some, appearing of an infirm or declining habit, the whole ball of old earth displaced clean to the roots, as it may seem proper, agreeable to foregoing intimations; giving also any occasional trimming or dressing to the root and top, as may appear requisite, conformably likewise to former remarks in that case; then having furnished the pots, either new ones or the same, with fresh earth, replace the plants therein, filling up the pot regularly with a sufficiency of the same fresh mould, and finish with a moderate watering to settle the whole close about the roots.

After Shifting, if not watered at the time of removal, generally give a moderate watering both to the earth in the pots to settle it close about the roots; and in most sorts, water also highly over the top or head of the plants to wash off any casual foulness; then set the pots of plants in their respective stations in the garden, &c. the hardy kinds, if warm sunny weather,

weather, may place in a shady border for two or three weeks, till struck fresh root in the new earth: the tender sorts dispose in their places among the green-house and stove plants, or some to have the benefit of Shading in the middle of hot sunny days, till fresh struck, as above observed; or probably some of the more tender plants of particular sorts will require to be plunged in a hot-bed or bark-bed, more especially some of the stove kinds; or also, on particular occasions, some principal sorts of the more curious or tenderer green-house plants, to expedite their fresh-rooting more effectually; and sometimes tender annuals in hot-beds, potted in their early young growth, will, at Shifting, require to be replunged in the hot-bed to fresh strike, and forward them till May or June; but generally all the full-ground or open-air plants will only sometimes require a little occasional Shading in hot dry weather the first two or three weeks, and some shifted with full balls about the roots, will only need occasional watering: observe in the whole, both hardy and tender kinds, to supply them with repeated moderate waterings.

SIDA, Indian Mallow.

A genus comprising some tender herbaceous perennial exotics of Africa and America, &c. introduced in our gardens principally as hot-house plants, for variety and ornamental flowering; adorned with heart-shaped, roundish and oblong leaves in the different species, and hermaphrodite columniferous flowers; having a simple calyx, five petals, and many united columnar stamina, erect germen, and many-parted style, crowned with thin stigmas; succeeded by a membranous, many-parted capsule, of many internal cells, one seed in each loculament.

Class and order, *Monodelphia Polyandria*.

The most noted species are,

1. SIDA cordifolia.

Heart-leaved Indian Mallow.] The leaves heart-shaped, sub-angular, sawed, and vilous.

2. SIDA Abutilon.

(Abutilon) or Round-heart-leaved Indian Mallow.] The leaves roundish-heart-shaped, and undivided peduncles, shorter than the leaves.

3. SIDA rhombifolia.

Rhombous-leaved Indian Mallow.] With the leaves lanceolate-rhombus-shaped; and the axillas mostly two-thorned.

4. SIDA periplocifolia.

Periploca-leaved Sida of Ceylon and America.] With the stem panicle-flowering; and oblong heart-shaped entire leaves.

5. SIDA triquetra.

Three-sided American Sida.] Having the

branches mostly three-sided, and heart-shaped, sawed leaves, somewhat downy.

6. SIDA americana.

American oblong-leaved Sida.] The leaves oblong-heart-shaped, and undivided; and capsules many-celled, the length of the calyx.

7. SIDA multiflora.

Many-flowered Indian Mallow.] All these plants being natives originally of the warm parts of the Indies, require culture in our hot-houses in this country; in which they claim admittance for variety and ornament, as they will form an agreeable diversity in their different foliage, and order of flowering; plant them in pots separately of lightish garden earth, and stationed any where in the stove, &c. and may be propagated by seed, off-sets, and cuttings.

SIDERITIS, Iron-wort.

This genus comprises, for the green-house, three species of under-shrubby, and taller shrubby exotics, natives originally of the south of Europe, Asia, and Africa, &c. growing with downy stalks, one or two feet, to five or six feet high, in the different species; garnished with lanceolate, heart-shaped, and oblong downy leaves; and tubular, labiated, or lip flowers, terminating the branches in whorled spikes: having tubulous, five-lobed calyxes, monopetalous, tubulose corolla, with trifid and bifid lips; two longer and two shorter stamina, a four-parted germen, single style, succeeded by four naked seeds.

Class and order, *Didynamia Gymnospermia*.

The principal species in our gardens are,

1. SIDERITIS syriaca.

Syrian Under-shrubby Iron-wort.] Grows with low, under-shrubby, downy-woolly stalks; spear-shaped entire leaves; and yellow flowers in a verticillus.

2. SIDERITIS canariensis.

Canary Shrubby Iron-wort.] Rises with taller, shrubby, hairy-downy stalks; large heart-shaped-oblongish, acute, woolly leaves; and verticillate spikes of whitish flowers.

3. SIDERITIS cretica.

Cretan Shrubby Iron-wort.] Grows with shrubby downy stalks, and divaricated branches; heart-shaped-oblong, obtuse, downy leaves; and verticillate spikes of flowers.

These are tender evergreen plants, require the protection of a green-house in this country in winter, and are therefore always kept in pots, and placed in the green-house collection, in which they form an agreeable variety at all seasons, and generally flower in June, July, and August; succeeded by ripe seeds in autumn, by which they may be propagated; sown in pots in the spring, and placed in a hot-

bed ; also by cuttings and layers, having the same assistance, especially the cuttings ; and by either of which method of propagation, when the new raised plants are a little advanced in their young growth, transplant them into separate small pots of light meilow earth : managing them afterwards as other shrubby exotics of the green-house ; in which they all succeed by the same mode of culture.

SIDEROXYLON, Iron-Wood.

It consists of shrubby ever-green exotics of Africa, retained here in our stoves and green-houses for variety, and a hardy deciduous American shrub for the shrubbery ; are adorned with oval and spear-shaped leaves, in one sort large, the others small, and monopetalous wheel-shaped flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is small, monophyllous, five-parted at top, and permanent. COROLLA is monopetalous, wheel-shaped, and five-parted. STAMINA, five awl-shaped filaments, having oblong incumbent antheræ. PISTILLUM, a roundish germen, awl-shaped style, and simple obtuse stigma. PERICARPIUM, a roundish umbilicated unilocular berry, containing one oval unilocular nut.

There are about three species, one of which is inermous, or without spines, the others are spinous.

1. SIDEROXYLON *inermis*.

Smooth Ethiopian Sideroxylon.] Rises with a shrubby stem, branching irregularly six or eight feet high, being inermous, or without spines, garnished with large, oblong-oval, firm, smooth, shining, green leaves, and flowers at the sides and ends of the branches.

2. SIDEROXYLON *spinosum*.

Spinous Malabar Sideroxylon.] Rises with a shrubby branching stem, several feet high, armed with spines, smaller oblong-oval, firm, smooth, perennial leaves, and flowers at the ends of the branches.

The above two plants rarely flower in England.

They being tender exotics from hot countries, are tender, and require protection here of a stove, or green-house, though they are commonly retained as stove-plants ; but will also succeed tolerably well, with the culture of green-house exotics, having residence of a good green-house in winter, so must always be kept in pots, and stationed among the plants of one or other of the above departments.

3. SIDEROXYLON *lycioides*.

Lycium-like, or Thorny Cananda Iron-wood.] Hath a shrubby stem and branches, armed

with spines, and garnished with spear-shaped, shining-green, deciduous leaves.

The wood of these shrubs being so very solid, remarkably hard and ponderous, as to sink in water, they obtained the appellation of Iron-wood.

The three species are kept in many of our principal gardens for variety ; the first two, being tender, are introduced in the stove or green-house collections, as they cannot stand the full air in this country, only in the principal warm summer months ; but the third is hardy, and proper to admit in the shrubbery plantations, as a deciduous shrub, in assemblage principally with others of the same tribe.

They are propagated by seeds procured from abroad, which of the two first sorts in particular, must be sown in spring, in pots of rich earth, and plunged in the bark-bed ; and when the seedlings are come up two or three inches high, pot them off separately ; try also cuttings and layers of the young shoots, by assistance of a hot-bed as above ; and the plants raised by either method, planted in separate pots, continue them always as residents of the stove or green-house, to have the protection and culture, as the other exotics of these departments, as before suggested.

The third sort is also raised from seed in the spring on a bed or border of light earth, or forwarded in a hot-bed ; likewise by slit-laying or cuttings of the young shoots, in the common method ; or generally nicking the layer shoots, &c. for being a hard wood it does not emit roots very freely.

SILENE, Viscous Campion, &c.

The plants are mostly hardy herbaceous annuals and perennials, some of which merit culture, as flowering plants, which are principally of erect growth, with stalks about twelve or fifteen inches to half a yard, or two or three feet high, in the different species ; garnished with oblong-oval, and narrow simple leaves, and the stalks terminated by bunches of small pentapetalous flowers.

Class and order, *Decandria Trigynia*.

Characters.] CALYX is monophyllous, quinque-dentate, and permanent. COROLLA, five plane, obtuse, sometimes bifid petals, with narrow unguis, and a nectarium formed of two denticles in the neck of each petal. STAMINA, ten awl-shaped filaments, alternately inserted into the unguis of the petals, having oblong antheræ. PISTILLUM, a cylindric germen, three simple styles, crowned by stigmas, reflexed contrary to the sun. PERICARPIUM, a cylindric trilocular capsule opening five ways at top, and many reniform seeds.

There

There are many species, annuals, biennials, and perennials, and of which the following are the most noted sorts.

1. *SILENE Armeria.* (Annual.)

Clammy Viscous Champion, commonly called Lobel's Catch-fly.] Rises with erect, branchy, clammy stalks, half a yard high, having the upper leaves heart-shaped, and all the branches terminated by fastigiated bunches of flowers, of different colours in the varieties.

Varieties.] Common red-flowered—white-flowered—purple-flowered.—All of which flower in June and July.

2. *SILENE quinquevulnera.* (Annual.)

Dwarf Viscous Champion, commonly called Dwarf Lychnis.] Rises with upright channeled stalks, branching numerously twelve or fifteen inches high, oval-spear-shaped, hairy, opposite leaves, and all the branches terminated by short spikes of purple flowers edged with white, having roundish entire petals, succeeded by erect fruit alternately:—flowering in May, June, and July.

3. *SILENE pendula.* (Annual.)

Pendulous Viscous Champion.] Rises with an upright branching stalk, a foot high, oval-spear-shaped pointed leaves, and branches terminated by spikes of bright-red flowers, succeeded by pendulous fruit, having ten rough angles, and filled with seeds, appearing in June and July.

The above species are hardy annual flowers, and have been long in estimation for adorning the borders in summer, being commonly sown in small patches in the places where they are to flower.

4. *SILENE muscipula.* (Biennial.)

Spanish Viscous Champion.] Hath a biennial root, an upright, round stalk with swelling joints, and branching by pairs, a foot and half high; narrow spear-shaped, smooth leaves, surrounding the stalk in clusters; and at the axillas, close-fitting, red flowers, with bifid petals.

5. *SILENE viridiflora.* (Biennial.)

Green-flowered Portugal Champion.] Hath a biennial root, upright, downy stalk branching alternately a foot or more high; oval-spear-shaped, downy leaves, and the branches terminated by panicles of whitish-green flowers.

6. *SILENE nutans.* (Perennial.)

Nodding Mountain Viscous Champion] Hath a fibrous perennial root; upright stalks, two feet high; spear-shaped leaves; and from the upper part of the stalks, nodding panicles of white flowers arranged, drooping on one side, having bifid petals.

7. *SILENE bupleuroides.* (Perennial.)

Bupleuroid-leaved Persian Viscous Champion.] Hath a perennial root, crowned with large clustered heads of spear-shaped acute leaves; upright stalks a foot and a half high; and opposite pedunculi, each sustaining two or three white flowers with bifid petals and short bracteæ.

8. *SILENE fruticosa.* (Perennial.)

Shrubby Sicilian Viscous Champion.] Rises with a low shrubby stem, branching a foot or more high, having broad spear-shaped leaves, and trichotomous panicles of greenish-white flowers.

All these plants flower here in summer from May till August in the different sorts, each flower having five petals, and several of the sorts produce ripe seeds, particularly the annuals and biennials, by which all the sorts may be raised, and the perennials also by seed, and by parting the roots, &c.

They are all hardy herbaceous plants, and for the general part have very viscous or clammy stalks, particularly just below the joints, to which flies often stick fast, hence the name Catchfly, and Viscous Champion, &c. See also *LYCHNIS viscaria.*

They will all prosper in any of the garden compartments, and may be employed for ornament and variety in different parts of the pleasure-garden.

The annual sorts, in particular, are cultivated in many gardens as flowery plants, which being raised from seed may be sown in autumn or spring, where they are to flower: the autumnal-sown plants flower earlier and strongest, though it is best to sow at both seasons, but principally in the spring, in March or April; repeating also the sowing in the early part of summer, in order to obtain a longer bloom, observing to sow them in patches about the borders; and after the plants come up, thin out the weakest, leaving only two or three in each patch, and they will then grow strong and flower plentifully in June and July, and ripen abundance of seeds in autumn.

The biennial sorts are raised from seeds sown in autumn or spring in a bed or border and raked in, and when the plants are come up an inch or two high, prick them out in nursery-beds till autumn, then transplant them into the borders, &c.

The perennials may be propagated by slipping their heads, and parting the roots, and the shrubby sort also by slips and cuttings of its branches or shoots, in spring and early part of summer, planted in a shady border.

They may also be raised from seeds like the biennial sorts.

SILPHIUM, Bastard Chrysanthemum.

The plants are principally tall-growing, herbaceous perennials, for ornamenting the pleasure-ground, rising with annual stalks several feet high, adorned with divided and entire leaves, and the stalks crowned with compound radiated flowers.

Class and order, *Syngenesia Polygamia Necessaria*.

Characters.] **CALYX** is oval, scaly, imbricated, and permanent, having the scales prominent and reflexed in the middle. **COROLLA**, a compound radiated flower, consisting of funnel-shaped, male florets in the disk, and spear-shaped females in the radius. **STAMINA**, five small filaments in the male florets, having cylindric antheræ. **PISTILLUM**, in the females, an oblong germen, slender simple style, and two bristly stigmas. **PERICARPIUM**, none. **SEMEN**, in the females a single oblong-heart-shaped seed, having a membranaceous two-horned border.

The species are,

1. **SILPHIUM trifoliatum.**

Trifoliate Virginian Silphium.] Hath a fibrated, ligneous, perennial root; upright, firm, purplish stalks, branching four or five feet high; large, oblong, rough, sharply-serrated leaves, generally by threes or fours round the stalk; and at the sides and ends of the branches long peduncles, each sustaining one radiated yellow flower.

2. **SILPHIUM solidaginoides.**

Solidaginoid Virginian Silphium.] Hath a fibrated perennial root; upright stalks a yard high; spear-shaped, acute, serrated, opposite leaves on short foot-stalks; and the stalks terminated by radiated yellow flowers loosely disposed.

3. **SILPHIUM Asteriscus.**

(Asteriscus)—or American Silphium.] Hath a fibrous, perennial root; upright, thick, hispid stalks three or four feet high; oblong, rough, undivided, close-sitting leaves, alternate below, but opposite above; and the stalks terminated by radiated yellow flowers.

4. **SILPHIUM laciniatum.**

Laciniated American Silphium.] Hath a fibrous, perennial root; upright, very thick, simple stems, eight or nine feet high; large pinnatifid, sinuated leaves alternately; and the stalks terminated by radiated yellow flowers.

All these four species flower here annually in July and August, the flowers are universally compound and radiated, each flower consisting of many florets in one scaly, imbricated general calyx, tubular florets in the disk,

and spear-shaped ones form the radius; but the seeds do not ripen freely in England.

They are all very hardy herbaceous perennials, durable in root, but renew their stalks annually in spring, which flowering in summer, decay to the root in autumn.

All the sorts are proper ornamental furniture for large compartments, in assemblage with other tall-growing perennials, where they will effect a good variety in summer.

They are all easily propagated by parting their roots in autumn, or spring, planting the slips at once where they are to remain, and they will flower the following Summer.

SINAPIS, Mustard.

The plants are mostly hardy herbaceous annuals, some of which merit culture as esculent herbs, both for sallading, and for their seeds for making mustard; all of which rise with erect branchy stalks from two to three or four feet high, garnished with broad, rough, deeply jagged leaves, and the branches terminated by spiked clusters of tetrapetalous cruciform flowers.

Class and order, *Tetradynamia Siliquosa*.

Characters.] **CALYX**, four narrow, cruciform, deciduous leaves. **COROLLA**, four roundish, plané, cruciform petals, and four oval nectari. **STAMINA**, four long and two short filaments, having erect patent antheræ. **PISTILLUM**, a taper germen, a style the length thereof, crowned with a headed stigma. **PERICARPIUM**, on oblong, swelling, rough, bilocular, bivalvous pod, having many globose seeds.

The principal species for general culture are,

1. **SINAPIS alba.**

Common White Mustard.] Rises with large, rough, jagged leaves, upright, branchy, hairy stalks two feet high, or more, garnished also with jagged rough leaves, and all the branches terminated by loose spikes of numerous small yellow flowers, succeeded by hispid pods, having long oblique beaks, and contain white seeds.

This is the common White Mustard usually cultivated in gardens as one of the small sallad herbs, and may also be raised for its seed to make Mustard.

2. **SINAPIS nigra.**

Black Mustard.] Rises with erect, branching stalks, three or four feet high, garnished with large, rough, jagged leaves, and the branches terminated by spiked clusters of yellow flowers, succeeded by smooth pods, tetragonous at top, containing blackish-red seeds.

This

This is the sort which is commonly cultivated in fields for its seed, of which to make the common Mustard for general use.

3 SINAPIS arvensis.

Field Mustard.] Rises with erect stalks two feet high, garnished with oblong, rough leaves, and the branches terminated by bunches of yellow flowers, succeeded by multangular, swelling, turgid pods, with long beaks.

The two first species flower in June, and the seeds ripen in July and August, but the third flowers in May, and the seeds ripen in June.

These three species of *Sinapis* are hardy herbaceous annuals, that grow naturally in the fields in England, and most parts of Europe; but the second and third sort, in particular, grows abundantly among the corn, and by way-sides in many parts of England, and are also cultivated in gardens and fields in large quantities for their seeds to manufacture for flour of mustard. The *Sinapis alba*, however, is cultivated in gardens principally as a small salad herb, and sometimes for its seed as above; but the *Sinapis nigra* is chiefly cultivated in fields or gardens in considerable quantities for its production of seed for the article Mustard, aforesaid, though good Mustard may be made of both these sorts; the seed of which being sown in the spring soon come up, shoot up to stalks, and produce ripe seeds in three or four months, then totally perish; so that a fresh supply is raised annually from seed.

The White Mustard, however, being used in gardens as a salad-herb, is sown along with other small sallading at all times of the year, even sometimes every week or fortnight, in a bed or border of light earth, sown generally in shallow drills very thick, covering it very thinly with earth; and in winter, and early in spring, during the cold weather, is sown also in hot-beds; and the herbs are always cut for use whilst in the seed-leaf and but a few days old; otherwise they will become too strong and rank tasted.

But for the particular methods of raising this sort as a salad-herb, together with other small sallading at different times of the year, see SALLAD-HERBS and SMALL SALLADING.

Observe, in order to save seed of this sort for garden use, sow it on an open spot of ground in March or April, either thinly in drills a foot asunder, or broad-cast all over the surface, and let the plants run up to stalk, and they will furnish ripe seeds in August.

To raise the plants for the seed for Mustard,

they should be sown in the spring, any time in March, in some open situation, either in a kitchen garden, or in the open fields, where large quantities are required for sale; in either case, having digged or ploughed the ground, then sow the seed broad-cast all over the surface, and rake or harrow them in lightly, or sow it in shallow drills a foot asunder. They will soon come up, observing, that when the plants have four or more leaves an inch or two broad, if they stand very thick, those sown in the broad-cast way particularly, should be hoed and thinned, leaving them six or eight inches asunder, and cut up all weeds, repeating it once or more if necessary; after this the plants will soon spread and cover the ground, and shoot fast up to stalks for flowers and seed, which will ripen in July or August, when the stalks should be cut or pulled up, and the seed being properly hardened, and dry in the pod, may either be threshed out directly, as much as convenient, or stacked up dry, and threshed at occasional opportunities.

SISYMBRIUM, Water-Cress.

Consists of hardy herbaceous annuals and perennials, mostly of the aquatic tribe, one of which is in high estimation as a salad-herb; are mostly of spreading growth, garnished with pinnated and pinnatifid leaves, and the stalks terminated by spikes of small tetrapetalous cruciform flowers.

Class and order, *Tetradynamia Siliquosa*.

Characters.] CALYX, four linear, spear-shaped, spreading, deciduous leaves. COROLLA, four oblong, patent, cruciform petals. STAMINA, four long and two short filaments, having simple antheræ. PISTILLUM, an oblong, slender germen, very short style, and obtuse stigma. PERICARPIUM, a long, taper, incurved, bivalvous, bilocular pod, having many small seeds.

There are many different species of this genus, but the greater part being plants of no merit are rarely cultivated: one sort, however, *Common Water-Cress*, demands attention as a wholesome salad-herb.

SISYMBRIUM nasturtium.

Nasturtium aquaticum, or Water-Cress.]

Hath a fibrous, spreading, perennial root, striking deep in the mud under the water, and sends up several branchy shoots, becoming hollow stalks, garnished with pinnated leaves of four or five pair of nearly heart-shaped lobes, and an odd one, and the branches terminated by loose spikes of small whitish flowers in June, and the seeds ripen in July.

This plant is a perennial, grows abundantly in shallow standing waters, on the margins

gins of small rivers, brooks, running springs, watery ditches, and moist meadows, almost every where; and being of a fine warm, agreeable, fat relish, is greatly esteemed as a winter and spring salad-herb, and as such every one may obtain it at an easy rate, either by gathering it themselves where it grows naturally, or by purchasing it of the simplers, or herb-people, especially about London, where great quantities are daily brought for sale in autumn, winter, and spring, tied in small bunches, which they retail in the markets, and about the streets, at about two pence or three pence *per* dozen; and many people buy them constantly as a choice, wholesome, palatable salad, to eat either alone, or mixed with other salad-herbs.

It is a good purifier of the blood, and is admirable against the scurvy.

This plant, however, as it grows wild in great plenty almost every where in watery places, is rarely cultivated in gardens, though it may be easily raised abundantly in any quite shallow water, or a pond, stream, ditch, &c. and other moist places, either by transplanting the plants with roots from the places of their growth, or by seed.

Its propagation therefore may be effected both by parting the roots and by seed.

By parting the Roots.—In spring, or any time of the year, whilst the plants are young, may easily slip off a quantity, with plenty of roots to each, which plant directly, in some shallow, watery place, as before observed; they will readily strike into the mud, spread considerably, and will ripen seed and sow themselves, and furnish plenty of plants for use.

By Seed.—Procure a quantity of the seed in summer as soon as ripe, in the places where the plants grow naturally, and sow them directly in any moist place to remain; or get a quantity of the plants just as the seeds begin to ripen, and throw them into any shallow water, they will strike root, ripen, and shed their seeds, which falling to the bottom will grow and furnish plenty of young plants.

SISYRINCHIUM, *Bermudiana*.

The plants are low, herbaceous, flowery perennials for the pleasure-garden, rising with sword-shaped leaves and stalks half a foot high, adorned at top with spathaceous hexapetalous flowers.

Class and order, *Gynandria Triandria*.

Characters.] **CALYX** is a spatha, or sheath, formed of two compressed, keel-shaped leaves. **COROLLA**, six oblong-oval, acute-pointed, spreading petals. **STAMINA**,

three very short gynandrious filaments, with bifid antheræ affixed to the style. **PISTILLUM**, an oval germen under the flower, awl-shaped style, and trifid reflexed stigma. **PERICARPium**, an oval, trigonous, trivalved, trilocular capsule, having numerous roundish seed.

The principal species is,

SISYRINCHIUM *Bermudiana*.

(*Bermudiana*) — or *Bermudian Sisyrrinchium*.] Hath a fibrous perennial root, crowned with several sword-shaped, two-edged, stiff leaves, five or six inches long; amidst them an erect, two-edged stalk, half a foot high, garnished also with sword-shaped, amplexicaule leaves, and adorned at top with several spreading deep-blue flowers, having yellow bottoms.

Variety.] *Virginian Sisyrrinchium*. Hath a fibrous perennial root, crowned with narrow sword-shaped leaves, but three or four inches long, and erect two-edged stalks the same height, terminated by two or three pale-blue flowers.

Both these varieties flower in June, and are succeeded by ripe seeds in autumn.

They may be employed as flowery plants in any of the compartments of the pleasure-ground, placing them towards the front in assemblage with other low perennials, where they will cause an agreeable variety.

Their propagation is by parting the roots, and by seed.

By parting the Roots.—This may be performed in autumn, any time in September or October, when the roots may be taken entirely up, and slipped into several separate off-sets, but not too small, planting them again directly, and they will root firmly before winter, and flower the year following.

By Seed.—Sow them in autumn, or early in spring, in an east border, in shallow drills, covering them half an inch deep; they will come up in April or May, like grass; keep them weeded all summer, and towards autumn prick out a quantity in nursery-rows six inches asunder, to stand till spring or autumn following, then transplanted with balls, to where they are to remain.

SIUM, Water-Parfnep and Skirret.

This genus is composed of hardy herbaceous perennials, one of which, (Skirret) having an esculent root, is sometimes cultivated in kitchen-gardens; the others being plants of no utility for use or ornament in gardens are rarely cultivated; they rise mostly with winged leaves and upright annual stalks, terminated by umbellate clusters of flowers.

Class and order, *Pentandria Digynia*.

Characters.] **CALYX**, umbellate flowers, having

having the general umbel composed of several smaller plane umbels, with the general involucre formed of many spear-shaped, reflexed leaves, and the partial ones of many small narrow leaves. **COROLLA**, the general umbel is uniform and composed of many small flowers, each having five heart-shaped, inflexed petals. **STAMINA**, five filaments with simple antheræ. **PISTILLUM**, a small germen under the flower, two reflexed styles, and obtuse stigmas. **PERICARPIUM**, none. **SEMEN**, two oval seeds to each floret.

There are seven or eight species of this genus, one of which only, an esculent, has merit as garden plants, some being wild weeds of ditches, and other moist places in England, &c. and seldom admitted into gardens.

The garden sort is,

Sium Sifarum.

(*Sifarum*)—or *Skirret*.] Hath a perennial eatable root, composed of several oblong, thick, fleshy fibres, collected into a head at top, crowned with pinnated leaves, of two or three pair of oblong folioles and an odd one, and when it shoots to seed, rises with an upright stalk a foot high, having ternate leaves above, and terminated by an umbel of white flowers.

The root of this plant is eatable, of a sweetish relish, being boiled and eaten like carrots and parsneps, and was formerly in much esteem, but has become in disrepute of late years; it is, however, accounted a very wholesome root.

Method of Propagation.

It is propagated both by seed and by off-sets of the roots.

By Seed.—In spring, any time in March, or beginning of April, is the season for sowing, choosing an open situation, which being properly digged, sow the seed either broad-cast all over the surface and raked in, or in shallow drills a foot asunder; they will come up in a month or five weeks, and in about three weeks after they must be cleaned from weeds, and thinned either by hand or hoe, leaving the plants six or eight inches distance; the plants will soon after cover the ground with their leaves, and the roots increase in growth till the leaves decay in autumn, then they will be fit for use, and continue good till next spring, when they will shoot up for seed.

By Off-sets of the Root.—The roots put out many side off-sets, which in spring being slipped off separately each with one or more buds or eyes at top; and in an open spot of ground plant them with a dibble in rows a foot asunder, with the crown of each slip an inch within the ground; or may plant them thin by trench planting, in small trenches, as for al-

paragus, placing them erect against the back of the trench, and cover in the mould over them the above depth; in either method the plants will soon come up strong, and by autumn following the roots will be full grown, and increased into large bunches fit to take up for use from October till March.

To save seeds of this plant, let a few of the large roots stand to shoot up into stalks, which will flower in July, and the seeds will ripen in autumn.

SLIPS, the propagating plants by Slips.

Great numbers of plants, both woody and herbaceous kinds, are propagated plentifully by Slips; and the method is very easy as well as very expeditiously performed.

It is effected in the woody kinds by slipping off small young shoots from the sides of the branches, &c. with the thumb and finger, instead of cutting them off with a knife, though we may observe, that there is no material difference, in the success of future growth, between Slips and cuttings, only the former in small young shoots is more applicable to be slipped off by the hand, as above, and are therefore called Slips, which in numerous small, shrubby plants will grow; but is more commonly practised to the lower ligneous plants, such as sage, winter-savory, hyssop, thyme, southern-wood, rosemary, rue, lavender, and most other low shrubby growths, which may with the utmost facility be multiplied by this method: and the best season of the year for effecting the work is generally in spring and beginning of summer, though many sorts will grow if planted at almost any time, from March or April till July; but the proper season for the various plants is always hinted in their culture, under their respective genera.

Observe, in performing the work of slipping these sorts, to chuse the young shoots chiefly of but one year's growth, and in many sorts the shoots of the year will grow the most readily even to plant the same summer they are produced, especially the hard wooded kinds; but in the more soft wooded plants, the Slips of one year's growth will also often readily grow; being careful always to chuse the moderately growing side-shoots situated on the outward part of the plants, from three to six or eight inches long, slipping them off close to the branches, and clear off the lower leaves; then plant them either in a shady border, if in summer, and watered, or so as they can be occasionally shaded in hot sunny weather, especially small Slips, inserting the whole two parts of three in the ground, giving occasional water, in dry warm weather, till properly rooted; and then towards autumn, or in spring

spring following, transplant them where they are to remain.

But in planting Slips of the shoots of tender shrubby exotics of the green-house and stove, many sorts will require aid of a hot-bed or bark-bed, to promote their emitting roots more effectually, which is generally intimated in their culture, under their respective genera: but some others of the shrubby kinds, such as geraniums, will root freely in the natural earth in summer; and many of the herbaceous tribe, producing bottom rooted off-sets for Slips, as in aloes, &c. will also readily grow, either with or without a hot-bed; only we may observe, where there is convenience of hot-beds, as above, in which to plunge the pots of Slips of tender plants, it runs them off more expeditiously; and most of the hot-house plants in particular require that assistance.

Many shrubby plants growing into large bunches from the root, both of the small under-shrubby kinds, as thyme, savory, hyssop, sage, &c. and in those of larger growth, such as roses, spiræas, raspberries, and numerous other sorts, all of which may be slipped quite to the bottom into separate plants, each furnished with roots, and may be planted either in nursery-rows, or at once where they are to remain.

As to the slipping of herbaceous plants, numerous sorts multiply by the root, &c. into large bunches, which may be slipped into many separate plants; and it is effected by slipping off the increased suckers or off-sets of the root, and some sorts by the off-sets from the sides of the head of the plants, and some few sorts by Slips of their bottom shoots, and some of those above, of the stalks and branches in plants of bushy growth; but the greater part by slipping the roots, as in many of the bulbous-rooted tribe, and numerous fibrous-rooted kinds.

The slipping of the bulbous plants is performed in summer when their leaves decay, and the roots being then taken up, slip off all the small off-sets from the main bulb, and the Slips and off-sets should generally be planted again soon in nursery-beds for a year or two. See BULBOS.

And as to the fibrous-rooted sorts, the slipping should generally be performed in the spring, or early part of autumn, which may be effected either by slipping the out-side off-sets with roots, as the plants stand in the ground; or to perform it more effectually, may take the whole bunch of plants up, and slip them into several separate parts, each Slip being furnished also with roots, planting them, if small, in nursery-rows for a year, to gain

strength; or such as are strong may be planted at once where they are to remain.

Farther particulars of the method of slipping plants is mentioned in the culture of the different sorts under the proper heads.

SMALL SALLAD HERBS.

Several young seedling-herbs of a warm nature are in estimation for Small Sallading to mix with the larger principal Sallad Herbs, as observed on a former occasion, such as lettuce, endive, and celery, in order to improve their flavour and wholesome quality.

The sorts therefore in general estimation as Small Sallad Herbs, are cresses, mustard, radish, rape, and turnep; also sometimes lap-cabbage-lettuce for winter and early spring use; all of which herbs, considered as Small Sallading, are always in perfection as such, when quite young, that is, not more than a week, or ten or twelve days old, whilst they remain mostly in the seed-leaf, being then cut up close to the ground for use; for they being mostly of a warm relish, in which consists their chief excellence for winter and spring Sallads, if suffered to grow large, and come into the rough leaf, they become of a disagreeable, strong, hot taste; but being used when only in the first young leaves, as just above observed, they eat exceedingly tender with an agreeable warm flavour, highly relishing to most palates, which renders them eminent furniture to mix in all winter and spring Sallads particularly; but from June till September they are not so generally regarded, though many persons are fond of them at all seasons of the year, and in default of other Sallad Herbs many often use them alone as Sallading in the winter and spring months; they, however, are preferable when mixed with lettuce and the other principal Sallad Herbs. See SALLAD HERBS.

Let it be observed, that as all the above-mentioned Small Herbs belong to different genera, besides their uses for Sallads, several of them are also cultivated for other useful purposes, all of which is hinted, together with their proper culture for their several uses under their respective genera; but considered as Sallad Herbs, they require a particular culture, and we therefore judged it eligible to exhibit their culture for that purpose under this head, *Small Sallad Herbs*, and, as such, the same culture serves for all the sorts, they being all raised from seeds at various sowings the year round, as directed in their culture below.

Observe, therefore, that for the purpose of Sallading they may be obtained young at all times of the year, in spring and summer in the

the open ground, and in winter under shelter of frames and glasses, and occasionally in hot-beds.

General Observations on their Culture.

They are all raised from seed, which, for Sallading, is sown at all times of the year, when they are required; in the open ground, from March till October or November; and in the winter months they will require shelter of frames and glasses, &c. and the assistance of hot-beds occasionally, as we before noticed: and where a constant supply is required, a repetition of sowing will be requisite every week, or ten days, or a fortnight, according to the season of the year and the demand for use, being sown generally in flat shallow drills, very thick, and only just covered with earth, and are also sometimes sown all over the surface, especially upon hot-beds.

But as they require somewhat different culture at different times of the year, we will explain it under different heads accordingly, viz. *Spring Culture, Summer Culture, Winter Culture.*

Spring Culture.

In the spring-culture of Small Sallading, it may be raised both in the open borders and in hot-beds occasionally, according as it may be required, early or late, but when it is required as early as possible, it must either be sown in hot-beds under frames and lights, &c. or, in default of a hot-bed, in a bed or border of natural earth under glasses.

First the early culture in Hot-beds.—You may begin to sow in hot-beds any time in January or February, and when a considerable supply is daily required, may continue sowing every week or fortnight in hot-beds till March, or during the cold weather. Let a moderate hot-bed of dung be made for one, two, or more garden frames, only half a yard or two feet depth of dung, according to the temperature of the season, as the heat is only required to bring up the plants quickly; and forward them a week or two in growth; place a frame thereon directly, and mould the bed all over with light rich earth, five or six inches thick, making the surface level and smooth; then if you would forward your Sallading as much as possible, you may directly sow the seed; which may be effected either in drills as shallow as possible, about two or three inches broad, and flat at the bottom, and three inches asunder, sowing the seeds of each sort separate and very thick, so as almost to cover the ground, and only just cover them with earth: or, to make the most of the bed, may sow the seed all over the surface, previously smoothing it lightly with the back of the spade, then sow the seeds all over the bed, the different sorts separately,

and all very thick, as just observed; and after pressing them all even and lightly down also with the spade, cover them very thinly with earth, by sifting over as much light mould as will only just cover the seed, as afore said; and as soon as the sowing is performed in either method, put on the lights: the seeds will quickly germinate, and will come up in two or three days or less, being careful at this time to give vent to the steam arising in the bed, as well as indulge the plants with plenty of free air daily, either by tilting the lights in back or front, according to the temperature of the weather, or by drawing the lights a little down, or taking them quite off occasionally in mild days at first; for the hot-bed being yet new, there will be a considerable steam arising; and the Sallading coming up very thick, unless due vent is given to pass off the steam and admit fresh air, they will be apt either to burn, or fog (as the gardeners term it), and mould off as fast as they come up. Such hot-beds, however, that are not fresh made, do not require all this precaution; but in new-made beds it must be strictly observed till the Sallading is all fairly come up, and as long as the strong steam continues; and the plants will be fit for use in a week or ten or twelve days from the time of sowing.

Thus continue to repeat the sowing in hot-beds every week or fortnight during the cold weather; the same hot-bed sometimes retaining its heat, will admit of two sowings, by sowing again as soon as the first crop is gathered; however, to obtain a regular supply daily, continue to make fresh hot-beds occasionally, sowing and managing them as above.

Sometimes where only a small quantity for family use may be wanted at a particular time as soon as possible, and that you have the convenience either of cucumber and melon hot-beds, or a hot-house, &c. some seed of each sort may be sown in pots or boxes, and placed in the said hot-beds or stove, just to bring up the plants fit for use; which on some particular occasion may be sufficient without making a hot-bed on purpose.

For want of frames and lights to place over the hot-bed, may use hand or bell-glasses, or arch the bed with low hoop-arches, in order to cover with mats every night, and in bad weather.

Or in default of hot-beds, in cold weather early in the spring, may prepare part of a warm border, or a bed of light earth in a sunny situation, for some garden-frames and lights, hand-glasses, &c. raising the ground somewhat to the sun; and having dug it, and raked it fine, then sow the seed either in shallow

low drills, as before observed, or all over the surface in the manner as directed also in the hot-bed culture; covering it lightly with earth, and having set on the frames and glasses, the seeds will soon come up, and the Sallading will be ready some considerable time sooner than in the open ground.

Their Culture in the full Ground.—From about the middle or end of February, or beginning of March, according to the forwardness or mildness of the season, may begin sowing Small Sallading in the open ground, repeating the sowings every week or ten days; the first sowing being performed on a warm border; and continue sowing in that situation till the beginning or middle of April; then it may be sown in any of the open quarters, and in which the sowings may be repeated weekly, or once a fortnight, as may be required; but according as the hot weather approaches, should rather sow in a somewhat shady situation.

Let the ground for each sowing, in the different situations, be properly digged, and the surface raked smooth.

And as to the method of sowing in the open ground, it is most commonly in shallow drills, which should be drawn with a small hoe either with the corner, or held edge-ways downward, horizontally, drawing the drill along evenly, as shallow as possible, and flat or level at bottom, at three or four inches asunder, in which sow the seed evenly all along the bottom, each sort separate, and very thick, covering them in evenly with the finest of the mould, not more than a quarter of an inch deep; or if the smaller seeds are but just covered it is sufficient; for the seeds being sown very thick, if deeply covered with mould, the plants will not be able to rise regularly.

Observe in the early spring sowings in the open ground, that in cold nights and all bad weather, it is eligible to cover the ground, both before and after the plants begin to rise, with large mats, which will be better if supported on low hoop-arches, or ranges of pegs stuck in the ground, just high enough to support the mats a little from the earth; and by assistance of this covering occasionally in the early sowings, you will insure a more effectual crop, as well as forward the Sallading some days.

Remark, likewise, of the later sowings, when the dry warm weather commences, it is proper to give occasional waterings.

Observe farther, that as Small Sallading being always sown extremely thick, and the plants consequently coming up very close together, and the ground being sometimes by means of wet, &c. crusted or caked at top, so as

they cannot readily make their way through separately, in which case it is proper to whisk the surface of the earth lightly with the hand, or slightly touched along with a light rake, or the end of a birch broom, just to break and separate the mould a little.

Summer Sowings.

Small Sallading is not in general esteem during the hot weather in summer, from the middle or end of May until September.

However, some require it all summer long, and it may be sown in any open situation from May till September: observing, however, that during the hot dry weather, it should either be sown in some shady borders, or shaded with mats in sunny days during the greatest heat, from about ten till four o'clock, till the seed come up: and the sowings should be repeated every ten or twelve days; but as in summer these herbs soon become very hot-tasted, to have them perfectly young and tender, it is advisable to repeat the sowings every week in very hot weather.

The sowings are to be performed in shallow flat drills, as observed in the *Spring Sowing*, in the open ground, the seed sown very thick, and but lightly covered with earth, for the reasons formerly given.

And in very dry weather give daily waterings both before and after the plants begin to appear.

Autumn and Winter Culture.

From September to January, February, or March, is to be understood for the *Autumn and Winter Culture* of Small Sallading; the first part of which time it may be obtained in the open ground; but as soon as the cold weather sets in, it must be raised under glasses, and in hot-beds occasionally.

We may continue sowing in the open ground all September and October, also occasionally in November in mild seasons; observing, that until towards the middle of October we may sow them in any open situation; but from the middle or latter end of October, and in November, the sowings must be on warm south borders, performing the sowings, as before advised; and in cold nights bestow a covering of mats, or hand-glasses, &c. repeating the sowings every week, or ten days, or a fortnight, as occasion requires.

But when the cold weather commences in November, &c. it is advisable to use garden-frames and lights, or hand or bell-glasses, choosing a spot of light, rich ground in a sunny situation, sowing the seeds either in drills or all over the surface, according to the former directions, using the shelter of the frames and glasses as above; and thus you may raise plenty

plenty of Sallading, almost any time in winter, in mild weather; but when frost comes, recourse must be had to hot-beds.

However, in default of hot-beds to raise a constant supply all winter, it may be obtained great part of that season, sown in the natural earth, under good frames and lights, and other occasional covering, except just during the time of long, severe frosts, when the aid of hot-beds will be necessary: however, in order to raise them as well as possible during winter without the constant aid of hot-beds, let a raised bed or border of light rich earth, in a warm dry situation, be prepared for one, two, or more shallow garden-frames, raising it on the north side six inches, or more, so as to form it sloping to the sun; and having smoothed the surface, set on the frames, sinking the back-part thereof near a foot, that the whole surface of the earth may be within eight or ten inches of the glasses, for it is of much advantage to have the glasses tolerably close to the earth at this season, in order to receive the greater influence of the sun's heat, more especially when without hot-bed heat at bottom. The seed may here be sown either in shallow flat drills, ranging from the back to the front of the frame, three inches asunder, as in the spring sowings, or may be sown all over the surface, patting it lightly down with the spade, and then just cover it with earth as thinly as possible; directly put on the lights, and keep them close, and the plants will soon come up; repeating the sowings once a week or fortnight; and thus you may continue a constant succession of young Sallading most part of the winter; observing, in very cold weather, to line the frames closely about with dry litter; also every cold night, cover the glasses with mats or litter: though, in severe frosty weather, recourse must be had to the assistance of hot-beds, as below.

By aid of hot-beds a plentiful supply may be had in all weathers, making slender dung hot-beds, for frames and glasses, as observed in the early spring sowings, performing the sowing also, as there directed, and manage the bed in the same manner; being careful in time of severe frosts to line the frame all around close with dry litter, covering the glasses also every night with the same material, or with garden mats.

Thus far is the whole practical method of raising a plentiful supply of Small Sallading at all seasons of the year.

In gathering Small Sallading for use at all times of the year, let it always be used when quite young and in the seed-leaf, before they grow large and send forth rough leaves, more

especially the mustard, radish, and other rough-leaved kinds; and when thus young, they may be cut up quite close to the ground, stalks and top together, all of which will then eat very tender and palatable.

But when they become large, and the rough leaves begin to advance apace, they are unfit for Sallading, as being rank and hot to the taste, so should have always young successions.

Though cresses in particular, being of a different nature of growth from the mustard and radish kinds, are sometimes retained, in case of omitting sowing in proper succession, as they will shoot up again in small fresh leaves, which being gathered young, serve occasionally in default of a successional supply of young seedling plants; but are not eligible for any long continuance in this production, as the leaves will become tough, and rankly hot-tasted; so should generally raise fresh supplies from seed, as above advised.

To save seed of all the above sorts of Small Sallading, should generally sow a portion of each for that purpose, more or less, according to the demand of a family, &c. or in proportion where large quantities of the seed are intended for public supply; and the proper season for sowing for this occasion is March and April, either broad-cast and raked in lightly, or in drills, six or eight inches asunder, each sort separate; they will shoot up to stalks in May and June, and the seeds will ripen in July and beginning of August. See each sort under its proper genus.

SMILAX, Rough Bindweed.

This genus consists principally of shrubby climbers, mostly of the ever-green tribe for the shrubbery, &c. rising with trailing and cirrhone-climbing stalks, mounting by support many feet high, adorned with heart-shaped, oval, and lanceolate leaves, in the different species, and apetalous, dioecious flowers.

Class and order, *Diœcia Hexandria*.

Characters.] CALYX, male and female flowers on separate plants, having bell-shaped, six-leaved, spreading cups, which in the females are deciduous. COROLLA, no petals. STAMINA, six filaments, with oblong antheræ in the males. PISTILLUM, an oval germen, three very small styles crowned by oblong, reflexed, downy stigmas in the females. PERICARPIUM, a globular, trilocular berry, having two globular seeds.

There are above twenty species of Smilax, mostly of a shrubby, climbing growth, some hardy, and some of tender nature; but it is principally some of the hardy kinds that are esteemed for culture in our gardens, having long trailing stalks, some armed with prickles,

others are inermous, or unarmed, and mostly climb by means of cirrhi, or clasps, upon the adjacent trees and bushes, many feet high; which renders them proper furniture for extensive shrubberies, thickets, and shady plantations, &c. are all exotics from different foreign countries, both in Europe, Asia and America; and the following are the most noted species, consisting of several shrubby climbers, and one herbaceous kind, all for hardy plantations, and some shrubby sorts for the greenhouse, &c.

Hardy Kinds.

Of these sorts the first seven are shrubby, and the eighth is an herbaceous plant, all of the climbing tribe.

1. SMILAX aspera.

Rough Spanish Smilax, or Common Rough Bindweed.] Rises with many long, slender, angular, trailing, prickly stalks, climbing ten or twelve feet high; heart-shaped, indented, prickly leaves, having nine longitudinal nerves, and small bunches of white flowers at the sides and ends of the branches, succeeded by rough red berries.

Variety.] With black berries.

2. SMILAX Sarsaparilla.

(Sarsaparilla)—or Medicinal Virginia Rough Bindweed.] Rises with angular, prickly, climbing stalks; oval, obtuse, trinervous, smooth leaves; and small bunches of white flowers at the axillas, succeeded by red berries.

3. SMILAX tamnoides.

(Tamnus-like)—or Black-Briony-leaved Carolina Rough Bindweed.] Rises with cylindric, prickly, climbing stalks; large, oblong, heart-shaped, septemnervous, smooth leaves; and at the sides of the stalks loose bunches of whitish flowers, succeeded by black berries.

4. SMILAX laurifolia.

Bay-leaved Virginia Rough Bindweed.] Rises with round, prickly, trailing, climbing stalks; oval-lanceolate, thick, stiff, smooth, trinervous leaves; and at the sides of the stalks round bunches of flowers, succeeded by black berries.

5. SMILAX excelsa.

Lofty-climbing Oriental Smilax.] Rises with angular prickly stalks, climbing to the tops of the highest trees; heart-shaped, smooth leaves, having nine nerves; and at the axillas, small bunches of whitish flowers succeeded by red berries.

6. SMILAX lanceolata.

Lanceolate Virginia Smilax.] Rises with round, inermous stalks; lanceolate, or spear-shaped, smooth leaves; and small clusters of flowers succeeded by red berries.

7. SMILAX rotundifolia.

Round-leaved Canada Smilax.] Hath cylindric, prickly, climbing stalks; roundish, heart-shaped, acuminate, smooth leaves, having seven or five nerves; and small bunches of flowers, succeeded by small fruit.

8. SMILAX herbacea.

Herbaceous Virginia Smilax.] Hath herbaceous, angular, inermous, climbing stalks; oval, septemnervous, smooth leaves; and umbellate bunches of flowers, succeeded by small berries.

Green-House Kinds.

They are ligneous climbers, like the others, but in winter require the shelter of a greenhouse.

9. SMILAX China.

China Rough Bindweed, or China Root.] Hath a thick, fleshy root; cylindric, prickly stalks, climbing near twenty feet high; oval-heart-shaped, quinquenervous, unarmed leaves; and at the axillas of the stalks, bunches of small flowers, succeeded by red berries.

10. SMILAX Pseudo-China.

Bastard China Root.] Hath a large fleshy root; cylindric, inermous stalks, garnished with heart-shaped, inermous leaves, those on the branches being oblong-oval, and quinquenervous; and at the axillas, bunches of small flowers, succeeded by red berries.

All the above ten species of *Smilax* flower mostly in June and July; which in all the sorts are apetalous, and male and female on separate plants, produced commonly in bunches from the sides of the branches; are small and make no ornamental appearance, and the female flowers are succeeded by berries, but they rarely ripen in England.

These plants are perennial in root, and all the woody kinds are durable in stalk, and mostly retain their leaves the year round.

Their roots are mostly composed of many fleshy fibres spreading widely on every side, sending up many trailing stalks, which in most sorts being furnished with cirrhi, they thereby mount upon any neighbouring support.

In their native soil abroad, they grow naturally in woods and hedges, and thrive best under the shelter, shade, and support of trees and bushes.

The hardy sorts therefore are singularly adapted as furniture for thickets, groves, wildernesses, and borders of wood walks, planting them towards the front between the trees and shrubs, where they will run and spread very agreeably, exhibiting themselves as ever-greens all the year.

And the tender sorts being potted and placed in the greenhouse collection, allowing them support to climb upon, they will effect a proper diversity.

Method of Propagation.

First the hardy kinds.—They are propagated by slipping the roots, by layers, and by seed.

By slipping the Roots.—Many stalks rising from the roots widely around, the outer young ones of which may be readily slipped off with roots to each, which being performed in autumn or spring, may be planted either in nursery rows for a year or two, or at once where they are to remain.

By Layers.—The stalks being layed in autumn, &c. they will be well rooted and fit for transplanting by autumn following.

By Seed.—This is commonly obtained from abroad by the seedsmen in the spring, which may be sown, some in pots, and plunged in a hot-bed to forward their germination, otherwise they are apt to remain a year or more before they grow; and some may be sown in the full ground near the shade of shrubs, &c. in a bed of light dry earth, in drills, thinly, and covered about an inch and half deep, marking each row with a stick, because they will probably not come up till next year; giving however the common nursery care of weeding and watering the pots or beds till the plants are come up, which should have occasional shelter in frosty weather, and when two or three years old may be planted out, finally to remain.

Tender kinds.—Both the tender species may be propagated by layers, and by dividing the roots. Perform the laying in spring on the young shoots, which by autumn or spring following will be fit for potting off separately: and by roots, these being slipped in March or April, and the off-sets potted separately, will soon take root; managing the whole as other woody exotics of the green-house.

SMYRNIUM, Alexanders.

The plants are large herbaceous biennials and perennials, one of which is occasionally cultivated in the kitchen-garden as a culinary herb, used for stewing, fallads, &c. they all rise with large compound, triternate, and pinnated, many-lobed leaves from the root, and erect stalks, several feet high, crowned with umbels of flowers.

Class and order, *Pentandria Digynia*.

Characters.] **CALYX**, umbellate flowers, having the general umbel unequal, and the smaller ones erect, without any involucre, and scarcely visible cups.—**COROLLA**, a uniform, general umbel, composed of numerous florets, having each five spear-shaped petals. **STAMINA**, five small filaments with simple antheræ. **PISTILLUM**, a germen under each floret, two styles, having simple stigmas. **PERICARPIMUM**, none; a nearly globular,

streaked, two-parted fruit, with two moon-shaped seeds.

There are several species, biennials, and perennials, mostly plants of but little merit; one sort, however, a biennial, being formerly in estimation as a culinary herb, we will give its description and mode of culture, &c.

SMYRNIUM Olusatrum. (Biennial.)

Common Alexanders.] Hath a largish, down-right, white, fibrated, biennial root, sending up several large, triternate, many-lobed leaves, and upright stalks, dividing and branching four or five feet high, garnished with ternate, serrated leaves, having foot-stalks, and all the branches terminated by large umbels of white flowers.

This plant is a biennial, and is raised commonly from seed, which rising in spring with large leaves, remains till spring following, then shoots up stalks for seed, and perishes in autumn after.

The whole plant is of a strong, warm, somewhat aromatic nature.

It being blanched like celery is then fit for use as a culinary plant, and is also used for medicine without blanching; its leaves and seeds being used for that purpose.

It is propagated by seed sown in the spring in any light soil and open situation, in shallow drills, fifteen or eighteen inches asunder; and when the plants are come up two or three inches high, thin them to six or eight inches distance in the rows, to give them room to shoot up strong; when earth must be drawn up about them gradually, in order to blanch or whiten them a little below, and that they may be more crisp and tender for autumn and winter use; but as, in spring following, they will shoot out again vigorously, let some earth be hoed up close about each plant, and in three or four weeks they will be blanched for use.

SOIL, see **EARTH**, **COMPOST**, **DUNG**, **MANURE**, &c.

SOLANUM, Night-shade, comprehending also the Love-Apple and Potatoe.

This genus furnishes many herbaceous and shrubby plants for ornament and variety, and some herbaceous esculents for domestic use; consisting of annuals and shrubby perennials for adorning the pleasure ground, green-house, and stove collections, and herbaceous culinary plants for the kitchen-garden; some being long trailers, others are of erect growth, garnished with pinnated and simple leaves in the different species, and all the sorts adorned with small, rotated, five-parted flowers, succeeded by roundish, soft, baccaceous fruit, of various shapes, sizes, and colours, in the several species,

cies, &c. being in some sorts as large as apples and eggs, in others like cherries, and in some as small as currants; exhibiting in the whole a great diversity in their different growths, flowering, and fruiting, some proper to cultivate for variety and ornament, in their general growth, others, as singularly curious in the appearance of their fruit; some also, (*Love-apple*) for its said fruit to use as an esculent in culinary purposes, and some as most valuable esculent rooted plants, particularly that admirable species, the *Solanum tuberosum*, or Potatoe, for its large, tuberous, edible root, which is obtained for use, very beneficially, the year round.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is monophyllous, cut half through into five acute segments, and is permanent. COROLLA is monopetalous and rotaceous, having a short tube below, with a large, spreading, plicated limb, dividing into five spreading, pointed segments. STAMINA, five small connivent filaments, terminated by oblong, connivent anthers. PISTILLUM, a roundish germen, slender style longer than the stamina, having an obtuse stigma. PERICARPIUM, a roundish and oval bilocular fruit of the berry kind, of various sizes and forms in the different species, &c. and is filled with many roundish compressed seeds.

To this genus *Solanum* is now added the *Lycopersicon*, or Love-Apple, the *Melongena*, or Egg-Plant, and the *Potatoe*; they being found to be all of the Night-shade tribe, both in the characters and quality, which, according to Linnæus, is supposed to be more or less poisonous, not excepting the Potatoe, though in a very small degree; and may be said to be the wholesomest of all the sorts of Night-shade; there being numerous different species, ten or twelve of which are cultivated in the English gardens for variety and use; consisting of some herbaceous annuals, and one shrubby perennial for the pleasure-garden, &c. a few shrubby exotics for the greenhouse and stove, and herbaceous annuals and perennials for the kitchen-garden.

Annual Kinds for the Pleasure-ground.

The principal sorts are the Love-Apple and Egg-Plant, there being many other annual sorts of less note; some are common weeds in our gardens, particularly the common black-berried Night-shade, comprehending many varieties; however, the most material annuals under this head are the following.

1. *SOLANUM Lycopersicon*.

(*Lycopersicon*)—or *Wolf's Peach*, commonly called *Love-Apple*, or *Tomatoes*.] Rises with strong, herbaceous, unrimed, procumbent

stalks, branching numerous six or eight feet long; large, pinnated, rank-scented leaves, of four or five pair of cut lobes, and an odd one; and simple racemous clusters of small yellow flowers at the axillas, succeeded by large, roundish, depressed, furrowed, soft, red fruit.

Varieties are,] Common large-furrowed-fruited Love-Apple—Cherry-fruited Love-Apple, having smooth, round, red fruit the size of large cherries—Yellow cherry-fruited—Scentless leaved—Burnet-leaved.

This species and varieties are all of large trailing growth, and flower in June, July, and August, and the fruit ripens in September and October, when they appear both ornamental, and are fit for culinary uses, particularly the common large-fruited kind, which is in high estimation in some families for improving soups, also for stewing, and sauces, &c. likewise, both in its green and ripe state for pickling; for which purposes they are highly valued by the Spaniards and Portuguese in particular, by which people they are commonly called *Tomatoes*: so that this species is employed both as an esculent and ornamental plant; and in both cases its chief merit is in the fruit.

It is an annual in this country, whatever it may be in its native soil, which is the hot parts of America, but is hardy enough to succeed here in the open air in summer, being previously raised in hot-beds, thence transplanted; and as being of very rampant trailing growth, require the support of walls, pales, or stakes, which should also be in a sunny situation, otherwise the fruit will not ripen freely.

2. *SOLANUM æthiopicum*.

(*Æthiopian hard-fruited Love-Apple*.) Rises with erect, smooth, herbaceous stalks, dividing and branching half a yard high; garnished with oval repand-angular leaves, and drooping pedunculi from the sides of the branches, each bearing one white flower, succeeded by round, striated, firm, red fruit.

3. *SOLANUM Melongena*.

(*Melongena*)—or *Egg-fruited Night-shade*, commonly called *Egg-plant*, sometimes *Mad-Apple*.] Rises with an erect, thick, firm, herbaceous stalk, branching erectly two or three feet high; large, oval-oblong, entire, downy leaves; and blue flowers singly from the sides of the branches, having prickly cups, succeeded by large, oval, egg-like, pendulous fruit of different colours in the varieties.

Varieties are,] Common white-fruited Egg-plant,

plant, having large, white, fleshy fruit, the size and shape of a very large egg—purple-fruited Egg-plant—red-fruited—yellow-fruited—prickly-fruited, &c.

This singular species and varieties are all of upright firm growth, branching and forming full heads, well garnished with fine large leaves, and flowers in June and July, and the fruit attains perfection in August and September, being all of the large egg-shape; but the white-fruited sort is in most esteem as a curiosity, for its very great resemblance to a hen's or swan's egg, effecting a singular appearance as they grow on the plants; and in some warm countries in the south of Europe they are very commonly eaten, and are accounted wholesome: in England, however, they are not at all relished, so that the plants are cultivated only as a curiosity, and, as such, highly merit culture in the pleasure-garden.

These plants being natives of Asia, Africa, and the warm parts of America, require to be raised and forwarded in hot-beds in this country.

4. *SOLANUM nigrum*.

Common Black Night-shade.] Rises with an upright herbaceous stalk, branching a yard, or two or three feet high; oval, angular-indented leaves; and from the sides of the branches roundish nodding umbels of white flowers, succeeded by black and other coloured berries in the varieties.

This common black Night-shade is chiefly used as a medicinal plant; it grows wild in gardens, fields, and dung-hills in England, and most parts of the world, often becoming a troublesome weed, so is rarely cultivated; it, however, comprehends several varieties which were formerly considered as distinct species, but prove to belong all to the *Solanum nigrum*, having all oval leaves, and nodding umbels, and are sometimes cultivated in gardens for variety.

The different varieties are,] Common black-berried Night-shade, as above—large, upright, spreading, black Night-shade—greenish-yellow-berried—red-berried—villous, yellow-berried, with round, hairy branches, and angular somewhat hairy leaves—Guinea black-cherry-berried, with angular dentated branches, and smooth entire leaves—Virginia, upright, black-berried, with angular branches, and repand smooth leaves—Jew's black Night-shade, with prickly branches. All of which produce their flowers in nodding umbels in summer, succeeded by umbellate clusters of berries in autumn.

All the above four species and varieties are

herbaceous annuals, being mostly but of one summer's duration, particularly the Love-apples and *Melongena*; but several of the varieties of the *Solanum nigrum* will often continue all winter, if potted and placed in the green-house: however, an annual supply of the principal species should be raised every spring from seed; remarking, that the first three species, being exotics from hot countries of Asia, Africa, and America, require to be raised in hot-beds in spring for transplantation into the full air in summer; but the fourth sort being hardy, most of its varieties may be raised in the open ground.

Most of the above annuals may be employed in the pleasure-ground for variety, more particularly the Love-apples and Egg-plants; and the former also as culinary plants for their fruit as aforesaid; but the *Melongena*, or Egg-plant, having great singularity in their egg-like fruit, merit a place in every curious garden: as to the *Solanum nigrum*, or Black Night-shade, the common sort is never cultivated; but some of its best varieties may be admitted in large gardens to increase the variety; and if some are also planted in pots, trained up straight, and placed in the green-house in October, they will remain green all winter, and exhibit an agreeable variety during that season, with their umbels of ripe fruit.

Their Propagation and Culture.

As to the propagation and culture of all these annual Night-shades, they are all easily raised from seed sown annually in the spring; the three tender kinds in hot-beds, for transplantation in May or June, and most of the varieties of the *Solanum nigrum* in a warm border in April, also for transplanting.

For the tender kinds, Love-apples, and Egg-plant, prepare a moderate hot-bed in March or April, serving for these and other tender annuals, covered with a frame and lights, and moulded over within the frame with light rich earth six inches thick, or may sow them in any hot-bed already made for other plants, such as cucumber beds, &c. provided there is room, sowing the seeds either in the earth of the bed in small drills, or in pots and plunged in the hot-bed; and when the plants come up, indulge them with fresh air and occasional waterings, in common with the other plants of the hot-bed, and thin them where they stand too thick, that they may have room to gather some strength previous to their transplantation; or if they are pricked out upon a fresh hot-bed, it will forward them considerably, which is more particularly necessary for the Egg-plants.

Observe,

Observe, however, of the Love-apple kinds, in particular, that towards the latter end of May, when the plants are from about four to six or seven inches high, and the season is become tolerably warm and settled, plant them out finally in the full ground on some warm border, placing them singly at some considerable distance, on account of their large spreading growth; planting some also against a south fence, &c. to have the full sun, as well as for the advantage of training their trailing branches along regularly; for, unless they have support, they will trail upon the ground, and overspread the neighbouring plants, and not ripen their fruit; but being trained against some sunny fence like a wall-tree, or to a treillage or stout stakes, they will show themselves to proper advantage, and ripen their fruit more early and perfect, and exhibit it more ornamentally.

But the *Melengenas* being raised as above in a hot-bed, it is also advisable to forward them as much as possible by the farther aid of one or more hot-beds, in order to run the plants up to a large growth, and exhibit themselves and fruit in full size and perfection.

Therefore when those seedling egg plants are one or two inches high, having a fresh hot-bed ready, prick them therein about four inches asunder, or plant some in small pots singly, and plunge them in the hot-bed, giving water and occasional shade from the sun till they are fresh rooted, repeating the waterings as occasion requires, and admit a due portion of fresh air every mild day by tilting the upper ends of the lights; then, when the plants have been forwarded about a month in this bed, some may be thinned out with balls to their roots, and placed upon another hot-bed six or eight inches asunder, managing them as before; it will still forward them more considerably to a large stature for flowering and fruiting in perfection; observing, as they advance in height, to raise the frame by degrees in proportion: likewise in their advanced growth, and as the warm season approaches, begin to harden them gradually to the open air, in fine days; and towards the middle of June, the plants being grown tall and strong, and the season become warm and settled, they should be removed into the full air, finally to remain: when those growing in the earth of the bed may be taken up, with balls of earth to the roots, planting them either in the borders or in pots; and those already in pots may be shifted into larger, and placed to adorn fore-courts, or any other conspicuous compartments, where they will effect a cu-

rious variety, with their egg-shaped fruit, all the autumn season.

The hardy kinds, consisting of several varieties, (*Annuals*) the offspring of the *Solanum nigrum*, or Common Black Night-shade, are easily raised from seed, sown in the latter end of March or in April, mostly in a bed or border of light earth, separately, in small shallow drills, and the plants, when about three inches high, planted out about the borders and in pots: or they may be sown at once where they are to remain, in patches in the different compartments, and the plants afterwards thinned to one in each place; or may sow some of the foreign varieties, in particular, in a hot-bed, to raise and forward them more effectually, planting them out as above.—Thus, in either method, they will arrive to a flowering state in July, and produce their umbels of berries in autumn; observing, if designed to keep any of the more curious sorts as long as possible, they must be potted, and placed in the greenhouse, where they will remain all winter.

Hardy Shrubby Kinds.

There is one hardy shrubby species, comprehending some varieties, mostly wild climbing plants of the hedges, in England and most parts of Europe, but are retained in many gardens for variety.

5. *SOLANUM Dulcamara.*

Bitter-sweet, or Climbing Woody Night-shade.

Rises with long, flexuous, inermous, woody stalks, climbing, by support, many feet high; oblong, pointed leaves, with the upper ones halberd-shaped; and cymose clusters of small blue flowers, succeeded by bunches of small, oval, red berries.

Varieties.] Common blue-flowered, as above — White-flowered — Variegated white-striped-leaved — Gold-striped-leaved — African thick-leaved, formerly ranged as a distinct species, but proves to be only a variety of the *Solanum Dulcamara*.

They all flower in June, July, and August, and the berries ripen soon after.

All the varieties of this species are of the climbing tribe, and durable in root and stem, &c. but deciduous in leaf. The common sort grows wild in field-hedges, in most parts of Europe, climbing over the neighbour plants; and is often cultivated in shrubberies as a climber, in assemblage with the variegated sorts.—But the variegated kinds are in most esteem as garden plants, for the beauty of their elegant striped leaves, and are therefore much employed as climbers.

As to the African thick-leaved variety, it being tender, requires to be potted, and treated as a green-house plant.

All the hardy varieties, however, i. e. the common, and two striped kinds, &c. will grow freely almost any where in the full ground: the common sort, in particular, will succeed also in any close place, so is often planted even in towns and cities; and all these sorts, considered as climbers, are proper furniture for shrubberies, borders of shady walks, &c. groves, and thickets, and to run over arbours; allowing them support of stakes, or placed to climb upon bushes, &c. Allow the variegated sorts generally a dry and rather poor soil, otherwise they will be inclined to grow too vigorous, and become plain, that is, lose their variegation:—They are easily propagated by layers and cuttings, in autumn, winter, or spring, and they will all be well rooted by autumn following, and fit for transplantation, either in nursery rows, or at once where they are to remain.

Shrubby Green-house Kinds.

There are many tender shrubby sorts of the quality of green-house plants, some of which are retained in our gardens for ornament and variety; which being exotics from warm countries, must be kept in pots, in order for moving to shelter in winter.

6. SOLANUM *Pseudo-capsicum*.

(*Bastard-Capsicum*)—commonly called *Amomum Plinii*, or *Winter Cherry*.] Rises with a shrubby, upright, inermous, green stalk, branching numerously and erectly all around, three or four feet high, forming a regular head, garnished with narrow, spear-shaped, repandous leaves; and white flowers, in sessile umbels, from the sides of the branches, succeeded by many beautiful red berries, like cherries, appearing very ornamental all winter.

Variety.] With yellow berries.

Both the varieties are beautiful shrubby plants from Madeira, flowering in June, July, and August, and the fruit ripens in autumn and winter, which in both sorts are of the shape and size of common cherries, but not eatable; appearing very beautiful all the winter season; effecting a pretty variety in the green-house collection.

7. SOLANUM *sodomum*.

Apple of Sodom, Pomum Amoris, or Shrubby African Love-Apple.] Rises with a shrubby, prickly stalk, branching two or three feet high, having the branches also armed with spines; ob-oval, pinnatifid-sinuated, prickly leaves, with the segments obtuse; and large blue flowers in bunches, from the sides of the branches, having prickly calyces; succeeded by large, round, compressed, yellow fruit, the size of a small apple, ripening in winter.

8. SOLANUM *indicum*.

Indian Shrubby Night-shade.] Rises with a shrubby, prickly stem, branching two or three feet high, with the branches also armed with spines; wedge-shaped, angular, entire, somewhat hairy leaves, prickly on both sides; and longish bunches of blue flowers at the sides of the branches, succeeded by round, golden-yellow fruit, the size of cherries; ripening in winter.

9. SOLANUM *verbasifolium*.

Verbascum-leaved, Downy, American Night-shade.] Rises with a shrubby, inermous stem, branching a yard high, or more; oval, entire, downy leaves, and compound umbels of flowers at the axillas of the branches, succeeded by small round berries.

10. SOLANUM *sanctum*.

Palestine Shrubby Night-shade.] Rises with shrubby, prickly stems; oblique, egg-oval, repandous, downy, prickly leaves.

11. SOLANUM *mammosum*.

Dug-fruited Virginia Night-shade.] Rises with upright, herbaceous, prickly stalks; heart-shaped, angularly-lobated, hairy, prickly leaves; and inverted pear-shaped yellow fruit.

12. SOLANUM *quercifolium*.

Oak-leaved Peruvian Night-shade.] Hath angular, flexuose, inermous stalks; oblong, sinuate-pinnatifid leaves, and cymose bunches of flowers.

These seven tender species flower here in June, July, and August; and they all ripen their fruit abundantly in the end of autumn, and in winter.

They are mostly of shrubby growth, durable in root, stem, and branches, and retain their leaves most part of the year. The first two sorts are the most noted of these kinds in the English gardens, but the first sort most of all; however, all the sorts merit culture, to increase the variety in the green-house collection, as they will form a pretty diversity, both in their flowers and fruit, most part of the year, but particularly in autumn and winter, when the fruit ripens, which exhibits a very ornamental appearance.

Their Propagation and Culture.

The propagation of all these green-house sorts is principally by seed in a hot-bed in the spring, and the seed of the principal sorts may be obtained at the nurseries and seed-shops.

Therefore, in March or April, prepare some pots of rich light earth, in which sow the seed thinly, and cover it half an inch deep, and plunge the pots in any common hot-bed, under frames and lights, giving frequent refreshments of water, and the plants will soon come up, when a due portion of fresh air must be admitted daily, together with repetitions of

moderate waterings occasionally; and when the seedlings are about two or three inches high, it is advisable to prick them out upon another hot-bed; which being framed, and earthed six or eight inches deep, plant the seedlings therein, six inches apart, giving water, and shade from the sun, till rooted. It is also eligible to prick some out in small pots singly, and plunge them also in a hot-bed; observing in both methods to give frequent waterings, and admit a large share of fresh air every day, by tilting the lights; and as the warm weather advances, harden the plants gradually to the full air, so as towards the middle or end of June they may bear to be fully exposed; at which time those not potted may be taken up with balls, and planted in proper pots (twenty-fours), and the already potted plants shifted into larger, placing them in the shade for a week or fortnight; managing them afterwards as other shrubby exotics of the green-house.

Tender Shrubby Kinds for the Hot-House.

Under this head is comprised four or five tender shrubby exotics, from the warm parts of America and Africa, and require the aid of a stove to preserve them in this country; so are kept in pots, and placed in that department for variety.

13. SOLANUM igneum.

Fiery-thorned American Night-shade.] Rises with a shrubby prickly stem, branching a yard or more high, closely armed with fiery-red thorns; spear-shaped, acuminate leaves, revolute at the base; and simple racemous clusters of white flowers at the sides of the branches, succeeded by red, cherry-like berries.

14. SOLANUM guineense.

Guinea Night-shade.] Rises with a shrubby, inermous stem, branching five or six feet high, having also smooth branches; oval, entire leaves, and very slender lateral peduncles, terminated by branches of small white flowers, succeeded by round yellow berries.

15. SOLANUM tomentosum.

Tomentose Ethiopian Night-shade.] Rises with a shrubby, tomentose, prickly stem, branching two or three feet high, armed with acerose prickles; heart-shaped, repandous, inermous, woolly leaves; and bunches of small purple-dusted flowers, succeeded by golden-yellow fruit, the size of gooseberries.

This species is remarkable for its tomentose property, it being almost totally covered with down.

16. SOLANUM bahamense.

Bahama Night-shade.] Rises with a shrub-

by, prickly stem, branching several feet high, spear-shaped, obtuse, repandous leaves, reflexed in the margin; and simple clusters of blue flowers at the sides of the branches, succeeded by red berries.

17. SOLANUM trilobatum.

Trilobate Jamaica Night-shade.] Rises with a slender, shrubby, prickly stem, branching five or six feet high; wedge-shaped, mostly trilobate smooth leaves, and some with five lobes; and small white flowers singly, succeeded by small fruit, the size of elder-berries.

18. SOLANUM bonariense.

Bonarian Shrubby Night-shade.] Shrubby stalks; and wedge-shaped sinuated leaves.

All these tender shrubby *Solanums* for the stove collections must always be kept in pots of light rich earth, and retained most part of the year in the stove, except about two or three months in the heat of summer; and thus they will flower annually, and ripen plenty of fruit.

They are all propagated by seed in a hot-bed in the spring; sowing it in pots of light earth, and plunge them in the hot-bed or when the plants are come up two or three inches high, prick them separately in small pots, which plunge also in the hot-bed, or bark-bed, and manage them afterwards as other shrubby exotics of the stove.

Their propagation may also be tried by cuttings: planting them in pots, plunge them in the bark-bed, and cover them close down with a hand-glass.

Hardy, Herbaceous, Esculent Kinds.

Under this head is comprised only one species, Potatoe; having already mentioned a culinary species, among the tender annual kinds, viz. *Lycopersicon*, or Love Apple, sometimes cultivated as an esculent, as well as an ornamental plant; but the most valuable esculent in this genus is the *Tuberous-rooted Night-shade*, commonly called Potatoe, comprehending several varieties, all of hardy temperature, and which, for their fine, large, eatable roots, may be said to be the most profitable culinary esculents in the world, as they may be obtained in great plenty the year round, and are almost universally admired by all ranks of people; and in many countries are become a principal article of food among the common people. But Linnæus, and some other modern botanists, as we formerly remarked, considering all the Night-shades of the lurid tribe of plants, i. e. such whose foliage, &c. assume a gloomy-green colour, of an ominous aspect, thereby suppose the plants to be more or less poisonous; not excepting the potatoe, though in a very small

small degree: and it is said a dullness attends the constant eating of them, and sometimes a griping, more especially when any considerable quantity is boiled and eaten in broth or soups, before the juice has been previously boiled out in another water. However, when Potatoes are thoroughly well boiled, roasted, or baked, they prove a very palatable and wholesome root, either to eat alone, or as sauce to flesh-meat, though they are cooked in various ways, in all of which they are exceedingly profitable for the service of a family.

The botanists admit of only one real species of the Potatoe, comprehending several varieties, as above observed, differing in the form, colour, and other properties of the root, and colour of the flowers.

19. *SOLANUM tuberosum*.

Tuberous-rooted Peruvian Night-shade, commonly called Potatoe.] Hath a tuberous root, emitting numerous fibres, productive of many large roundish, and oblongish, fleshy, edible tubers; and immediately from the root rise herbaceous, flexuose, smooth stalks, somewhat erectly, a yard long, garnished with large pinnated leaves, of several pair of entire lobes; and terminated by subdivided peduncles, supporting bunches of small purple, or white flowers, in the different varieties, succeeded by roundish fruit, furnishing ripe seed in autumn.

It is the tubers of the root only of this plant that is eatable; the fruit, the product of the stalk, is never used in culinary preparations, only sometimes while green to pickle.

Varieties.] It comprehends two principal varieties, viz.—Red-rooted Potatoe, generally producing reddish or purple flowers.—White-rooted Potatoe, commonly bearing white flowers.—Each of which principal varieties comprise several intermediate ones, such as —Round-red—Oblong-red—Pale-red—Dark-red—Rough-red—Smooth-Red—Red and white—Early dwarf-red—Round-white—oblong white—Kidney-shaped white—Large red-ended white kidney-shaped—Early dwarf white—Large conglomerated American Potatoe, being generally clustered together considerably, each root or tuber attaining a prodigious large size, being in estimation principally for feeding cattle.

This species, *Solanum tuberosum*, is supposed to be originally a native of Peru, where the natives of the country commonly call it *Batatas*, and hence it here derived the European name Potatoe.

It may be considered both as an annual and perennial; observing in the first case, that the same individual root is only of one year's duration; for being planted in spring, each root

sends out numerous off-sets, becoming proper Potatoes by autumn following, at which time the said parent roots will be almost totally decayed; hence it becomes an annual: but in the second case, the off-sets of the parent root remaining sound till the next year, when they also furnish an abundant supply of off-sets, hereby the species is perpetuated in great abundance from year to year, and becomes of a perennial nature: remarking, however, that a fresh plantation must be performed every spring.

With respect to the properties of the different varieties of Potatoes for use, there is no very material difference; though the red sorts were formerly in greatest esteem, and, in our opinion, are equally good as the whites; though of late years, the Potatoe cultivators about London, and other parts who raise considerable quantities annually, generally prefer the round, and oblong white, or whitish-red sorts and kidney kinds, as being esteemed to be both more prolific in produce, more saleable in market, as well as the finest eating Potatoes, therefore they have almost totally neglected the culture of the fine large red Potatoes, which by many are held superior to the others for richness of flavour. It is, however, proper to cultivate a due share of the best sorts of each kind, all of which are raised in great plenty by cuttings of the roots; that is, the Potatoes cut into several pieces, and being planted in the spring, each multiplies into a large cluster of new Potatoes, fit for use the following summer, autumn, and winter; sometimes the early sorts will be fit to take up for use in June or the beginning of July, of the size of large walnuts; only small quantities at a time in this early growth, just for immediate use, as they will not keep good above a day or two: but towards the latter end of July, and in August, they will be grown to some tolerable size, when they may be taken up in larger supplies; and in September the roots will have attained almost full growth and maturity, to dig up in more considerable quantities as may be required; though not in general in the later main crops for long keeping, till October; so may continue lifting some occasionally as wanted, from June or July, till October afore-said, or beginning of November, when the main crops will be full grown; at which period of growth, and not before, they are in the highest perfection; and the moderately large full-grown Potatoes are considerably finer eating than the small ones, which generally eat waxy, livery, and watery, entirely devoid of that fine rich mealy flavour peculiar to large full-grown Potatoes, nor are they altogether so wholesome for general use.

Observations on their general Culture.

Potatoes may be obtained for use plentifully almost the year round; the early sorts being planted forward in the spring, they often afford tolerable little Potatoes fit to take up in June and July following, as formerly observed, especially in the rich warm grounds about London, where they generally begin taking them up for market in June, before they are a quarter grown, or as soon as they attain the size of good walnuts, and thence continue taking them up occasionally till the general crops arrive to full growth in the latter end of October; both because early Potatoes fetch an extra price, and that the ground may be cleared time enough for the reception of some other crops, such as turneps, cole-worts, cabbage, favoys, &c. for winter, in which there is a double advantage; which may also be practised in private gardens, taking up small quantities at a time, just for the immediate supply of a family; suffering, however, great part of the main crops of Potatoes to remain untouched until September and October, to attain mature growth, and thereby obtain the roots in their ultimate perfection, both for eating and long keeping: for Potatoes that are taken up before they have had their full growth, consequently prove inferior both in size, quality and duration; but some of the main crops being permitted to continue growing till autumn, about the latter end of October, or beginning of November, as above said, till the stalks or haulm begin to decay, the roots will be arrived to full maturity; and being then taken out of the ground in due time, and housed in some close dry apartment, they will keep in good perfection for eating all winter and spring, until the arrival of the new crops next summer.

All the varieties of Potatoes may be cultivated with success in any open situation, both in gardens and the open fields; very considerable quantities being now cultivated in the fields round London, and most other great towns, for the supply of markets, they proving very beneficial crops; and some of the main crops in fields being cleared off in due time, the ground is often sown with wheat, which generally succeeds remarkably well immediately after Potatoes.

As to the American Cluster-Potatoe, it generally grows to a vast size, in a conglomerated or clustered manner, each often weighing several pounds, and at present is cultivated chiefly for feeding of cattle. Its culture is the same as the common sorts, only requires more room to grow.

All the sorts delight in a moderately light

dry soil, and open situation, and if enriched with dung, the greater success may be expected.

The plants are propagated most commonly by the root, *i. e.* the Potatoe, either whole or cut in pieces, each cutting forming a proper set or plant: and being planted in March or April, in rows two or three feet asunder, twelve or eighteen inches apart in the rows, and four or five inches deep, they come up in a month or six weeks after, requiring no other culture than a little hoeing to kill the weeds, and loosen the ground; and each set will thus multiply into a large cluster, just within the surface of the earth, attaining full growth the same year, fit to dig up for use in autumn, continuing good till summer following. See their *General Method of Propagation*, &c.

As Potatoes, therefore, are the most profitable of all our esculent roots, and being of easy culture, their cultivation merits universal attention for the service of families of all ranks, and are now in many places cultivated to great advantage for the supply of the markets, where they always prove a very saleable commodity.

General Method and Season of Propagation, proper Soil, &c. and Method of Planting.

The general method of propagating Potatoes is by the root or Potatoe itself, being the tuberos eatable part of the root, and the only part to plant for propagation; and which may be planted either whole or cut in pieces, as formerly mentioned, and each planted separately at certain distances, directed below.—Potatoes may also be raised from seed, by way of experiment, to gain new varieties: by roots, however, is the only eligible method of propagation for general culture.

First by Roots.—As we above observed, the propagation by roots being by planting the tubers or Potatoes themselves, a proper quantity should be procured in due time in the spring for planting, observing always to procure the finest moderately large roots of the respective varieties for sets; though some use only the small chats for planting; but we have always found that the middling, or full-sized roots, generally yielded the largest Potatoes in return. Likewise observe, that it is of much importance to change your sets; that is, not always continue using those of your own crops, or of any other place constantly, but every two or three years at most procure a fresh parcel of some different distant growth, which will be found of great advantage, both in preventing a degeneracy, and in the goodness of the crops; remarking likewise, the sets

sets, when small, are sometimes planted whole, but more generally each cut in three, four, or more pieces, preserving one or more eyes, or buds, to each cutting: they, however, should not be cut until just the time for planting.

The general season for planting Potatoes is from about the middle or the latter end of February to the middle of April; remarking that the early sorts, &c. for forward crops, may be planted in the latter end of February, and early in March, in a dry warm situation; but for the general crops, March, and the first fortnight in April, is the most eligible planting season; especially in moist land, as if planted earlier, and much wet should succeed, it might rot the sets, more particularly if cuttings: though in cases of necessity, where the ground is not ready, &c. Potatoes may be planted any time in April, or even in May, and will yield tolerable crops by October: however, those planted towards the middle or latter end of March, and early in April, are principally to be depended on for the main crops to attain full perfection.

Observe, as to the proper situation and soil in which to plant Potatoes, always allow them an open exposure, and tolerably dry situation; and as to soil, they are generally the most prosperous in a moderately light pliable ground; none better than a good sandy loam, in which they commonly yield fine crops: however, chuse any the most convenient moderately light land, of a pliant free-working nature, and not wet; and most generally such as has been in constant digging or ploughing before, or occasionally in grass-sward; observing in the former case, that if the ground be rather poor, be sure to bestow a good coat of dung, to be dug or ploughed in; but if the ground is in sward, and a fresh good soil, hardly any dung will be required; for the sward being dug or ploughed in properly, it generally answers the purpose of dung the first year, and is commonly productive of excellent crops.

The ground may either be dug or ploughed for the reception of the plants. The digging is generally the most practicable for gardens, and being performed one full spade deep will be sufficient; and as to the ploughing, this is commonly practised for large quantities in fields, being careful to plough the full depth; and, if not grass-ground, if ploughed again cross-ways it will be the greater advantage; or in stubborn land, two or three ploughings may be necessary to divide and break the soil properly, performing the first ploughing in autumn or beginning of winter, and cross-ploughed in spring to

wards the time for planting; and if after the ploughing, the surface is rough and stubborn, a good harrowing will be proper for the better reception of the plants.

Then with respect to the method and order of planting the Potatoes, they are planted either with a dibble, or holed in with a spade, or drilled in with an hoe, &c. as hereafter explained, in rows two feet asunder, twelve or fifteen inches distant in each row, and not more than four or five inches deep, as directed below; remarking, however, the American clustered Potatoe in particular should generally be allowed a yard distance between the rows; but some advise all the sorts to be planted at that distance in the field-culture, in order both to admit of horse-hoeing frequently between the rows, to loosen the surface of the earth effectually, and to allow a greater scope for growth, and a more free admission of sun and free air, to give all the chance possible for improving the size of the Potatoes; however, two feet is sufficient.

But as to the particular methods of planting them, the following are occasionally practised, &c. dibble planting, drill planting, holing-in-planting, and bedding-in-planting.

By Dibble-planting.—This being the most general method may be performed either with a common large garden dibble, blunted at the bottom, making holes therewith about four or five inches deep, at the distance before mentioned, dropping one set in each hole as you go on, and striking the earth over them; but those who plant large quantities in fields, have generally a Potatoe-dibble for this purpose, being a large long dibble, about a yard in length, with a cross handle at top for both hands, having the lower end thick, blunt, and shod with iron about six inches up, the iron being also obtuse or blunted at the lower end: and about four or five inches from the bottom is fixed an iron shoulder, cross-ways, three inches length on each side, ranging parallel with the top cross-handle; both for the convenience of a tread for using the feet occasionally to thrust it into the ground, and that by striking it in always to the shoulder, it makes the holes all an equal depth. With this instrument one person is employed in making the holes a foot or more asunder, whilst another follows close after, and immediately drops one Potatoe-set in each hole; then the ground is well raked or harrowed over to cover in all the holes properly. But in gardens, where only moderate quantities are planted for family use, the dibbling-in the sets may be performed with any common garden dibble, thick and blunt at the lower end as hinted above;

above; and one person may both dibble the holes and drop the sets as he goes on, striking the earth in upon them with the dibble, and afterwards rake the ground.—See the articles *DIBBLE* and *PLANTING*.

By *Drill-planting*.—Drills may be formed either with a large hoe or plough, two feet asunder, and four or five inches deep, in which drop the sets, a foot asunder, and cover them in with the earth equally the depth of the drill.

By *Holing-in-planting*.—This is performed with a spade. A man, having a light handy spade, and beginning at one end of the line, takes out a spit of earth, forms a small aperture four or five inches deep, another person directly following after drops a set in the hole, the earth of the next spit immediately covers it up, and so on to the end.

By *Furrow-planting*.—This is sometimes performed in fields, in very light pliable land, and is performed by dropping the sets in the furrow immediately after the plough, and the ploughing of the next furrow turns the earth in upon the sets of the first; and in another furrow two feet from this, drop another row of sets, which are covered in as above; and so on till the whole is finished.

By *Trenching-in*.—This is sometimes practised in gardens, in light ground, by way of experiment, and is effected as they proceed in digging or trenching the ground, being trenched in the common way, each trench two spades wide, and one spade deep, placing one row of Potatoes in each trench. Beginning, therefore, at one end of the ground, open a trench the proper width and depth, as above, then pating in the top of the next trench deeply, together with some good dung in the bottom of the first, levelling it evenly; then digging along about half the width of the next or second trench, turn the earth into the first upon the dung, only two or three inches deep, and upon which lay the Potatoe-sets in a row along the middle a foot or more asunder: then digging along the rest or whole width of the said second trench a moderate spade deep, turning the earth thereof into the first trench, over the sets, three or four inches deep; this done, dung the bottom of the open trench, and proceed with the digging and planting as before; and thus continue trench and trench to the end.

By *Bedding-in*.—This is sometimes done in low wettilsh land, for the sake of raising the beds, and sinking the alleys deep enough to drain off the too copious moisture, and is thus performed. The ground is divided into four, five, or six feet wide beds, with alleys two or three feet wide between bed and bed; and the

beds being digged, the Potatoe sets may then be placed upon the surface in rows lengthwise; and then dig out the alleys a spade deep, casting the earth thereof over the sets about three or four inches thick; or the alleys may be first digged out to raise the beds, and the sets then planted with a dibble in the common method. Thus, by either of these methods, in wet ground, the alleys being sunk, and the beds raised, the alleys drain off the redundant moisture, which might rot the sets before they begin to sprout.

In the above method of planting in beds, it is sometimes performed on grass sward; marking out beds as above, with alleys between, of proportionable width; then, without digging the beds, the Potatoe sets are placed immediately upon the sward, at proper distances; the alleys are then digged, and the spits turned grass-side downward upon the beds, over the sets, covering them the proper depth as above, in which, if any additional depth is wanted, it may be supplied from the under earth of the alleys; and thus the sets being between two swards, they will grow, and often are productive of very good crops, if permitted to have full growth; and when proceeding to take them up, may readily turn off the top sward under which to gather the produce.

But Potatoes are occasionally planted in some other different methods by way of experiment, such as planting them in small clumps of three, four, or five sets together, fifteen or eighteen inches asunder, and five or six feet between the clumps; so that when the plants shoot into stalks a foot or two long, these are layed down along in the ground in different directions, and earthed over three or four inches, repeating the layings once or twice as the stems advance in length, earthing them over as above; they striking root in the ground, produce Potatoes accordingly their whole length as far as they are layed in the earth.

But in all the above methods of planting Potatoes, those of dibbling-in, drilling, and holing-in, &c. in continued rows, are the most in practice; and more generally, the ground being properly prepared by digging or ploughing, the dibbling them in being the most ready and expeditious, is the most commonly practised.

Culture of the Plants.

The Potatoes being however planted in either of the above methods, it now remains to speak of their future management; observing, therefore, they are to remain in the same place to grow to perfection; and as to culture, when the plants come up, and weeds begin

begin to over-run the ground, they require only two or three hoeings to kill the weeds, and loosen the surface of the soil; the Potatoes generally coming up in about a month or five or six weeks after planting, being generally accompanied by numerous weeds, which should be hoed down in due time, before they grow large and overspread the surface, or over-top the plants; performing the hoeings generally in dry weather by broad-hoeing, or in fields by horse-hoeing, for the greater expedition; repeating the hoeings according as the future growth of weeds shall render it necessary, as well as to stir and loosen the surface of the ground about and between the plants, which will also prove very beneficial culture in improving their general growth. After, however, two good hoeings, the plants will generally be advanced sufficiently out of the reach of weeds, and become so spreading as to prevent their future progress, when no farther care will be required till the Potatoes are arrived to perfection. In hoeing Potatoes, many take the pains to hoe up a ridge of earth close to each side of every row of plants in the first or second hoeing, to strengthen their growth more effectually, and render them more prolific, as the bottom of the stalks, so landed up, generally emitting roots in the earth that become productive of Potatoes the same as the principal roots.—Thus far is the principal culture of Potatoes, they hardly ever requiring any farther care after June and July; but the crops, however, continue growing till autumn, and the main crops in particular, which you design shall stand to have their full growth, will continue growing till October, or till the haulm begins to decay in November, when the Potatoes being full grown, they should be then wholly taken up before they are attacked by frost, and deposited in some dry apartment for keeping; remarking, however, as we before observed, that new Potatoes being by many required as forward in the season as possible; and sometimes the early sorts, growing in warm rich land, afford young Potatoes in June and July, as big as walnuts, or little apples, in which case may begin to dig up some for present use; though only a few should be taken up at a time at this early season, just by way of rarity, not more than can be used in a day or two; for, being not a quarter grown, they will not keep long out of the ground; if even but a few days, they will neither boil, bake, or eat well; but as before intimated, they in the more advanced part of July and in August, will have attained some considerable growth, to take up in large quantities; so may continue

thus taking up a few at a time occasionally, so as to have a constant supply from June or July, till the perfection of the general crops in September, October, and November.

Method of digging them up, and housing them for Winter and Spring Use.

As to the method of digging up the Potatoes for use, it is most commonly performed in gardens with a three-tined fork; and some times in fields they are ploughed up for the sake of making quicker dispatch for considerable quantities; but the forking them up, however, makes the cleanest work; and there are Potatoe-forks for the purpose, being made with flat tines, blunted at the point, and fixed upon a spade-handle. Most country smiths know how to make them; and are sold at the iron-mongers, and at many of the nurseries.

Previous to the digging up the Potatoes, the haulm should be cleared away for some considerable space close to the ground, turning it off in heaps, to clear the surface, for the greater convenience and expedition in digging, &c. then, if intended to fork them up, proceed by first opening a trench along one end of the ground one spade wide and deep, and then go on with the digging up the Potatoes the same depth, having large baskets, &c. placed, in which to throw them as they are digged up, being careful to dig all the ground regularly along spit and spit, the bottom part of the haulm remaining to each root will be some direction for placing the fork, turning the spits clean up before you into the open trench, and pick the Potatoes of each plant clean out, great and small, as you go on, and put them in the baskets. As you advance with the digging, continue clearing off the haulm upon the dug ground in heaps, which may afterwards be burned to serve as manure, and thus proceed till the whole is digged up, taking the opportunity, whilst dry, to house those directly that are intended for long keeping.

The taking up Potatoes by the plough is performed by ploughing the ground in the common method, which turns up the Potatoes very expeditiously to the top, several hands following immediately after to pick them clean out.

Immediately after the Potatoes are taken up, pick out all the cut and bruised ones; likewise may sort out the small chats from the large ware, and then let the main crops for keeping be housed, when they are perfectly dry, in some dry close place, well defended from the free air, wet, and frost, in which the Potatoes may be deposited in a large heap, if brought.

brought in quite dry; previously clearing them from all adhering earth and fibres, &c. for the drier and cleaner they are housed, it will prove advantageous in keeping them in greater perfection, covering the whole, however, at last, with a good thickness of dry straw, and keep the apartment close shut; for the more the external air is excluded the better they will keep.

Thus the main crops of Potatoes being taken up and housed, they will remain sound all winter and spring, till the arrival of new ones next summer, as we before remarked, provided they are well defended, as above, from wet and frost.

It is, however, to be remarked, that at the approach of spring, January, February, March, and April, many of the Potatoes will vegetate and sprout forth in the house, so should be turned over occasionally, and still continue a thick covering of straw, to exclude the external air as much as possible, and they will keep till June.

Raising them from Seed.

By Seed.—This is very rarely practised, because their great increase by roots render it unnecessary; besides, the propagation by roots is considerably the most expeditious and effectual method: so that raising Potatoes from seed is only sometimes practised by way of experiment, and to try to gain new varieties. However, when this is intended, let some of the first flowering-plants be marked for seed, which gather in autumn when full ripe, and in March or April following sow it in some light soil, in an open situation, in shallow drills, a foot asunder; and when the plants come up, keep them clear from weeds till autumn, when, about the end of October or beginning of November, take up the roots, select the finest and largest, which preserve in sand till spring, then plant them in the common way, and by autumn following they will have made proper increase, and attain full perfection; and you will then judge of their properties.

SOLDANELLA, Soldanel. A low herbaceous perennial plant, garnished with kidney-shaped leaves, and bell-shaped flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX, five-parted, lanceolate, and persistent. COROLLA, monopetalous and campanulated, with the border cut into many acute segments. STAMINA, five subulate filaments, topped with arrow-shaped antheræ. PISTILLUM, a roundish germen, style slender, crowned with a simple stigma. PERICARPUM, an oblong taper capsule, of one cell, containing a number of small, pointed seeds.

There is but one species,

SOLDANELLA alpina.

Alpine Soldanel.] Hath a fibrous perennial root, with leaves almost kidney-shaped, about an inch wide, standing on long foot-stalks; between these arise naked flower-stalks about four inches high, each supporting two purple bell-shaped flowers, with their border divided into many small segments, which are succeeded by capules, containing the seeds.

Varieties.] With blue flowers—with white flowers—with flowers very much fringed.

These plants make a pretty appearance in March, they require a moist soil and shady situation, but should have some protection in winter, and are propagated by parting the roots early in autumn.

SOLIDAGO, Golden-Rod. (*Virga aurea.*)

It comprises many herbaceous flowery perennials, of upright growth, for adorning the pleasure ground; rising with numerous erect stalks, from one to several feet high, garnished mostly with narrow, spear-shaped, and oval leaves, and the top terminated by numerous spikes of small, compound, radiated, golden-yellow flowers.

Class and order, *Syngenesia Polygamia Superflua*.

Characters.] CALYX, a compound radiated flower, having an oblong imbricated cup, composed of several narrow connivent scales. COROLLA is compound and radiated, having numerous funnel-shaped, quinque-dentate, hermaphrodite florets in the disk, and tongue-shaped, tridentate, female florets in the radius. STAMINA, five short hair-like filaments, with cylindric antheræ. PISTILLUM, an oblong germen, filiform style, crowned with a bifid stigma, and in the females two revolute stigmas. PERICARPUM, none. SEMEN, a single oblong seed in each floret.

The species of Golden-Rod are very numerous, but not more than ten or twelve are of estimation for our purpose, one of which is a native of England and most parts of Europe, and most of the others are from North America; but all the sorts are very hardy, and retained in our gardens as flowering plants.

They are all fibrous-rooted perennials, that renew their stalks annually in spring.

The species most common are,

1. **SOLIDAGO Virga aurea.**

(*Virga aurea*)—or *Common Golden Rod.*] Rises with several angular, slender, almost flexuose stems, from one to two feet high, garnished with narrow spear-shaped leaves, and

and divide upward into paniculated, erect, clustered spikes of golden-yellow flowers, in August and September.

Varieties.] Tallest Purple-stalked.—Broad sawed-leaved, — Narrow slightly-sawed-leaved, — Low-stalked, &c. — Each of which was formerly ranged as a distinct species, but prove to be varieties only of the common *Virga aurea*.

This species and varieties grow naturally in many parts of England, &c.

2. *SOLIDAGO canadensis*.

Canada Rough-leaved Golden Rod.] Rises with several round smooth stems, two feet high; narrow, rough, trinervous, slightly-ferrated leaves, and terminated by corymbose panicles, with recurved spikes of ascending yellow flowers, appearing in July and August.

3. *SOLIDAGO altissima*.

Tallest, Late-blowing, American Golden Rod.] Rises with numerous round smooth stems, four or five feet high; spear-shaped, sawed, enervous, or unveined leaves, and terminated at top by large corymbose panicles, with recurved spikes of ascending yellow flowers, in September and October.

Varieties.] There are many varieties of this species, differing somewhat from one another, but distinguishing themselves specifically, as this sort, by their tallish growth, enervous or unveined leaves, and large corymbose - paniculated recurved clusters of flowers, as above, flowering late in autumn.

4. *SOLIDAGO latifolia*.

Broad-leaved Canada Golden Rod.] Rises with erect angular stalks, two or three feet high; broad, oval, sharp-pointed, sawed leaves, and lateral single spikes of yellow flowers, appearing in September.

5. *SOLIDAGO flexicaulis*.

Flexible Canada Golden Rod, with a Fig-wort Leaf.] Rises with slender flexuose stalks, two feet high; oval, sharp-pointed, ferrated leaves, lateral single spikes of pale-yellow flowers, in September.

6. *SOLIDAGO mexicana*.

Mexican Golden Rod.] Rises with oblique brown stalks, a foot and half high; spear-shaped entire leaves, and erect, branching, leafy peduncles, bearing yellow flowers in August and September.

7. *SOLIDAGO caesia*.

Grey Smooth-stalked Maryland Golden Rod.] Rises with naked smooth stems, a foot and half high; garnished with narrow, spear-shaped, acute-pointed leaves, and terminated by corymbose panicles of yellow flowers, the spikes thickening above, appearing in September.

8. *SOLIDAGO lateriflora*.

Lateral-flowering American Golden Rod.] Rises with small stalks a foot and half high; narrow, unferrated, pointed leaves, and the stalks branching laterally below, almost from bottom to top, in floriferous spikes, shortening, and terminating upwards in corymbose panicles, with recurved spikes of yellow flowers, in September.

9. *SOLIDAGO rigida*.

Stiff-leaved, Pennsylvania Golden Rod.] Rises with many upright stalks, two feet high, branching alternately; oval, stiff, rough, cauline leaves, and the stalks and branches terminated by a corymbus of yellow flowers, in September.

10. *SOLIDAGO novaboracensis*.

New York Golden Rod.] Hath oval, oblong, radical leaves, having foot-stalks, branching naked stalks, near two feet high, garnished with very small leaves, and terminated by panicles of bright-yellow flowers, in September.

11. *SOLIDAGO minuta*.

Least Pyrenean Golden Rod.] Rises with small single stalks, only about a foot high, spear-shaped entire leaves, and the pedunculi rising at the axillas, each supporting but one yellow flower, appearing in August.

12. *SOLIDAGO sempervirens*.

Ever-green, Fleshy-leaved, New York, Golden Rod.] Rises with several upright reddish stalks, five or six feet high; spear-shaped, almost fleshy, smooth leaves, with roughish margins, and the stalks terminated by large corymbose panicles of bright-yellow flowers, appearing in October, and great part of the winter, in mild seasons.

All these twelve species of *Solidago* are very hardy fibrous-rooted perennials, of great duration in root, but mostly annual in stalk, which rising in spring, many from each root, arrive to a flowering state in summer and autumn; all the stalks adorned upward with long spikes of numerous small flowers, exhibiting a very conspicuous bloom a month or six weeks, or two or three months in different species; and totally decay to the root in winter.

They are so hardy as to prosper in any common soil and situation, with but very little trouble in their culture.

Considered, therefore, as garden furniture, they are proper autumnal ornaments for almost every compartment of the pleasure ground, and should be introduced in assemblage in all large borders, shrubberies, wilderness quarters, and the borders of wood-walks, &c. where, being judiciously distributed

buted at eligible distances, they will effect a grand autumnal bloom for three or four months, in the different sorts, as each root generally sends up numerous stems close together, often forming a large bush, adorned above with numerous long panicles of golden-yellow flowers, which, though separately small, they being numerous and closely placed in each spike, are remarkably conspicuous and ornamental, particularly all the foreign kinds.

The flowers in all the sorts are compound and radiated, composed each of numerous hermaphrodite and female florets, as expressed in the *Characters*.

Most of these plants increase exceedingly by the roots, a small slip of which often multiplies, in one season, into a large bunch; and several of the sorts being apt to spread considerably, require to be slipped, or cut in all round every year or two, to keep them within proper bounds.

They should, therefore, be always planted at some considerable distance from one another, and not too near small plants.

Method of Propagation and Culture.

The propagation of all the sorts is effected with great facility, by slipping or parting the roots in autumn and winter, soon after their stalks decay, or early in spring, before they begin to shoot; not slip them too small; and may be planted at once where they are designed to flower, and will all blow in good perfection the following summer and autumn.

All the culture they require is to have the decayed stems cut down every winter; and when the roots have increased considerably spreading, should be slipped or cut in all around, as before observed.

SOPHORA, (Sophora.)

In this genus are comprehended several species of herbaceous flowering perennials for the pleasure ground, and tender shrubby exotics for the hot-house; growing two or three, to four, five, or six feet high, in different species; adorned with compound pinnated, and some with simple leaves, and papilionaceous, quinquepetalous, blue, yellow, and other coloured flowers produced in lateral and terminal spikes.

Class and order, *Decandria Monogynia*.

Characters.] CALYX is monophyllous, short, bell-shaped, divided at top into five oblique, blunt segments. COROLLA is papilionaceous, of five dissimilar petals, consisting of an oblong vexillum, broader at top, reflexed at the sides; two oblong wings appendiculated at the base, and the carina form-

ed of two petals, like two wings joining at their lower edges. STAMINA, ten distinct awl-shaped filaments, inclosed in the carina, topped with very small assurgent antheræ. PISTILLUM, an oblong cylindric germin, one subulate style, situated as the stamina. PERICARPIUM, the germin becomes a very long, slender pod, filled with many roundish seeds.

The species of principal note are the following; consisting first of three herbaceous perennials for the pleasure garden, and several shrubby and other kinds for the stove hot-house.

Hardy Herbaceous Kinds.

Comprises three species of perennial exotics, of moderately hardy growth, to introduce in the borders, &c. as decorative flowering plants.

1. *SOPHORA alopecuroides.*

Fox-tail-like, Oriental Sophora.] Hath a creeping perennial root, sending up erect, firm stems, three or four feet high; pinnated leaves of many pair of small oblong folioles, terminated by an odd one; and the stalks producing lateral and terminal spikes of blue flowers, in July or August.

2. *SOPHORA tinctoria.*

Tinctorious Yellow Virginia Sophora.] Hath a perennial root, sending up many weak procumbent stalks, leaves composed of three roundish lobes, united at the base, and supported on very short foot-stalks, and lateral and terminal short spikes of yellow flowers, in July; succeeded by ripe seeds in autumn.

3. *SOPHORA tetraptera.*

Four-winged-podded Sophora.] Hath a creeping perennial root, upright tree-like stalks, pinnated leaves, formed of several oblong, pointed, opposite folioles, terminated by an odd one, and spikes of large, rich-yellow flowers, in May or June; succeeded by long, membranous, quadrangular, winged pods.

The above three species are proper to introduce in pleasure grounds, as ornamental flowering plants; allotting them some dry warm compartments: and some plants of the third sort in particular should be trained against a warm wall, where they will flower in the fullest perfection, and being rather tenderish, may be covered in severe weather, to preserve them more effectually.

All the three sorts may be planted in autumn or spring; and they will flower very conspicuously in summer, in their respective seasons, May, June, July, August, in the different species.

They are propagated by parting the roots in autumn or spring, and also by seeds in the latter-mentioned season.

Tender

Tender Kinds for the Stove.

These consist principally of elegant shrubby exotics, from Asia, Africa, and America, all of the most tender temperature, requiring the protection of a hot-house in this country; growing four, five, or six feet high, garnished with pinnated and simple leaves, and lateral and terminal spikes of flowers very ornamentally in summer and autumn.

4. *SOPHORA tomentosa.*

Tomentous Silvery Sophora of Ceylon.] Rises with an upright, branchy, downy stem, five or six feet high; garnished with pinnated woolly-silvery leaves, composed of five or six pair of roundish folioles; and spikes of yellow flowers, succeeded by cylindric, woolly seed-pods.

5. *SOPHORA biflora.*

Two-flowered African Sophora.] Groweth with upright stalks, ob-oval, somewhat downy simple leaves; and peduncles having two flowers.

6. *SOPHORA heptaphylla.*

Seven-leaved Indian Sophora.] Having pinnated leaves, composed of seven smooth folioles.

7. *SOPHORA microphylla.*

Small-leaved Otaheitean Sophora.] A plant of elegant growth, adorned with pinnated or winged leaves, composed of numerous very minute, roundish, smooth pinnæ, about a quarter of an inch long, of a dark-green colour.

The following are less noted kinds,

8. *SOPHORA angulata.* — Angular-leaved Sophora.

9. *SOPHORA alba.* — White-flowered Sophora.

10. *SOPHORA lupinoides.* — Lupine-like Sophora.

11. *SOPHORA capensis.* — Cape Sophora.

Most of the above tender *Sophoras* are very elegant plants, all originally from distant hot countries, and cannot be cultivated in these parts, without having a constant residence in our hot-houses or stoves, in which, being potted in good mellow light earth, they will grow very agreeably, and form an elegant variety at all seasons.

They are propagated by seeds sown in the spring, in pots plunged in a hot-bed, under glasses, or in the bark-bed; and when the seedling plants are a little advanced in growth, transplant them into separate pots, watered and placed in the bark-bed till fresh rooted, and continued always in the stove; and have the culture in common with other exotics of that department: may also try the propagation by

layers and cuttings, by similar assistance as above.

SORBUS. Sorb, or Service-tree

This genus is composed of noted deciduous trees, of middling stature, principally for ornamental plantations; growing from twenty to thirty or forty feet high, or more, adorned with beautiful pinnated leaves of many pair of folioles, and pentapetalous flowers in umbellate clusters towards the ends of the branches, succeeded by large bunches of red berries.

Class and order, *Icosandria Trigynia.*

Characters.] **CALYX** is monophyllous, concave-spreading, quinque-dentate, and permanent. **COROLLA**, five roundish concave petals, inserted into the calyx. **STAMINA**, about twenty awl-shaped filaments, having roundish antheræ. **PISTILLUM**, a germen under the receptacle, three slender styles, and capitated stigmas. **PERICARPIUM**, a roundish, soft, umbilicated berry, containing three oblong cartilaginous seeds.

There are only three species in this genus; all hardy deciduous trees; one of which is a native of England, &c. the others are exotics from the continent of Europe and other foreign parts; the two first sorts in particular are common in most of the nurseries and eminent plantations.

1. *SORBUS domestica.*

Domestic or cultivated Service-Tree, with large eatable fruit.] Grows with an upright stem, branching thirty or forty feet high, or more, having a brownish bark, and the young shoots in summer covered with a mealy down; pinnated leaves of eight or ten pair of broadish deeply serrated lobes and an odd one, downy underneath, and large umbellate clusters of white flowers at the sides and ends of the branches, succeeded by bunches of large, fleshy, edible, red fruit, of various shapes and sizes in the varieties.

Varieties of the fruit are,] With Apple-shaped fruit—Pear-shaped fruit—Oval-fruited—With turbinate fruit—Compressed-fruited, &c.—all of which ripen in autumn; generally two, three, or four in a bunch, being sometimes as big as little apples and pears, but are rarely palatable till they begin to assume a state of decay, as it were, becoming soft and tender.

This tree is a native of the southern warm parts of Europe, where its fruit is in high esteem to serve up in desserts, and is cultivated here, in many of our gardens, both as a fruit-tree, and to diversify hardy plantations.

2. *SORBUS aucuparia.*

(*Birds' Service*)—or *Mountain Sorbus*, commonly called *Mountain Ash*; also *Quicken Tree*, *Quick Beam*, or *Roan Tree*.] Rises with a straight upright stem, and regular branching head, twenty or thirty feet high, or more, covered with a smooth greyish-brown bark; pinnated leaves of eight or ten pair of long, narrow, serrated folioles, and an odd one, smooth on both sides; and large umbellate clusters of white flowers at the sides and ends of the branches, succeeded by clusters of small red berries, ripe in autumn and winter, of a harsh sour taste, unpalatable to eat.

Variety.] Yellow-striped-leaved.

This species grows wild in many parts of this island, on mountainous places, woods, and hedge-rows, often arriving to the growth of timber, and is admitted in most ornamental plantations, for the beauty of its growth, foliage, flowers, and fruit; the latter, in particular, being produced in numerous large red bunches all over the tree, exhibit a fine appearance in autumn and winter, till devoured by the birds, especially the blackbird and thrush, which are so allured by these fruit, as to flock from all parts and feed on them voraciously, but are not fit for domestic or household use.

3. *SORBUS hybrida*.

Mongrel, or Bastard Service Tree.] Grows twenty or thirty feet high; half-pinnated leaves, very downy underneath, and clusters of white flowers, succeeded by bunches of roundish red berries in autumn.

These three trees are all of the deciduous tribe, and of hardy temperature, growing freely in any of our open plantations in any common soil and situation; their foliage and flowering is generally pretty forward, commonly expanding their leaves in April, or early in May, being all of the beautiful, pinnated, many-lobed kind; and the flowers appear in May and June, composed each of five small petals, but many growing together in clusters, are conspicuous enough; succeeded by baccaceous fruit, ripening in August, September, and October, often remaining on the trees after the fall of the leaf, particularly the *Sorbus aucuparia*, which often retains its fruit all winter, or till devoured by the birds, as before remarked.

As to the merit of these trees in gardening, they are all very applicable for diversifying the shrubbery and other hardy plantations; being introduced as standards, they will effect a fine variety in assemblage, with their elegant pinnated leaves and clusters of flowers and fruit: the *Mountain Sorbus*, particularly, should be

plenteously interspersed in all extensive shrubberies, for the singularity of their numerous clusters of berries in autumn and winter, which also prove food to encourage plenty of singing birds in the plantations.

But the *Sorbus aucuparia* may also be introduced as a forest tree in timber plantations; being mostly all heart, is valued for many purposes.

And some of the *Sorbus domestica* may also be employed as fruit-trees in the garden and orchard; some being trained as standards, others as dwarfs, and against walls and in espaliers for variety, training them nearly as directed for pears and apples.

They are raised in all the public nurseries for sale, particularly the first two sorts.

Method of Propagation, &c.

They are all easily propagated in abundance, by seed, in the open ground, also by layers, though the seedlings generally make the handsomest plants.

By Seed.—The berries, or fruit containing the seeds, ripen abundantly in autumn, which is the proper time for sowing them, being careful to have them perfectly ripened, gathering them in due time before devoured by the birds, and prepare to sow them as soon after they are gathered as possible. For their reception, dig a spot of lightish ground in the nursery, and divide it into four-feet-wide beds, in which sow the seeds, either in drills an inch deep, or bed them in, by raking the earth from off the bed near that depth; then sowing the seed all over the surface, cover them all an equal depth, with the earth drawn off, as above, for that purpose: some of them will probably rise the following spring: they, however, frequently remain till the second spring before they come up; observing, in either case, that, in spring following, when the seedlings are a year old, they should be planted out in nursery rows, to remain till they acquire a proper size for final transplantation.

Sometimes, in order to forward the germination of these seeds, particularly the *Sorbus domestica*, we sow them in large pots, which being sheltered under a frame in winter, and in spring plunged in a hot-bed, will bring up the plants the same year fit for transplantation in nursery rows the following autumn or spring.

By Layers.—Having some of the trees, while young, cut down near the ground, it will force out lower shoots, which being layed, in the common way, in autumn and spring, they will readily emit roots, and be

fit

fit for transplantation in nursery rows in one year. This is also a certain method to continue any particular variety.

But the cultivated Service in particular, when designed to raise a quantity as fruit-trees for their fruit, they should generally be propagated by grafting or budding the choicer-fruited kinds upon stocks of any of the sorts of *Sorbus*, raised from seeds or layers as above; they will also take upon pear-stocks.

Generally in rearing these three species of *Sorbus* by any of the above methods of propagation, should train them principally for standards, each with a single upright stem; and being thus trained in the nursery till three, four or five, to six or eight feet high, are then proper for any plantation intended, and may be transplanted as required, at the usual planting season of autumn or spring.

When the said trees are of eligible growth, as above, for final transplanting, they may be introduced in any large shrubbery compartments, and other ornamental plantations, and in those of forest trees; allotting also some of the domestic services as fruit-trees in gardens and orchards, as before observed, principally as standards, or some occasionally in espaliers, &c. and, in both of which, planted and managed similarly as advised for apple and pear-trees; permitting the standards to shoot freely above into full heads; the others regulate according to their order of training; and in due time they will produce plentiful crops of fruit annually to gather in autumn; observing generally, in gathering this fruit for the table, it is proper to lay some in the fruitery, &c. a little time to mellow, soft and tender; in which state it becomes eatable, of an agreeable taste and flavour; and in the final gathering of the whole in October, &c. the bunches of fruit being deposited in a similar manner, they will mellow gradually for eating in November and December.

SOUP HERBS.

Many sorts of herbaceous vegetables, of the culinary tribe, are in great estimation for the improvement of soups, &c. a list of which, collected under this head, will serve to assist the memory in furnishing the garden with the proper sorts; remarking, that under the denomination of Soup Herbs, may also be understood all the sorts of Pot-herbs used occasionally in soups and broths, &c. and in which are also included several sorts used likewise as salad herbs.

In some families a great variety of Soup or Pot-herbs are occasionally required, and in others a few only of the common sorts are used, so that every kitchen-garden ought to be furnished accordingly with the proper sorts.

The following is, therefore, a list of the principal sorts occasionally used as soup-herbs, &c. several of which, however, are also employed in various other culinary uses, salads, &c. as well as for soups. Celery—Endive—Leeks—Lettuce—Spinach—Green and White Beet—Chard Beet—Orach—Borage—Bugloss—Burnet—Chervil—Sorrel—Parsley—Coriander—Pot-Marigold—Thyme—Winter Savory—Summer Savory—Pot or Winter Marjoram—Sweet Marjoram—Spear-Mint—Tarragon—Basil—Love-Apple, or Tomatoes.

In all of which, except the Marigold and Love-Apple, the leaves are the only useful parts; but in the Marigold the flowers are the only part used, and in Love-Apple the fruit; remarking, likewise, that all the sorts, but the last two of the list, (Basil and Love-Apple) are of a hardy temperature, and may be easily raised in the natural ground; and the greater part are biennials and annuals, that require to be annually raised from seed; but the Thyme, Winter Savory, Pot or Winter Marjoram, Sorrel, Mint, Burnet, and Tarragon, are perennials of many years' duration, being raised some both by seeds and slips, others principally by slips; and the Basil and Love-Apple, being tender annuals, require to be raised from seed in a hot-bed. See the culture of all the sorts under their respective genera.

But the most prevailing Soup or Pot-herbs, of the above list, for general use, are, Celery, Endive, Leeks, Spinach, Beet, Parsley, Chervil, Thyme, Marjoram, Savory, and Spear-Mint.

However, the particular merit of the different sorts, together with the proper culture, is fully exhibited, each under its proper head.

SOWING OF SEEDS.

Different methods of sowing Seeds are practised occasionally, as different sorts require, and according to different practitioners; such as broad-cast sowing and raking-in, —drill-sowing,—bedding-in-sowing, &c.

BROAD-CAST SOWING, &c.—This is the most common and expeditious method of sowing in practice, particularly in the kitchen-garden, both for many of the principal crops to remain, and for transplantation; and is performed by sowing the Seed with a spreading cast evenly all over the surface of the ground, either in one continued plat, or divided into beds, which is immediately raked with a large rake to bury all the seeds a due depth in the earth, some requiring to be raked in as light as possible, others half an inch or an inch or more deep, according to their size, &c.

In preparing for this method of sowing, the ground is previously dug in the common way, making the surface level with the spade

as you go on; no occasion, however, to break the surface very fine, nor rake it, only breaking all lumpy clods, and forming it even with the spade, as just observed, and leave it a little roughish, more or less, in proportion to the size of the Seeds, that, in raking them in, they may be more effectually buried a proper depth for germination; observing, for the general part, that the ground should be sown whilst fresh stirred, before the surface is rendered either too dry and hard by the sun and wind, or made wet by rain, but when it is so moderately dry as not to clog to the feet or rake, and that it will readily fall under the rake in raking in the Seed.

All broad-cast Sowing should generally be performed in dry weather, more particularly all early sowing in winter and spring; but in hot weather, in summer and autumn, it may often be eligible to take advantage of sowing immediately after a shower or moderate rain.

After, however, having digged the ground as above, the Seeds are then to be sown broad cast, all over the surface, either in one continued plat, and raked in as before remarked; or the ground may be previously stepped out into four or five feet wide beds, with small alleys between bed and bed, then sowing the seed on each bed separately, or, on particular occasions, may first sow the ground broad-cast, as above, and afterwards mark the ground out in beds, as aforesaid, paring up the earth of the alleys an inch or two deep, spread it over the beds, and rake them evenly lengthways. The laying out the ground in beds may, in some cases, be the most eligible way; such for example, if wet ground that cannot bear treading, we can stand in the alleys both to sow the Seed and rake it in, without trampling the beds; and when weeding and watering becomes necessary, can also stand in the alleys to perform those works; likewise to cull and gather the produce, or transplant where necessary; however, in kitchen-gardens, where ground is scarce, or that it is of importance to make the most of every part of the ground, as well as use the most expeditious method of sowing possible, the broad-cast sowing all over the surface, in one continued plat, as above observed, may be the more eligible practice, especially in large grounds, for the main crops of carrots, parsneps, turneps, onions, leeks, spinach, lettuce, radishes, &c.

As to the method of sowing the Seed in the Broad-cast way, it is effected occasionally both with an open and locked hand.

In the former case (sowing open-handed) it is performed by delivering the Seeds with an open hand, and broad-spreading cast, as

practised in sowing corn in the open fields, previously stepping out the ground in breaks, or certain widths, as a guide to sow with the greater regularity; so proceeding with the sowing along each space with a regular step and cast, giving the hand a proper sweeping cant forward, fully expanded at the delivery of the Seeds, making them spread abroad evenly in every part; and thus proceed up one space and down another till finished; which method of Broad-cast sowing is practised in large kitchen grounds in sowing any considerable space in one continued plat, as observed above.

But in the other case, (sowing close-handed) it is practised occasionally, both in sowing large continued plats of ground, and narrow beds, &c. but more generally the latter; especially when we intend sowing them bed and bed separately, or narrow borders, and other small plats of ground, we commonly sow or deliver the Seeds with a locked or close hand, discharging them from between the fore-finger and thumb, opening or pinching the thumb more or less, according to the size and nature of the Seeds, and thickness they require to be sown, giving the hand a sort of jerking turn, or cant forward at the delivery, to cause the Seeds to spread regularly.

As soon as the seeds are sown in either of the above methods of sowing, let them be directly raked in before the surface of the ground is rendered either too dry by the sun and wind, or made wet by rain, if likely to happen; observe as below.

But previous to the raking in the Seeds sown broad-cast on the general surface in one continued space, as above, that if the ground is loose, light, and dry, and a dry season, it is advisable immediately, after sowing, to tread them in evenly by treading the ground all over light and regularly with the feet; it being more particularly necessary in light loose ground in the above Broad-cast Sowing, which not only settles the Seeds, so as to be more effectually buried all an eligible regular depth in the raking, but also settles the ground evenly in every part, as that when we stand thereon to rake in the Seeds, the feet will not sink in holes, as would be the case at every step in light ground, if not previously trodden; it also prevents the drought of the spring from penetrating too freely: but, indeed, if the ground is laid out in beds, we may either tread in the Seeds or not, as we may readily stand in the alleys to rake them in without trampling the beds; which, in wetish ground in particular, may be the more eligible practice; however, even in the sowing in beds immediately on the surface, as above, in ve-

ry light loose soils, with a dry surface and dry season, it is eligible enough to tread in the Seed, previous to raking the ground after sowing; and it may also sometimes be proper to pare up the loose earth of the alleys an inch or two deep, and spread it thinly over the surface; observing in general, that the work of treading in the Seeds, in both the above methods of sowing, is performed with the feet nearly close together, taking short regular steps, treading the surface lightly all over, once in a place, with but small spaces between the steppings.

Directly after Sowing the Seeds, as above, let the ground be regularly raked over to cover all the seeds effectually a proper depth, using a large or good middling rake for this purpose (see **RAKE**); being careful to rake very regularly, not to draw the earth and Seed in heaps, raking only once or twice in a place; which is generally sufficient, especially where the Seed has been previously trodden down in the above manner; taking care, however, to perform it so effectually as to bury all the Seeds properly: and as you advance in the raking, trim off lightly all large stones, hard lumpy clods, and rubbish.

Observing, some Seeds require to be raked in as lightly as possible, such as all the very small Seeds; others require to be a quarter or half an inch deep, others a whole inch or more; so use smaller or larger rakes accordingly. See **RAKE**.

The above methods of Broad-cast Sowing and raking in, both in large spaces, and in beds, borders, &c. may be practised to numerous sorts of Seeds, particularly the greater part of the esculents of the kitchen-garden, numerous flower seeds and others, as is generally hinted in their culture; and, being the most ready and expeditious mode of Sowing, is proper for general practice, especially in extensive grounds, except for some particular sorts of Seeds that require to be sown either in drills or by bedding in, as directed below; which is particularised in treating of the respective plants in their proper places.

But in many of the extensive market kitchen-gardens, where they sow large tracts of ground at once, instead of raking in the Seed sown in the Broad-cast way immediately on the surface, they, for the sake of expedition and cheapness, have light short-tined harrows to draw with men, with which they harrow in the Seeds; and sometimes in light dry ground, and a dry surface, they afterwards roll the ground with a light wooden roller, to close and smooth the surface over the Seeds

more effectually, performing it when the surface is a little dried so as not to adhere to the roller.

And in the large garden-farms in fields, where they commonly plough and harrow the ground for the reception of Seeds, they practise only the Broad-cast Sowing in continued tracts for almost all their esculent seeds, except for peas, beans, and kidney-beans; the ground being prepared by ploughing, and afterwards rough-harrowed, to smooth the surface moderately, the seeds are then sown broad-cast, in the spreading open-handed manner, and then harrowed in either with a light short-toothed horse-harrow, or harrowed in with men for particular crops; then, if very dry weather, roll the surface afterwards with a wooden roller, drawn also by horses, &c. to smooth the surface, as aforesaid.

DRILL SOWING.—This method of Sowing is necessary for many sorts of seeds, both esculents, flowers, and tree and shrub kinds in the nursery, both for the plants to remain where sown, and for transplantation, and is performed by drawing drills with an hoe, from a quarter or half an inch, to two or three inches deep, according to the sizes and sorts of seeds, which being sown evenly along the bottom of the drill, the earth is drawn evenly over them with a hoe or rake, the depths as above, and the surface lightly raked smooth.

As to the sorts of seeds that may be sown in drills, numerous sorts may with propriety be sown in that method, but is particularly eligible for many large kinds, such as peas, beans, kidney-beans, and many large kinds of tree and shrub seeds, nuts, and berries; it being not only the most ready method of committing those large seeds to the ground the proper depth; but being sown in rows at a distance, best suits the nature of growth of many sorts of plants, and their method of culture. Many kinds of small seeds are the most conveniently sown and cultivated in drills, such as several of the kitchen garden plants, as parsley, chervil, coriander, all the sorts of small-sallading, and sometimes spinach, beet, &c. also some of the aromatics when designed as edgings, or also occasionally in rows in beds, both to remain and for transplanting,—such as thyme, savory, hyssop, and the like, which is generally mentioned in treating of their culture; likewise many sorts of flower-seeds are the most commodiously sown in drills, both when designed for transplantation, and sometimes to remain, as is exhibited under their proper genera: but many of the tree and shrub seeds, in particular, are the most conveniently sown in drills: all of which.

which is properly noticed under the genera of the respective sorts.

For by Sowing in Drills, to all such plants as admit of it, proves not only an eligible method of sowing to bury all the seeds regularly an equal depth; but the drills being at some distance from one another, admits the sun, air, and rains more effectually to the plants, and gives them a greater scope of growth, than such as are sown broad-cast, or promiscuously all over the surface, but admits also of introducing a hoe between the drills to hoe down weeds and loosen the soil; which always proves a most beneficial culture.

The method of drill-sowing is both easy and expeditious: in gardens it is performed by drawing the drills with a common drawing-hoe, large or small, in proportion to the sorts of seeds to be sown, generally setting a line as a guide to draw the drills straight, which, as before observed, are drawn of different depths, from a quarter or half an inch to two or three deep, as the sorts and sizes of seed may require, and at proportionable distances, from three or four inches to so many feet, according to the nature of the plants; all of which particulars are always noted in the culture of the respective sorts, ranged under their proper heads.

The general method of drawing of drills for the reception of seeds is with a common drawing-hoe, as before noticed, sometimes with a large hoe, and sometimes a middling or small hoe, according to the size of the drill required, size and nature of the seeds; drawing the drill most generally with the corner of the hoe, especially for larger seeds, and sometimes with the edge of the hoe flat-ways or horizontally; but for large seeds, such as peas, kidney-beans, many of the nut kinds, and many other large seeds both of trees, shrubs, and herbaceous plants, require a deep angular drill, drawn with the corner of the hoe, turning the edge close to the line, so draw the drill along with an angular bottom evenly the depth required, the earth remaining close along the side of the drill, ready for turning in again over the seeds; but where flat or shallow drills are required for smaller seeds, it may, in many cases of some particular sorts, be more eligible to draw the drill with the hoe flat-ways, holding the edge in a horizontal position, as before observed, drawing the drill along with a flat bottom evenly the whole width of the hoe, the proper depth, suitable to the sorts of seeds intended to be so sown.

Sometimes, when very small drills are required for some particular fine or small seeds,

to be sown in a bed, border, or hot-bed, &c. we draw them with the end of the fingers, or with the end of a small flat stick.

Having, however, drawn the drills in either of the above methods, the seeds should generally be sown and covered in directly, if the ground is dry and in good order: but if the soil is wet, especially at an early season, it may be proper to suffer the drills to lie open exposed to the sun and air an hour or two, or more, to dry a little, particularly for tender seeds in early sowings, in the full ground, as just above observed, such as kidney-beans, &c.

As to the method of sowing in the drills, it is performed for the general part with a locked or close hand, discharging the seeds from between the fore-finger and thumb, as before related, scattering the seeds evenly along the bottom of the drill, some sorts requiring to be sown thinly just along the middle, such as in the angular drills drawn corner-ways of the hoe, for peas and many other larger seeds: also sometimes for smaller seeds when intended for edgings; but in the shallow flat-bottomed drills it is generally intended for the seeds to be scattered evenly the whole width of the drill, thicker or thinner according to the nature of growth of their respective plants, sometimes to remain, and in some sorts for transplanting; proper hints of which are generally exhibited in their culture, observing to cover in the seeds generally as soon as sown, as already hinted, raking or hoeing the earth evenly over them, just the depth of the drills.

Remarking, the work of covering, or turning in the earth in the drills over the seeds, may be performed occasionally both with the rake, hoe, and feet; but the rake or hoe is the most eligible for general practice for all smaller seeds, drawing the earth evenly into the drills a regular depth fully to the depth of the drill, whether deep or shallow; however as to peas, beans, kidney-beans, and the like larger seeds in large drills at wide distances, they are often covered in with the feet, by slipping them lightly along each side of the drill alternately, turning the earth evenly in over the seeds; but generally for all small seeds in close drills, it is proper to cover in with the rake or hoe, sometimes using the teeth of the rake, and sometimes the back occasionally, as it shall seem most convenient; observing that as soon as the drills are covered in by either of the methods, let the surface be lightly trimmed along with the rake, to smooth it and clear off large stones, &c.

In the husbandry Drill Sowing, the drills are generally drawn with the drill plough by horses,

horses, which effects that work very expeditiously, and for some seeds is so contrived as to draw the drills, sow the seed, and cover them in all at the same time.

BEDDING-IN SOWING.—This is another sort of broad-cast Sowing in beds, because the seeds are sown all over the surface, but in a different way from the above mentioned: in this method the ground being digged and formed into four or five feet-wide beds, with alleys, a spade width or more between bed and bed, and the earth being drawn off the top of the bed with a rake or spade half an inch or an inch or more deep into the alley, the seed is then sown all over the surface of the bed; which done, the earth in the alley is immediately, either with a rake, drawn spreadingly upon the bed again over the seeds the same depth, or spread over with a spade similarly, and the surface raked smooth.

This mode of sowing is often practised in the nurseries, especially in sowing some large sorts of seeds, and others occasionally, but not very frequently in kitchen-gardens, except in some parts of the North; it is not so expeditious as the broad-cast Sowing, but is nevertheless very proper for many sorts of small seeds, and many sorts of the tree and shrub kind, being a very regular method of Sowing so as to cover all the seeds an equal depth, and is performed two or three different ways, such as by rake, by spade, and by sifting.

In performing it by the rake, the ground is digged in the common way, raking the surface as you go on, every eight or ten feet, standing on the undug ground to perform the raking; and when the plat of ground is thus digged and raked, mark it out into four-feet-wide beds with moderate alleys between bed and bed; then having a large rake, turning the teeth upwards, and with the back thereof shove the earth evenly from off the surface of the bed, a quarter or half an inch to an inch or more deep, as may be required, into the opposite alley in a little ridge all the way along; this done, sow the seed evenly all over the surface of the bed, then directly with the rake turned the right way, teeth downward, proceed to draw the ridge of earth out of the alley over the seed, striking the teeth of the rake smartly down on the farther side of the ridge of earth, and drawing it toward with a kind of jerk, make the earth spread evenly over the seed quite from one side of the bed to the other, proceeding in that manner, drawing one stroke after another to the end of the bed; then proceed to the next in the same manner, and so continue bed and bed till all is finished; then with a light rake gently trim the surface

smooth, and clear off stones and hard clods, as on former occasions.

In some places this method is practised almost in general in sowing all sorts of small seeds, and by many preferred as a very eligible method of broad-cast sowing, so as to cover all the seeds evenly an equal depth; it, however, is not near so expeditious for large grounds as the common broad-cast Sowing and raking in.

However, those that are used to this method of Sowing rid it off a great pace; sometimes two or three hands being employed on the same work, one shoves the earth from off the bed, another follows immediately after with the sowing, and this followed directly by a third, draws the earth over the seed, and so proceed bed and bed.

But nearly the same method of sowing is also sometimes performed with the rake and spade together, particularly when intended to sow any larger seeds a good depth, using the rake to shove or rake the earth from off the bed, into the alleys; or if it cannot be conveniently performed with the rake a proper depth, it is effected with the spade, trimming or paring the earth evenly off the surface, into the alleys; then sow the seeds all over the surface as before, and if they are of the larger berry, nut, or stone kind, or any other large seed, previous to covering them, press or pat them all evenly down into the earth, with the back of the spade; and then, either with the rake or spade, spread the earth out of the alleys evenly over them; though if it is a deep covering, especially if taken off with the spade, it is most eligible to use the same implement in returning it, being careful to spread it evenly to cover the seeds all equally a proper depth, smoothing the surface with the rake.

Another method sometimes practised in Bedding-in Sowing any common large seeds is, the ground being laid out in beds unraked, the seeds is sown on the surface, and with the rake strike it a little into the earth, then with the spade pare the alley, and cast the earth evenly over the bed, half an inch, or an inch or more deep, as may be required, and rake the surface even. This is also sometimes designedly practised in wetish ground, at an early season, when it does not readily admit of treading or raking. And by deepening the alleys, and raising the beds, it drains the moisture from the surface.

The method of Bedding-in Sowing by sifting, as formerly mentioned, is sometimes practised for several small or light seeds of a more delicate nature, that require a very light covering of the earth when sown. So in

order to bury them as shallow as possible, covering them in, by sifting fine earth over them out of a wire or chip sieve. Previous to Sowing such Seed, the surface of the bed, &c. is raked fine; then either shove the earth thinly off the surface of the bed with the back of the rake into the alley, making the surface as smooth as possible, and then sow the seed, smooth it down lightly with the spade, and sift the earth in the alley evenly over it, some very small sorts only just covered, not more than half a quarter or a quarter of an inch deep; or sometimes the surface being only raked as smooth as may be, without drawing off the earth as above, or sometimes also lightly smoothed with the back of the spade, then sow the seed, and let some loose fine earth from the alley, or some brought for the purpose, in a wheel-barrow, be sifted thinly over it, as just above-mentioned.

SPADE.

A spade is the most useful garden implement for digging, and preparing the soil for the reception of all sorts of seeds and plants.

There are several sorts and sizes of spades occasionally used, though the common large digging Spade is, in most places, almost commonly used for all kinds of digging and Spade-work, which however, in many instances, cannot be so conveniently used as a middling or small Spade; it is therefore eligible for every general garden to be furnished with three different sizes of Spades, to suit every department of gardening the more commodiously, such as the common large digging Spade, for all common digging and Spade-work as above observed, and a middling, and a small Spade for digging particular narrow compartments, and digging between small plants closely placed in beds and borders, &c. and in many other occasions.—See each as below.

Common digging Spade, &c.—This is designed for all common digging, and trenching of ground, and all kinds of strong Spade-work; so is of the largest size, being generally from fourteen to fifteen inches long in the plate, and nine broad, narrowing gradually half an inch, or an inch less at the bottom. Though in some of the kitchen gardens about London, where the ground is light and deep, they use spades full fifteen inches long in the plate; however, for the general part, a Spade of fourteen inches by eight or nine wide, proves the most handy size for all common digging in every district of gardening; but as they are made of different sizes, from twelve or fourteen to sixteen inches long in the plate, as aforesaid, so every one may suit

himself according to the depth and nature of his soil, and method of working.

Middling Spade.—Being as to size about a foot long in the plate, and seven or eight inches broad; which will prove very useful in light work, and in digging any small compartments, and between rows of small plants; also in flower beds, and borders; likewise in stirring, and fresh earthing the surface of beds occasionally, between close-placed plants of long standing; planting and transplanting many sorts, both in the ground, and in pots, and for many other sorts of light Spade-work.

Small Spade.—The size eight or nine inches long in the plate, and five wide, and is convenient in pointing up or slight digging, and in fresh loosening the surface between close-placed small plants, in beds and borders, &c. where none of the two former Spades can be readily introduced; likewise is useful in planting and potting many sorts of small plants, taking up small roots, and other light purposes occasionally.

Proper garden Spades have the plate wholly of iron, not above a quarter of an inch thick upward, growing gradually thinner from the middle downward; the tree or handle being generally of ash, about two feet long, and an inch and half thick, with a firm open handle at top, formed out of the solid wood, just big enough to admit of taking ready hold, one hand at top, and the other below.

Small Narrow Spade.—Having the plate about seven inches long, by three and a half or four wide; and is very useful in small compartments of beds, borders, &c. containing some particular close-placed, small plants of flowers, and others, both in occasionally slight digging, or loosening the earth between them with greater care and effect, than a larger sized spade; also sometimes in similar compartments in occasionally trimming round the bottom part of some straggling fibrous-rooted plants; and is often useful in taking up and transplanting small plants, and taking off root off-sets and slips, in particular sorts, in which a larger Spade would not be so commodiously handy.

Semicircular, or scooped Spade.—Besides the sorts of spades abovementioned, there is also another sort, of a smallish size, having the plate made semicircular like a scooped garden-trowel, and is very useful in taking up small plants with balls of earth, to preserve the ball more firmly about the roots.

All the sorts of Spades are sold by most of the nursery and seedsmen, and by the ironmongers; the prices being according to the sizes, from five shillings to half a crown; so

that the whole price of a set of spades is but trifling.

SPADICEUS *flos*, (from *spadix*) a flower, or an aggregate of flowers, produced on that particular receptacle called a *spadix*, which is protruded from a sort of calyx called a *spatha* or sheath, as in *Narcissus*, *Amaryllis*, snow-drop, &c. See **SPADIX**, **SPATHA**, and **SPATHACEÆ**.

Many of the bulbous and tuberous rooted tribe, produce Spadiceous Flowers, the principal of which are, *Amaryllis*, or lily daffodil, Guernsey lily, &c.—*Allium*, garlick, onion, leek, &c.—*Crocus*, all the varieties.—*Colchicum*, meadow saffron.—*Narcissus*, daffodil; jonquils, &c.—*Galanthus*, snow-drop.—*Leucojum*, greater snow-drop.—*Arum*, wake-robin, &c.—*Calla*, Æthiopian Arum.—*Orchis*, fool-stones, &c.—*Satyrion*, bee-flower.—*Ophrys*, twy-blade.—*Dracontium*, dragon-plant.—*Hæmanthus*, blood-flower.—*Crimm*, Asphodel lily.—*Pancratium*, sea-daffodil, &c. all of which are perennials, sending up stalks annually, terminated at top by that kind of calyx denominated a *spatha*, inclosing a *spadix* of flowers, and after obtaining a certain growth, the *spatha* or sheath bursts open, and protrudes the *spadix*, supporting sometimes but one or few flowers, and sometimes many. See **SPADIX**.

Many of the above plants are somewhat of the liliaceous tribe, or nearly allied thereto in their habit and structure; distinguished however, from others of the liliaceous tribe of plants by their *spatha*, out of which, the *spadix* of flowers is protruded; the other liliaceous kinds, having no *spatha* or any other sort of calyx; such as the White, and Orange Lily, Martagons, Crown-imperial, Tulip, Tuberoſe, &c.

SPADIX.

The particular receptacle and pedicles of spadiceous or spathaceous flowers above described, being protruded out of that kind of calyx, called a *spatha*; and sustains from one to many flowers, as in *Narcissus*, &c. See **SPATHA**.

The *Spadix* was originally applied to palms only, but it is now extended to all receptacles and pedicles of flowers, whether single or aggregate, that have a *spatha* or sheath for their calyx; which kind of calyx being in form of a sheath or scabbard, bursts lengthways and protrudes the *Spadix*. See **SPATHA**.

SPARTIUM, Broom.

Consists of shrubby flexible plants, of the deciduous and evergreen tribe, both hardy and tender, for diversifying the pleasure-ground, and green-house collections; all of upright moderate growth, with long rush-like shoots,

thinly garnished with trifoliate, and single spear-shaped leaves, and numerous papilionaceous flowers.

Class and order, *Diadelphia Decandria*.

Characters.] **CALYX** is monophyllous, tubulous, heart-shaped, with a short margin, having five small denticles. **COROLLA** is papilionaceous, with five petals, consisting of a large obcordated, wholly reflected vexillum, two oblong-oval wings shorter than the standard, annexed to the filaments, and a dipetalous, oblong, hairy carina, situated below the wings. **STAMINA**, ten unequal, diadelphous filaments, with oblong antheræ. **PISTILLUM**, an oblong hairy germen, awl-shaped, rising style, having an oblong hairy stigma. **PERICARPIUM**, a long, cylindric, obtuse, bivalvovous, unilocular pod, containing roundish seeds.

There are many species in this genus, all of shrubby growth: the first of which grows wild abundantly in England, &c. all the others are exotics, chiefly from Spain, Portugal, Italy, and other southern parts of Europe, and the Levant; about six or seven species are retained in our gardens as flowering-shrubs, for variety and ornament in the shrubbery and green-house collection. Some of them being very hardy, others somewhat tender, requiring shelter of a green-house in severe winters.

Hardy Kinds.

About three or four species are hardier than the rest, and succeed in the open ground in all weathers the year round; the first of which is our common English Broom, and the others are originally from abroad, the countries above-mentioned.

1. SPARTIUM *scoparium*.

(*Sweeping Besom Broom*)—or *Common English Broom*.] Rises with a shrubby flexible stem, and numerous, angular, smooth, green, flexible branches, five or six feet high; ternate and single leaves; and numerous bright-yellow flowers all along the sides of the young branches in May and June, succeeded by plenty of ripe seed in Autumn.

This plant grows wild in sterile grounds in England, and most parts of Europe, and not very commonly admitted into gardens, only in some extensive shrubberies, for the variety of its singular growth, and conspicuous bloom of flowers. In the country it being made into besoms, thence denominated Brooms; hence the name *Spartium scoparium*, Sweeping Broom.

2. SPARTIUM *Junceum*.

Rushy Spartium, or *Common Yellow Spanish Broom*.] Rises with a shrubby stem, and cylindric, opposite, flexible, rush-like, green branches

eight or ten feet high; small lanceolate leaves; and the tops of the branches floriferous, being terminated by loose spikes of large yellow flowers, from July till September, succeeded by plenty of seeds in autumn.

Variety.] Double-flowered Spanish Broom; producing large full double-flowers, but no seed.

3. *SPARTIUM radiatum.*

Starry Italian Broom.] Grows two or three feet high, with numerous angular opposite branches all around, assuming a bushy growth; ternate, linear, close-fitting, opposite leaves, having the folioles spreading round the stalks in a radius; and clusters of yellow flowers at the ends of the branches, appearing in June and July.

Of the above three species, the two latter are the most commonly cultivated, having been long residents of our shrubberies: all three, however, succeed any where, producing abundance of flowers and seed annually; and from the scattered, or self-sown seeds, many young plants often rise without care, the following spring.

Tenderer Kinds.

The following sorts being rather of a more tender nature, especially while young, are often potted, and treated as green-house plants; yet they mostly stand our moderately sharp winters, tolerably in the full ground; it is, however, proper to pot some for shelter in winter, and plant some in the full ground in a warm situation, to take their chance.

4. *SPARTIUM monospermum.*

Single-seeded, White Spanish Broom.] Grows six or eight feet high, with numerous angular, rush-shaped, silvery branches; small spear-shaped leaves; and lateral clusters of numerous white flowers along the sides of the branches, in July and August; succeeded by pods containing a single seed only.

Variety.] With yellow flowers.

This species being moderately hardy, is very commonly planted in the open shrubberies, as an ornamental flowering shrub; it is however proper to retain some also in pots, especially while young, to have occasional shelter from severe frost.

5. *SPARTIUM spinosum.*

Spiny Italian Maritime Broom, or Prickly Cytisus.] Grows five or six feet high, with angular slender branches, armed with spines; ternate, thinly placed leaves, and clusters of bright-yellow flowers at the ends of the branches, in June and July.

6. *SPARTIUM Scorpius.*

Spreading Prickly Spanish Broom.] Hath

spreading spinous branches, oval leaves, and largish yellow flowers, in July and August.

7. *SPARTIUM angulatum.*

Angulated Eastern Broom.] Grows six or eight feet high, with numerous sexangular branches, garnished with single and ternate leaves; and the tops of the branches floriferous, being terminated by loose spikes of pale-yellow flowers, appearing in July.

8. *SPARTIUM sphaerocarpum.* — Spherical-fruited Spanish Broom.

9. *SPARTIUM complicatum* — Complicated Montpelier Broom.

All the above species of *Spartium* rise with shrubby durable stems and branches, mostly of a flexible nature, the branches in particular being very slender and pliable, producing long rushy green shoots, generally, however, assuming an erect growth; the leaves generally small, and thinly placed, and the flowers moderately large and conspicuous, all of the papilionaceous or butterfly kind, with five petals, as in the *Characters*, and mostly of a strong agreeable odour; succeeded by long cylindrical leguminous seed-pods, ripening in autumn: though some of the foreign sorts do not always ripen plentifully in England, but are obtained in abundance from Spain, Portugal, and countries adjacent.

They all grow naturally in most of the southern parts of Europe; and the first sort, *Spartium scoparium*, also in great abundance in this country, in barren uncultivated lands, often proving a most troublesome plant to extirpate in grounds intended for cultivation.

As to the merit of all these shrubs, in gardening they may be all employed as flowering shrubs, or furniture to embellish the shrubbery compartments; the Common Spanish Broom, Radiated, and Monospermous kinds, &c. particularly, are the most common sorts in the English gardens; and the *Spartium scoparium* is also often thinly interspersed in extensive shrubberies, to increase the variety: but all the species, both hardy and tenderer kinds, may be exhibited in the shrubbery plantations; being careful, however, to station the tenderer sorts in the warmest situations, to take their chance of all weathers the year round, in common with the hardiest kinds.

It is, however, also proper to have some of the tenderer kinds always in pots, to be treated as green-house exotics, for the greater certainty of preserving the species, in case the others in the shrubbery should suffer by the severity of rigorous winters.

Most of these plants having long naked or thinly fibrated roots, often inclining to run down

down with a long tap-root, should generally be planted where they are finally to remain while young, as they do not succeed well, if removed when large and old.

All the sorts may be planted for their different purposes, either in autumn, any time in October or November in open weather, or in the spring, in February, March, or beginning of April, and may be planted in any common soil of a garden, will continue in growth many years, and flower abundantly every summer and autumn, in their respective season very conspicuously and ornamentally: and as to culture, those in the shrubbery require only what is necessary for the other shrubs in assemblage, keeping clear from weeds in summer, digging between them every winter or spring, at the same time pruning any disorderly growths, and casual decayed shoots, &c. and the tenderer kinds in pots, have the occasional culture of green-house plants.

They are raised in abundance in all the public nurseries for sale.

Method of Propagation, &c.

They are all propagated by seed in the full ground, sown in the spring of the year; and the double-blossomed varieties, &c. by layers and cuttings.

Some of the sorts ripen plenty of seeds in this country, but that of all the sorts is procured in abundance by the nursery and seedsmen for sale; which should be sown in the beginning of April, in four-feet-wide beds of common earth, either in drills near an inch deep, or bedded in that depth; they will soon germinate, and the plants rise freely in a short time, giving occasional watering and weeding all summer; and in winter, it is eligible to hoop the beds of the tenderer sorts, in order to be matted in frosty weather; and in the spring following, it is advisable to prick out the whole in nursery rows, it being proper to remove them out of the seed-beds, when but one year old, on account of their tap-root aforesaid, which should now be shortened; then plant them in rows two feet asunder, and one foot apart in each row; here to remain two or three years, or till advanced to two or three feet growth, then transplanted finally into the shrubbery; planting also some of the seedlings of the tenderer kinds, immediately from the seed-bed into pots, and placed in the green-house in winter.

Observe however, in raising the tenderer sorts, that, for the greater certainty of success, it will also be proper to sow some in pots, plunging them in a shady border all summer;

where the plants will come up freely, being careful to remove them under a garden-frame, or green-house in winter, to have shelter till spring, then pot the seedlings off separately as above, in order to be managed as hardy green-house plants; and in a year or two, having acquired strength, some of them may be turned out into the full ground, and some retained in pots, placed among the green-house exotics.

By Layers and Cuttings.—The double blossomed Spanish Broom, and the other varieties, not continuing the same from seed, must be propagated by layers or cuttings, to preserve the sorts with certainty. Make the layers in autumn or spring, and plant the cuttings in spring or summer, some in the full ground, others in pots, and plunged in a hot-bed to forward their rooting.

SPATHA, a Sheath.

Being the common calyx of the spadiceous flowers; and which, being in form of a sheath or scabbard, bursts open on one side, longitudinally, from bottom to top, and protrudes the *spadix*, a sort of receptacle and pedicles sustaining the flowers, consisting sometimes of but one, and sometimes of many florets. See SPADICEUS Flos, and SPADIX.

Examples of the Spathaceous plants are *Narcissus*, *Amaryllis*, *Galanthus*, and *Crocus*, &c. See SPADICEUS Flos.

The *Spatha* always terminates the main flower-stalk, is mostly of an oblong form, and sometimes globular, as an onion and leek, &c. closely inclosing the *spadix*, till the flowers acquire maturity enough to burst it open, and consists either of one piece, as in the greater number of spathaceous plants; of two, as in some few sorts; or of a number of scales placed imbricatum, as in the plantain-tree.

SPATHACEÆ *Plantæ*, (from *spatha*, a sheath.)—Spathaceous plants, such whose flowers are protruded from a *spatha* or sheath. See SPATHA.

SPATHÉLIA. (*Spathelia*.)

One species, a shrubby exotic from the West Indies, retained in some of our stove-collections, rising with a high stem, garnished with pinnated leaves, and racemes of flowers; having five-leaved cups, five petals, five stamina and three styles, succeeded by trilocular capsules, with three seeds singly in each cell.

Class and order, *Pentandria Trigynia*.

The species is.

SPATHÉLIA *simplex*.

Simple-stalked Jamaica Spathelia.] The stem single; with frondose pinnated, tufted leaves;

leaves ; and with flower-racemes most simple, loose and terminal.

This plant must be kept in pots and stationed in the stove ; is propagated by seeds, layers, cuttings, &c. in pots plunged in a bark-bed.

SPAWN, a progeny or off-spring.

In gardening, is often applied to such small off-sets, suckers, and sprouts that rise numerous from the roots, &c. of certain plants, serving for the purpose of propagation.

Therefore this small Spawn, or off-spring of vegetables, may be considered as parts similar to the whole plant, as that being separated from the parent vegetable, and planted, they readily grow, and commence proper plants, and thereby renew or propagate their respective species with great facility and abundance.

But Spawn among gardeners, in the general acceptation, is more peculiarly applied to the progeny of mushrooms, being an off-spring from the root of those *fungi*, consisting of minute white parts, shooting and running in the earth or dung, like small white, thready fibres, assuming the appearance of slender white strings, productive of numerous minute white knobs, appearing at first the size of small pin-heads, the whole smelling strong of the mushroom ; and those little knobs being infant plants, they gradually increase in size to proper mushrooms, which are quick of growth, and of very short duration ; but the same Spawn running in the earth, &c. furnishes a plentiful supply of mushrooms from the bottom in regular succession, for a considerable time, sometimes for several months.

So that mushrooms propagate in great abundance by this Spawn detached from the root, and is the only method of propagation yet discovered, for raising them by the progress of horticulture : for the lumps of spawny earth or dung being planted in a sort of hot-bed of horse-dung, the spawn soon vegetates, and increases considerably, furnishing mushrooms in a short time fit to gather ; these hot-beds in which we deposit the mushroom Spawn, being always made with new horse-dung from the stables, previously fermented in a heap, to evaporate the first violent heat, then formed in a long narrow ridge from three to four feet wide and three feet and a half high, like the roof of an house to shoot off the wet ; and having remained exposed to the weather two or three weeks or more, till the great heat abates, the lumps of Spawn are planted all over every part of the bed at little distances, just within the surface ; and the bed is then earthed all over an inch or two thick, and closely covered a foot thick, with dry li-

ter ; thus the moderate heat and peculiar quality of the dung, sets the Spawn a working, so as often to produce plenty of mushrooms in six or eight weeks : and the same bed frequently continues furnishing a supply five or six months, or longer ; but new beds must be made every year, or probably two or three times in that period, whereby to furnish a constant succession of mushrooms. See AGARICUS.

Thus, through the effects of the peculiar warmth and quality of horse stable-dung, consisting of the moist litter, and plenty of the short stuff together, formed into a hot-bed as above, the mushroom Spawn increases, furnishing both mushrooms, and sometimes a supply of young Spawn for future beds : likewise any common horse-dung hot-beds, horse-dunghills, &c. moderately rotted, are often productive of a great deal of good mushroom Spawn naturally ; probably from some fine spawny matter, or the mushroom seed having accidentally mixed in the dung or earth, &c. And thus the Spawn produced by either of these effects, is the only certain resource yet known for propagating that species by art, no seed having as yet been sufficiently discovered, by which we can raise this plant ; but the Spawn from the root, being as it were living foetuses or infant plants, which renew their species as certainly as seed.

However, besides this Spawn or off-spring of the root, the naturalists in botany are agreed that mushrooms have also generative organs, and produce flowers and seed like other plants, and naturally propagate themselves also by seed, as well as by the Spawn ; but from the exceeding minuteness both of the genital organs and seed, and their great obscurity, or concealed situation, they yet remain invisible ; though it is supposed they are contained in the *lamellæ* or gills of the mushroom, and which, when full-grown, discharges the seed upon the adjacent ground, and thence probably some is disseminated by the winds, &c. to other distant soils and situations adapted to their growth ; and penetrating into the earth, grow and become mushrooms, the roots of which multiply and furnish proper Spawn also for the work of propagation.

But it was long the opinion of many, that mushrooms never possessed the power of propagation at all, but supposed to owe their existence to the putrefaction of earth, dung, &c, which doctrine, however, is now sufficiently refuted.

For mushrooms being proper plants, they, either by Spawn or seed, or both, propagate themselves

themselves like other vegetables; and it is probably from the dissemination of the seed, to peculiar soils and situations, that we often find both mushroom Spawn and mushrooms growing in obscure places.

By Spawn, however, in particular, it is obvious that mushrooms propagate themselves plentifully, and by which, with proper garden culture, we can raise abundance of mushrooms at pleasure.

Therefore the mushroom cultivators always furnish themselves with a sufficient quantity of fresh Spawn, for every new bed, procuring it all times of the year, but more plentifully towards the end of summer, and in autumn, from the places of its growth, such as old mushroom-beds; any old horse-dung hot-beds, and horse-dunghills, that are moderately dry, and remained undisturbed several months; also sometimes in old compost heaps, consisting chiefly of horse-dung; in all of which the spawny substance discovers itself in dry lumps of dung and earth, which lumps should be taken up entire, as hereafter noticed; likewise in stable-yards, where any quantity of horse-dung has lain dry and undisturbed any considerable time, lumps of Spawn are often obtained. It is also found in fine perfection in the horse rides belonging to great inns, livery stables and horse-dealers, such as about London, &c. which rides being places to exercise the horses under cover to shelter them from wet, and the ground spread thick with the short dung from the stables for the horses to tread on more lightly, being generally permitted to remain some considerable time without cleaning out, and being always dry, upon examining towards the sides next the wall, is frequently found most excellent mushroom-Spawn in large cakes; likewise in horse-mill tracks, where horses are constantly employed in working mills, engines, and other large machinery, and they dunging, &c. in the tracks, it being occasionally swept up towards the sides, and the bottom sometimes permitted to lie some considerable thickness a long time, upon turning it up, are frequently found fine lumps of strong Spawn: also in kitchen gardens, where any piece of ground having been dunged in the spring, with new or but moderately-rotted stable-dung, or old dry hot-bed dung, &c. probably having embryo Spawn already formed therein, and which dungs happening to be but slightly digged in, or covered but a moderate depth with earth, sometimes is productive of clusters of mushrooms in patches, towards autumn in dry seasons, and in which places we often find lumps of very good Spawn: in all the above places the Spawn is met with

occasionally at all times of the year, but more certain and plentiful towards the end of summer, and in autumn, before perished by the wet and cold in winter; being found in dry lumps, and cakes of dung and earth, appearing, as before said, white and stringy, smelling strong of the mushroom.

And sometimes mushroom Spawn is produced naturally all over the surface of an old cucumber, or melon hot-bed, both in the dung and earth, in autumn or winter, where the frame and lights have been continued over the bed; and I have sometimes observed, that where the earth of the bed was of a loamy nature, the Spawn has been remarkably fine and strong, for in this kind of earth, of a moderately-light quality, the Spawn is generally superiorly substantial, increasive, and productive; so as sometimes in old beds as above, in which Spawn is discovered, the frames and glasses remaining, and the surface of the bed covered thickly with dry straw, litter, or hay, under the glasses, have produced a full crop of mushrooms towards the spring, large, thick of flesh, and of a peculiar firm texture, and rich flavour. See AGARICUS.

But mushroom Spawn is also obtained in meadows and pastures towards the end of summer, and in autumn, before the rain and cold commences; the months of August and September being generally the proper season when the mushrooms rise naturally, serving as a direction to the place to find the Spawn; then carefully opening the ground, the Spawn will appear in the earth as above, which may be digged up in lumps, and carried home in baskets for use; this field Spawn however, cannot always be so readily obtained in any considerable quantity; and as it is found only in pasture grounds, it may be very inconvenient to break up, and spoil the sward in search of it; besides, many poisonous sorts of *fungi* grow in the fields, also from Spawn; we ought to be cautious when we are gathering Spawn for mushroom beds.

From the above hints of the places of growth of mushroom Spawn, we may readily know where to obtain it in sufficient quantity for the purpose of spawning mushroom beds.

But after all, garden or bed Spawn produced in any horse-dung beds, heaps or lays of horse-dung, &c. before-mentioned, is preferable to the field Spawn for garden culture, it generally producing much thicker, more fleshy, and firmer mushrooms, of a richer flavour.

Therefore, it is incumbent on us to preserve

five all the lumps of young fresh Spawn, such as we occasionally meet with in any old dung hot-beds, dunghills, &c. laying the lumps up in the dry till wanted; rejecting, however, any very old worn-out Spawn, as far as it can be distinguished; and the virgin Spawn, or such that has not been in production, generally yields the finest mushrooms; for sometimes, even the young off-spring Spawn of such that have been long worked from bed to bed, is apt to degenerate, there being often a very material difference in the goodness of Spawn; that which is fresh and full of heart, will often produce abundance of fine mushrooms for several months in the same bed; but such that is worn out or degenerated, send up only a flash of trifling little heads at first, of no substance, and probably never produce any more to signify.

There is also a fruitful and barren sort of mushroom Spawn: the former is distinguished by the substance of the fibry or stringy white shoots, &c. and mushroom-like smell, as before observed; but in the base sort, the thready fibres are considerably more abundant, fine, and downy, often appearing like a fine white down, and being of no substance, produce only a flash of small white *fungi* destitute of the fleshy part, and which by the mushroom men is commonly called white-cup; and by not perfectly distinguishing it, many have been disappointed in their crop.

It is observable that horse or stable-dung of all others is the most remarkable for promoting mushroom Spawn, even often alone in the dung-heap, without any addition of earth, though having a small portion of any earthy substance, it may probably have the greater effect; for new horse-dung consisting of the wet litter, and the short stuff together from the stables, but the more short the better, and being collected in any considerable quantity, either in any common hot-beds, or remaining in the dung-heap a considerable time, it often becomes of a certain agreeable temperament, peculiar to the growth of mushrooms, especially if it does not burn in its collected state, by the first violent heat; and that after remaining from winter or spring, until autumn or spring following, it frequently furnishes lumps of excellent Spawn.

Methods are sometimes practised to obtain Spawn more abundantly by art, by the effects of horse-dung, both in hot-beds and in compost heaps; sometimes in the former case, by planting small pieces of Spawn, or spawny earth along the top edge of the later cucumber hot-beds in summer, or in the sides of any horse-dung heaps, having a little warmth re-

maining; so that the moderate heat of the dung in the bed or heap, sets the Spawn a-running, as sometimes both to produce a few mushrooms in autumn, and increase considerably for future use in spawning proper mushroom beds. And in the second case, it is performed by a compost of dung and loamy earth together; procuring in spring, or early in summer, a quantity of fresh horse-dung, consisting of plenty of short stuff, and a due proportion of long together; and casting the whole in a heap to ferment a fortnight or a month, that the rank burning vapour may pass away; then having some loamy earth, or other good substantial mould, or any spawny soil from old beds, form the dung into a long narrow ridge, mixing some of the earth occasionally towards the outside, and in a fortnight or three weeks, the heat becoming quite moderate, cover the whole with a dry long litter to defend it from the wet, permitting the whole to remain some considerable time; and thus probably some generating substance of mushrooms, either Spawn, or seed, or both, having by some means previously, and accidentally introduced itself in the compost, which by its certain warmth and quality promotes its vegetation, and increase, as sometimes in three or four months to furnish a good quantity of eligible Spawn.

Observe, in collecting the mushroom Spawn found occasionally in all the afore-mentioned places of growth, the lumps of dung and earth, in which it appears, should be taken up as entire as possible in a basket, and carried into some dry shed or other apartment, there deposited till wanted; or may plant it directly if the bed is ready, otherwise lay it up close in some dry apartment, or put it up in hampers, covering the whole thickly with dry litter or garden-mats: and here it may remain till wanted, for the purpose of spawning mushroom beds, as it will retain its vegetating property several months; and the drier it is kept in moderation, the better it will improve in its vegetable faculty, and take more freely with the bed when planted.

About London good mushroom Spawn is a valuable article among the kitchen gardeners, who raise great quantities of mushrooms for the markets, and in consequence thereof, some of their labourers make it their business, at certain times of the year, but more particularly in autumn, to go about to different places collecting it, which generally pays them well for their trouble, as they find a ready sale for it, from three or four to five or six shillings per bushel.

Whosoever may have occasion to purchase
Spawn

Spawn from the environs of London, will meet with it most readily in the Neat-house gardens near Chelsea; also in the neighbourhood of Lambeth, Battersea, Hammer-smith, &c. or by application in Covent-garden, Spitalfields, or Newgate Market, on a market day morning, to the gardeners who attend there with their vegetable goods for sale; and also at most of the principal nurseries.

It may be packed up in hampers, and sent to any distance, either by land or water-carriage.

For further particulars respecting the Spawn, and the general directions for the different methods of making, Spawning, and whole management of mushroom beds, see the article AGARICUS.

SPECIES.

The species of plants, being the individual plants of a genus or family of vegetables, consisting of one or two to numerous species, in different genera.

The Species of a genus are an assemblage of plants, which resemble each other in the most essential parts; that is, the characteristic mark of distinction of a genus must run through all the Species of the same family invariably, in the principal characters that constitute the said genus, which is always founded on the fructification, i. e. the different parts of the flower and fruit, &c. so as the respective Species of any particular genus are thereby distinguished from those of all other genera; and therefore the Species of a genus may in a manner be compared to the relations of a family, which all bear the same surname, although every individual is distinguished by a particular specific name; for so it is with the Species or plants of a genus, all having the same generical name prefixed to that of the specific.

Though it may be observed, that Species of the same genus often differ very materially in the appearance of their general habit, nature, and dimensions of growth; as sometimes in the same genus are comprehended both trees, shrubs, and herbaceous plants, which, although thus ultimately different in the general appearance, are found to possess invariably certain generical relations in their essential parts in the characteristic distinctions, such as those of the flower and fruit; and thus all those of the same genus are arranged under one denomination, termed the generic name.

The Species of a genus sometimes consist of only one or two, and in some many or numerous different sorts, although it is in but very few instances that a genus consists of only one Species, such as in Superb-lily, Flowering-ruth, Tamarind, African Fly, Ho-

ney-suckle, Hop, &c. but more generally most genera are composed of a greater number, some of many Species, as in Aster, Campanula, Sunflower, Geranium, Saxifrage, Oak Tree, Ash, Willow, Honey-suckle, and numerous others; and many of which comprise numerous Species, extending in some to fifty, sixty, to an hundred or more different sorts, as may be observed in some merely botanic books; though probably, in some genera, not one quarter of those great numbers are cultivated plants, or that possess any merit for garden culture, or any other materially useful purpose; as sometimes many of the Species therein enumerated are wild or noxious weeds; in other cases many genera, of smaller or moderate extent, consist mostly, or in the greater part, of estimable plants, either principally for introduction in the different districts of gardens and plantations, or for some essential economical occasions in trades, &c.

So that, according to our plan in the process of this work, displaying the general practice of gardening, systematic arrangements and descriptions of the various genera and Species of garden plants, and the essentials of horticultural botany, we, in the arrangement of the Species of the respective genera, omit the useless and improper, and only introduce principally those of all the more valuably useful, estimable, or desirable plants, trees, shrubs, flowers, fruits, &c. as possess some requisite degree of merit, according to their respective kinds, proper for horticultural purposes, either useful, ornamental, or curious, &c. in the several garden departments, such as the kitchen garden, fruit-garden, pleasure-ground, flower-garden, shrubbery and plantations, greenhouse and hot-house, &c. all arranged systematically, with their general and particular description, respective and general uses, methods of propagation and culture.

Generally Species of the same genus possess, in some degree, similar medical powers, and often in domestic and other economical uses; such as is exemplified in the genus *Allium*, consisting of the garlick, onion, leek, shallot, cives, &c. the *Brassica*, comprising the Cabbages, Savoy, Broccoli, Cauliflower; the *Laurus*, containing the Bay, Benjamin Tree, Sassafras, Cinnamon; and the genus *Artemisia*, comprehending the Mugwort, Wormwood, and Southernwood, Tarragon, &c. and in various other instances.

SPERMATOCOE, Button Weed.

An annual and shrubby plant for the stove, garnished with linear or spear-shaped leaves, and monopetalous flowers.

Class and order, *Tetrandria Monogynia*.

[*Characters*.] CALYX, a small four-toothed
6 U perma.

permanent cup. **COROLLA**, monopetalous and funnel-shaped, with the border cut into four obtuse, reflexed, spreading parts. **STAMINA**, four awl-shaped filaments, topped with simple antheræ. **PISTILLUM**, a roundish compressed germen; style, the upper part bifid, crowned with blunt stigmata. **PERICARPIUM**, two oblong capsules, joined together, containing single roundish seeds.

There are several species of this genus: these for our purpose are,

1. **SPERMACOE tenuior.**

Slender Button-weed.] Is annual, and rises to the height of two feet and a half; the branches and leaves come out by pairs; the leaves are linear and smooth; the flowers grow in slender whorls toward the top of the stalk; they are small and white, and are succeeded by horned capsules.

2. **SPERMACOE verticillata.**

Whorled-flowered Button-weed.] Rises with a shrubby stem three or four feet high, furnished with a few slender branches, garnished with smooth, lanceolate leaves, growing in whorls; the flowers come out near the top of the branches in globular whorls, of a very white colour.

The propagation of these plants is by seeds, sown on a hot-bed in spring, and when come up, must be transplanted into single pots of earth, and replunged to forward them; afterwards they must be removed to the stove, and treated as other plants of the like kind.

SPICA, a Spike.

A mode of inflorescence, or manner of flowering, peculiar to many plants; consisting of a simple peduncle or flower-stalk, supporting many flowers all along its sides, without any pedicle or partial foot-stalk, but are sessile, or sit close to the main stalk, generally in alternate arrangement.

But the florets of a Spike are also sometimes single-rowed, and sometimes double-rowed, &c.—When single-rowed (*Spica secunda*) the flowers are all turned towards one side; and double-rowed (*Spica disticha*) when they stand two ways.

SPIGELIA. Worm Grass.

Consists of an annual and perennial plant, with quaternate or opposite leaves, and monopetalous funnel-shaped flowers.

Class and order, *Pentandria Monogynia*.

Character.] **CALYX**, a monophyllous, five-parted, pointed cup. **COROLLA**, monopetalous and funnel-shaped; the tube is long and narrow at bottom, the border is spreading and cut into five pointed segments. **STAMINA**, five filaments, topped with simple antheræ. **PISTILLUM**, a germen composed of two globose parts, with a subulate style and simple

stigma. **PERICARPIUM**, a twin bilocular capsule, containing many small seeds.

The species are,

1. **SPIGELIA anthelmia.** (*Annual.*)

Worm Grass of America.] Hath a fibrous root, from which arises an erect herbaceous channeled stalk a foot and a half high, garnished with four oblong-oval, pointed leaves, placed crosswise round the stalk; from the joints of the stalk are produced two small branches placed opposite, furnished with lesser leaves, and short spikes of herbaceous flowers ranged on one side of the footstalks.

2. **SPIGELIA marilandica.** (*Perennial.*)

Maryland Worm Grass.] Hath a perennial fibrous root, from which arise two or three erect stalks, eight or ten inches high, garnished with oval pointed opposite leaves in pairs, the stalk is terminated with a spike of flowers ranged on one side; the outside of the flower is of a bright-red, and inside of a deep-orange colour, making an elegant and beautiful appearance in June and July.

These plants are esteemed in America for their efficacy in destroying worms.

The first species is propagated by seeds sown on a hot-bed in the spring, and treated as other tender annuals.

The second species, although hardy, ripens not its seeds in England; the propagation is by parting the roots in autumn or spring.

SPINA, a Spine or Thorn.

One of the armature of plants, and are protruded immediately from the wood, being an expansion of the ligneous body; by some compared to the horns of animals, which adhere to the bones of the skull; so that the Spine or Thorn differ from the prickle, *aculeus*, which are detached only from the bark, and not so strong and hard as Spines. See **ACULEUS**.

Spines are intended by nature as armour to certain plants, to keep off cattle and other animals that would injure them.

Thorns arise either upon the stem and branches, as in buckthorn, boxthorn, white-thorn, sloe, wild-plum, pear, orange, triple-thorned acacia, false-acacia, furze, and many others of the tree and shrub-kind; or on the leaves, as in holly, American aloe, acanthus, thistle, Adam's needle, juniper, butcher's-broom, &c. On the calyx, as in thistle, centaury and mad-apple; or on the seed-vessel and fruit, as in thorn-apple, prickly spinach, &c.

Spines rise either singly, as in most spinous plants; doubly or by pairs, as in many sorts; and triple, as in the three-thorned acacia.

By culture many plants lose their Spines, as plum, pear, medlar, orange, citron, &c. and the leaves of holly by age.

SPINACIA,

SPINACIA, Spinach.

Spinach is a noted culinary herb of the annual tribe, valuable as an esculent for its large leaves for various culinary purposes most times of the year; having broad triangular and roundish leaves, rising in clusters close to the ground; succeeded by upright tall stems, supporting spikes and clusters of small apetalous male and female flowers on separate plants.

Class and order, *Diœcia Pentandria*.

Characters.] CALYX, diœcious flowers, having in the males a calyx cut into five oblong, obtuse, concave segments; and in the females is monophyllous and permanent, cut into four acute parts, two of them being very small. COROLLA, no petals. STAMINA, five capillary filaments, with oblong didymous antheræ. PISTILLUM, in the females a roundish compressed germen, and four hair-like styles with simple stigmas. PERICARPUM, no seed-vessel; the seed is roundish, and lodged in the permanent calyx, and is either thorny or smooth in the different varieties.

There are but two species in this genus, one of which only is cultivated, being the common culinary Spinach, comprehending two valuable varieties; namely, triangular leaved, with prickly seed,—round-leaved, with smooth seed: the former being the hardiest, is more valued for the winter crop; but the latter having larger, thicker, and more succulent leaves, is preferable for spring and summer.

The species is,

SPINACIA *oleracea*.

Common Culinary Spinach.] Hath a somewhat spindly fibrous-root, crowned with a tuft of large, broad, triangular, and roundish leaves on foot-stalks, close to the ground; and when it shoots for seed, rises with upright, hollow branchy stalks three feet high, producing spikes and clusters of numerous small, apetalous, greenish flowers, male and female on separate plants; succeeded in the females by roundish close-fitting seeds, in some armed with spines, in others smooth.

Remarking, the male plants generally produce their flowers in spikes, and the females in close clusters at every joint.

Varieties.] There are two remarkable varieties of this species, each of which was formerly considered as a distinct species; but are only varieties of one and the same species, their specific determination being in the close-fitting seeds, *fructibus sessilibus*, which is exactly the same in both varieties; there is, however, a pretty permanent distinction in their leaves and seed; one variety having tri-

angular arrow-pointed leaves, and prickly seed; the other having roundish leaves and smooth seed, as below.

Triangular Spinach with Prickly Seed.] Hath large, triangular, arrow-pointed leaves, five or six inches long or more, being broad and angular each way at the base, running up to a narrow point at top; and the seeds are mostly armed more or less with short spines.

Round Spinach with Smooth Seed.] Hath large roundish or oval leaves, five or six inches broad or more, of a more thick, fleshy, succulent consistence; and the seeds more round, mostly free from spines, and quite smooth.

Both these varieties admit of some variations in the shape and size of the leaves; the broadest and thickest leaved sorts are consequently superior in goodness; remarking of the Round Spinach in particular, some will have roundish leaves, others oval or oblong, and one sort exhibits itself with much rounder, broader, and thicker leaves than the others, generally of a more stocky and luxuriant growth, and stronger green colour, and is the most valuable variety of the round-leaved kind: but observing both of the triangular and round-leaved varieties, we should endeavour, as much as possible, to mark the most stocky and broad-leaved plants to run up for seed, in order to obtain and continue the proper breed of such eligible varieties only, as well as possible, sufficiently for general culture.

As to the merit of each variety,—the triangular Spinach being of a more hardy nature, is generally cultivated for the main winter crops; and the round-leaved sort claims precedence for the size and thick consistence of its leaves, but being more succulent, is not quite so hardy as the other to stand the winter; it is cultivated principally for the spring and summer crops.

Both the varieties are herbaceous annuals, that succeed in the open ground, requiring to be raised annually from seed sown in an open situation, in spring, summer, and autumn, to remain where sown; and the plants coming up in a fortnight, they attain perfection for use in two or three months; in which those sown in spring and summer remain but a short time in full perfection, and then run up to stalk, producing flowers and seed, and totally decay, root and all, the same year; but those sown in autumn come up the same season, and stand the winter till next spring, but not longer than April or May, before they run to seed, and perish as soon as it is ripe.

They commonly flower in June; and when

in flower, the male and female plants are then distinguishable, the former generally producing the flowers in spikes, having the flowers furnished with the stamina, sustaining a yellow farina, being the male dust for the impregnation of the flowers of the female plants, which have no stamina, only the female organs, the germen and styles, on which the male plants naturally discharge their farina, and soon after decay; but the female plants continuing their growth, and being thus fecundated, the embryo seeds grow fast to perfection, being also thereby fertilised or rendered prolific, as that when sown they will readily grow; for without the vicinity of the male flowers, many of the females would prove abortive, and all the seeds sterile; which determines how necessary it is in Spinach, and other dioecious plants, to have a sufficiency of the males to impregnate the females.

Spinach is obtained for use almost the year round by different sowings, from January till August or September, at about a month's interval between the early sowings, two or three weeks in the main spring crops, and not more than a fortnight in summer; for the plants of each crop of the spring and summer sowings will not continue longer for use, before they will fly up to seed; but the autumn sowings, performed from about the middle or latter end of July, to the middle or end of August, do not run so soon, more especially those sown in August, which is the only proper season for sowing the winter crops, and which coming in for use in October, continue all winter and spring, until May, then shoot up to seed; being succeeded abundantly by the spring-sown crops, as above.

As to the culture of Spinach, it is very easy: both the varieties may be raised in any situation from seed, sown either broad-cast and raked in, or in drills; the plants remaining where raised, require only a little thinning and clearing from weeds; however, there being several material hints necessary to be generally known in order to obtain Spinach in full perfection in the different seasons of the year, we will therefore treat of its culture accordingly; first exhibiting hints for its general culture, afterwards the culture of each variety, separately in the different seasons.

Of its Propagation and General Culture.

The propagation of Spinach is effected only by seed, as being an annual, sowing it every year in spring and autumn; the former season of sowing furnishing the main spring and summer crops; and the autumn sowings in August furnishes Spinach all winter, and for early spring use, until May.

It may be sown at several intervals of time, from January till August, as every month, three weeks, and fortnight, according to the earliness or advanced period of the season, so as to obtain a regular succession of Spinach most part of the year; the spring and summer sowings attaining perfection for use from April till August or September, and run to seed, and totally perish the same year; but the autumn sowings in August being designed not to come in for use till October, in order that the plants may remain all winter, and the following spring, until succeeded by the spring-sown crops, as before remarked.

Observe of the spring sowing, that as the very early sowings in January run soon to seed, should sow but a moderate quantity; but may sow freely in February, March, and April, every three weeks, for the main spring crops, which will attain full perfection in useful growth, before it begins to run; and will supply plenty of young Spinach in great perfection, from April or May, till towards midsummer.

But if Spinach is required throughout the summer, continue the sowings every fortnight, all May, June, and July; though the summer-sown Spinach rarely attains full perfection, like the spring sowings, as it runs hastily up to seed; but should sow frequent accordingly; and always in a free open situation, the seed sown thin, and the plants thinned timely in their advancing young growth.

And as to the autumn sowings, as the plants do not run the same year, should always sow a good full crop to stand for winter and early spring use, as aforesaid.

With respect to the soil and situation for the culture of Spinach, it succeeds in any common soil of a kitchen-garden; but the richer in dung, the better; for a well-enriched soil makes great difference in the growth of Spinach, by exhibiting the plants of a luxuriant growth, in respect to size and thick consistence of the leaves, a material excellence to be regarded in Spinach; always choosing an open situation, not too near low-spreading trees, &c. for Spinach never succeeds in close or shady places, in which it always draws up weak, and soon runs to seed, without attaining perfection; but having a free exposure open to the sun and air, encourages a stocky growth, and large expansion of its leaves. A warm border may be proper for the early crops; but for the main crops in general, the open quarters are the most eligible; though a broad warm-lying border may also be proper for some part of the later sown winter-crops occasionally, for the

the sake of having the advantage of a little shelter of the fence, and benefit of the sun during the winter season.

Let fresh seed not more than a year old be procured for each sowing; for this will be found of much importance in the free growth of the plants; and for the autumn sowings of the winter crops, it is of advantage to procure new seed of the same year's sowing, if possible.

The ground being digged, the seed may either be sown broad-cast and raked in, or in shallow drills a-foot asunder; though broad-cast is the most expeditious, and probably the most eligible method for the growth of the crop, in the product of large full leaves; sowing it all over the surface moderately thin, either in one continued plat, and trodden down evenly, if light ground, and raked in with a large rake, or light harrow; or may divide the ground into four or five-feet-wide beds, with foot-wide alleys between; more especially for the early and winter crops in wet ground; and the seeds being sown as above, rake them in evenly: but drill-sowing may also be occasionally practised, drawing the drills with an hoe flatways, near an inch deep, and ten or twelve inches asunder, scattering the seeds thinly along the drills, and rake the earth over, full half an inch deep; which mode of sowing Spinach may be more particularly eligible, when obliged to sow between other crops, as between wide rows of beans, peas, cabbages, &c. it also more readily admits of hoeing up the weeds between the rows; and if sown thin, and the plants also thinned proportionably, they will grow as large and fine as in the other method of sowing, and the produce very conveniently gathered; so that drill-sowing of Spinach, the spring-crops particularly, may also be effected occasionally, between other crops already growing in rows; as beans, cabbage, cauliflowers, &c. and may likewise be sown in wide drills alone; i. e. either about a foot distance for a distinct full crop; or in rows two feet asunder, to admit of intercropping in the intervals with rows of cabbages, beans, and other things occasionally: however, the broad-cast sowing being the most ready and expeditious for a large full crop, and generally also the most advantageous for making the most of the ground when necessary, is the most commonly adopted method of sowing Spinach, for large tracts of ground especially. See SOWING OF SEEDS.

Observe, in either of these methods of sowing Spinach, to scatter the seeds moderately thin, as the plants at any rate require to be

thinned to three or four inches distance at least; do not however spare seed in a moderate way, and let it be directly raked regularly in; previously observing of that sown broad-cast all over the surface, if in light loose land particularly, and a dry warm season in the advanced part of spring, and in summer and autumn, it may be proper first to tread the seed evenly down, then rake it in effectually with a large rake; and of that sown in drills, rake the earth evenly over it the depth aforesaid, and rake the surface smooth.

These seeds quickly germinate, and the plants will come up in a fortnight; or perhaps, if sown very early in spring, it will be three weeks or a month before they come up.

Observing, however, in respect to their culture, that when the plants have three or four leaves an inch broad, they should be thinned and cleared from weeds, performed either by hoe or hand; but the former is the most eligible, especially for the broad-cast-sown crops: chusing dry weather, and cut out the plants to three or four inches distance, together with all the weeds in every part; the above distance, however, is scarcely sufficient, unless intended to begin thinning out the plants for use while young; otherwise it is advisable to hoe them out six or eight inches asunder, especially the spring and summer crops of the round Spinach, which having proper room, will grow very large, and spread its broad leaves widely around, and will not run to seed so soon as if left close; for the spring and summer-sown Spinach in particular, if left too close, draw up weak and trifling, and soon go to seed; but as to the winter crops of triangular or prickly Spinach, if thinned finally to three or four inches distance, will be sufficient. See their *Spring, Summer, and Winter Culture*, under separate heads.

Spinach is often sown in spring with other crops, for the sake of cropping the ground to the best advantage, where necessary; especially where straitened for kitchen-ground room, or also when occasionally necessary to sow any considerable space of ground for a large crop of spring Spinach; for as the plants are of low spreading growth, soon acquiring useful perfection, and of short duration in the spring-sown crops, generally terminating their useful growth early in summer, for clearing off the ground to give full scope for any intervening succession crops; so that, agreeable to these intimations, where thought expedient, by way of saving or gaining ground, may occasionally perform some of the spring sowings, less or more, between rows of some particular crops, such as in final transplanted young cabbages
cauli.

cauliflowers, also between rows of beans, peas, &c. sowing the seed either broad-cast thinly, and raked in regularly, or in middle drills singly, or doubly between wide rows; sometimes also the market gardeners in sowing the large main crops of spring Spinach, they on the same consideration, to save or gain ground, &c. sow Spinach and short-top radishes mixed together, in February and March, &c. both on large borders and in the main quarters, often on the same ground where the general crops of spring-planted cabbages and cauliflowers are intended, generally sowing the Spinach and radishes first by broad-cast all over the ground, and rake or harrow them in; then either directly, or in a week, fortnight, or a month after, as it suits, plant the cabbages and cauliflowers in rows at proper distances, as directed under their proper heads. See BRASSICA. They will soon take root, and get the start of the Spinach and radishes, without retarding their growth; and the two latter will be all gathered off for use, by the end of May, and beginning and middle of June; when the ground is hoed to cut up weeds, loosen the soil, and draw up earth to the stems of the cauliflowers and cabbage-plants.

But the above methods of sowing Spinach with other crops are only intimated for occasional practice in the aforementioned cases; for in gardens where they are not necessitated to make the greatest advantage of the ground, it may be more advisable to sow the main crops mostly alone, without the incumbrance of other crops; in which the Spinach will most generally attain the greater perfection; in this however, every one will suit his own convenience.

When the plants have leaves two or three inches broad, may begin thinning out some for use.

As to the method of gathering Spinach for use, it may either be cut up with a knife wholly to the bottom, or clean out by the root if the crop wants thinning; or only crop the large outer leaves; the root and heart remaining, shoots out again.

In gathering the spring crops, however, we may at first, if the plants want thinning, cut them up wholly to the root, thinning them out where thickest in a gradual manner, so as to leave the standing plants at least six or eight inches distant to grow to perfection, which, when beginning to shoot for seed, may also be cut up wholly to the bottom.

And in gathering the winter crop of Spinach, if the plants stand too close at first, some may be thinned out quite to the bottom;

afterwards must only crop the larger outer leaves all winter, and early part of the spring; but when the spring is more advanced, and the plants grown large and require thinning, or when they begin to run to seed, you may then cut them up to the bottom, in a thinning order.

Having thus exhibited hints for the general culture of Spinach, we now proceed to treat of the culture of each variety separately, in its proper season; first, the spring and summer crops; second, the winter crop.

Spring and Summer Crops.

The round or smooth Spinach being the most eligible sort for the spring and summer culture, for the reasons before observed, February, March, and April are the principal months for spring-sowing the main crops thereof; though, to obtain a succession of this Spinach as early and late as possible, several sowings may be performed, from January till August, as already observed.

The first sowings may be performed in the beginning or any time of January, if the weather is open; or, for the greater chance of success, may sow twice in that month, if the weather permits, in a warm dry situation; sowing only a moderate portion at this early season, especially in the beginning of the month, as it may be cut off by inclement weather; or if the crop survives the frost, these early plants are apt to go to seed soon after they acquire their proper growth.

In February, however, for the main spring crops, may sow more freely in almost any open situation, especially towards the middle of the month; it will, however, be proper to sow also twice in this month, at two or three weeks' interval; which will ensure the greater success of plenty in a regular succession a long time, to succeed the winter crops, which will run to seed in April and May, about the time these sowings arrive to the first state of maturity for the table.

In March and April, it is also advisable to continue sowing the same sort of Spinach every three weeks, in an open situation, which will furnish a regular supply for the table or market in May and June.

And in the months of May, June, and July, if a constant succession is required all summer, it is proper to repeat the sowings almost every fortnight during those months, for these plants very soon shoot up for seed at this season: choosing for these summer-crops the moistest soil the garden affords in a free situation: and if you can have the opportunity of moist weather for sowing them, it will be a particular advantage; being careful to sow the seed moderately thin and regular, either broad-

broad-cast and raked well into the ground, or in drills and earthed in an inch deep: and let the plants be moderately thinned in proportion; otherwise will soon draw one another up into stalk for seed. Observing, that if a regular succession is required to be extended also quite through the autumn, we must continue the summer sowings till the middle or latter end of July; and thus we procure a constant succession till the beginning of winter, or till succeeded by the winter crops in October.

With respect to the method of sowing all the above spring and summer crops of Spinach, it may be principally by broad-cast and raked in, or occasionally in drills, as before observed in the *General Culture*.

But such persons as are not particularly anxious about having the Spinach in the fullest growth in large thick leaves, may sow it thick in drills, six inches to a foot or less asunder, so when the plants are up, permit the whole to stand to grow up together in close rows; and when two or three inches high, cut them off close according as wanted, leaving the bottom to shoot up again, to afford one or two more cuttings; but which will be greatly inferior in goodness of growth, to those crops in which the plants are thinned to moderate distances; however, every one may suit his own inclination and convenience, in the methods of sowing, agreeable to the foregoing intimations.

As to the culture of these spring and summer crops of Spinach, it is nearly the same as observed in the general culture; that when the plants have three or four leaves an inch broad, hoeing them out in dry weather to about three or four inches distance, cutting up all weeds; and when they are advanced in growth, so as nearly to meet, they will be fit for the table: when may either gather the large leaves, or if the plants stand close, they may be thinned out regularly, the largest for use, cutting them up close within the ground; repeating the thinnings according as they are wanted for the family or market: and those remaining at last, having full scope, will attain great perfection, in large broad spreading leaves, thick and succulent.

After, however, all these spring and summer crops attain full perfection for use, they soon shoot up stalks for seed, the same season, and become useless; which renders a repetition of several sowings necessary.

Some of the best plants of the February and March sown crops should be left to run up, and produce seed for next year's sowing. See *Saving the Seed*.

Winter Crop.

Winter Spinach is principally the triangular or prickly sort, as being the hardiest, sown in the end of July or beginning of August, and arriving to perfection for use the same year, in the latter end of September, or in October; and stands without running all winter, supplying the table all that season, and the following spring; being, however, generally in good perfection all October, November, and December if mild weather, and often in moderate seasons continues growing all winter long; is liable however to suffer by severe frost; but the root and heart remaining sound, it recovers strength apace as the spring advances, and shoots out into large leaves abundantly till May; then it shoots for seed, being succeeded by the spring-sown crop.

It is advisable to chuse principally the triangular or prickly Spinach for this main crop, as being the hardiest to endure the frost and wet in winter. The leaves not being so succulent as those of the round-leaved Spinach, are less liable to be affected in winter, by severe cutting cold, or excessive moisture; however, some of the round-leaved sort may also be sown in a warm-lying dry situation, in which the plants often stand the winter effectually, and produce fine large leaves towards the spring.

The proper season for sowing this crop is principally the first and second week in August; for if sown sooner, it will get too forward, and be apt to run to seed the same autumn, or very early in the spring; however, in cold or poor soils, in very exposed situations, it is proper to sow early in the first week of this month, as the forwarding the sowings a few days in such soils and situation is of importance, that the crop may get properly forward and obtain sufficient strength before the approach of winter. But in good, rich, warm-lying ground, if the sowing is performed any time in the first fortnight of the month, it may be time enough; and in some of the rich grounds about London, they often sow this crop of Spinach in the middle of this month, especially for the later crop; however, it is most advisable to sow the main winter crops rather early in August, which generally proves a very successful season in most situations for sowing winter Spinach; observing, if showery weather happen about this time, it will prove an advantageous opportunity for sowing; as, when sown in dry hot weather, this seed is apt to germinate irregularly, and the plants rise sparingly and straggling; do not however omit the proper sowing season as above.

Chuse generally for this crop an open situation, that lies tolerably dry in winter, and that enjoys the winter's sun.

And the ground being properly digged, immediately sow the seed while the surface is fresh and moist, sowing it generally by broadcast all over the surface, either in one continued plat to make the most of the ground, or in four or five-foot wide beds, for the convenience of standing in the alleys to do the necessary culture and gather the produce; and may scatter a sprinkling of brown Dutch, and common cabbage lettuce, &c. along with the Spinach seed, to take their chance for culling out in winter and spring: directly, as soon as sown, tread and rake it in evenly.

Or some may be occasionally sown in drills, eight to ten or twelve inches asunder, as formerly intimated: but I would more generally prefer the broad-cast sowing for the principal crop, either in a continued space, or in beds, as above: especially when intended to give the plants a regular thinning, which is always the most effectual mode of culture, whereby to have Spinach in best perfection.

In large crops of winter Spinach, as in most of the market gardens, they very commonly plant rows of early cabbages, in October or November, whereby to make all possible advantage of the ground; the rows of cabbage being three feet and an half or four feet asunder, or more, as, at that distance, they in their advancing growth, will not be any impediment to the Spinach, which in spring being all cleared off for use, there remains a full crop of cabbages, &c. in good forwardness; so we thus both gain time and ground.

But with respect to the culture of this crop of winter Spinach, the plants coming up in a week or fortnight after sowing, will, in three or four weeks after that, when their leaves are an inch broad, want thinning and clearing from weeds, performing it if possible by hoeing in dry weather, leaving the plants three or four inches asunder; which will be room enough for the present, as some may afterwards be gradually thinned out for use, so as to leave them finally about four or five inches apart; afterwards, must only gather the leaves for use all winter, taking always the larger outer ones; and the smaller leaves in the centre gradually expand themselves in their turn for use in regular succession all winter and spring; but in the spring, when the plants grow large and crowd one another, or begin to shoot for seed, they may be cut up clean to the root.

Particular attention is required to keep this crop clear from weeds by occasional hoeings

and hand-weeding as may be convenient, being particularly careful to clear away chick-weed, which is apt to infest this crop greatly in winter; always shaking the largest of the weeds entirely off the ground, which, if left at this moist season, would soon strike root again and grow.

Towards spring, after the rigours of winter are past, take opportunity of a fine dry mild day, and lightly hoe the surface of the ground about the Spinach, which will greatly recruit the vigour of the plants, and in February and March will shoot out strong, and attain fine perfection again for use: still cropping only the largest outer leaves at first, unless they stand too thick, or when they begin to shoot for seed, as before hinted; then may be cut up by the root, as they are wanted, leaving a portion to produce seed, as below.

Saving the Seed.

When intended to save Spinach seed, may allot a portion both of the spring and winter crops to stand and run up for that purpose.

Remarking, you may either sow a quantity of both varieties on purpose, in spring and autumn, in an open situation, to stand for seed; or may leave a parcel of some of the crops that were raised for use; observing of the spring-crops, chuse principally that of the February or beginning of March sowing, which will run up early the same year, and ripen seed the beginning of autumn following: and as to the winter crops, they being not raised till August, do not shoot till the following spring; though as they run earlier to stalk than the spring-sown plants, they probably will ripen their seeds somewhat earlier in autumn.

Note, in the plants designed for seed, it may be of some advantage to have the two varieties, round and triangular Spinach, at some distance from another, lest by the intercommunication of the farina it may cause a degeneracy.

Observe likewise, in the plants allotted for seed, should draw out all the bad sorts, preferring those of the most stocky growth, with the largest, most expanded, and thickest leaves; thinning the whole eight or ten inches distance, and cut up all weeds.

They will begin to run up to seed-stalks in April and May: the winter crops generally shoot first, and are soon followed by the spring crops, flowering in June; at which time the male and female plants discover themselves distinctly; leaving, however, the whole to nature, the males will sufficiently fecundate the flowers of the female plants, to

as the latter will be loaded with abundance of ripe fertile seeds, in the end of July or beginning of August.

When the seed is full ripe, which is obvious by its changing brown and hardening, the stalks must be pulled up, and spread to dry a few days, turning them occasionally to dry, and harden all the seed properly : then thresh them out, and bag them for use.

This newly-saved seed is excellent to sow for the winter crop, provided it is ripe time enough ; it however remains perfectly good for next year's sowing, but is not to be trusted to if more than a year old.

SPIRÆA, *Spiræa frutex*, &c.

This genus is composed of shrubby and herbaceous plants, consisting of many beautiful, deciduous, flowering shrubs, and floriferous herbaceous perennials, all of hardy temperament ; and eminent for decorating the pleasure-ground, being of upright growth, adorned with spear-shaped, pinnated, trifoliate, and decompound leaves in the different species, and terminated by spikes and clusters of pentapetalous flowers.

Class and order, *Icosandria Pentagynia*.

Characters.] CALYX is monophyllous, acutely quinque-dentate, and permanent. COROLLA, five oblong roundish petals inserted into the calyx. STAMINA, twenty or more slender filaments, having roundish antheræ. PISTILLUM, five or more germens, supporting five styles, having capitated stigmas. PERICARPIUM, oblong, acuminate, compressed, bivalvular capsules, containing a few small acuminate seeds.

There are many species of *Spiræa*, the greater part of them being shrubby, with durable stems, &c. and others are herbaceous, having durable roots, but mostly annual in stalk. All the shrubby kinds are originally exotics, from different parts of the continent of Europe, Siberia, &c. and North America ; and of the herbaceous kinds, some are indigenous plants of England, others exotics ; but all the sorts, both shrubby and herbaceous, are very hardy, and most of them have been long inhabitants in our gardens for ornamenting the shrubbery, &c.

Shrubby Kinds.

Under this head are exhibited some very eminent hardy, deciduous, flowering shrubs, obtaining from about three or four to six or eight feet stature, mostly with slender pliant shoots, some garnished with oblong simple leaves, others with lobated and pinnated foliage ; and the branches terminated by spikes and clusters of flowers of very ornamental appearance ; hence these shrubs are in good

estimation among the curious for embellishing the shrubbery compartments, particularly the first three or four species, which have been long residents of our gardens.

There being eight or nine species of these shrubby *Spiræas*, are all originally from abroad, in different parts of Europe, Asia and America, &c. but are all hardy enough to succeed in our open plantations.

The chief species are,

1. *SPIRÆA salicifolia*.

Willow-leaved Siberian Spiræa, or Common Spiræa frutex.] Rises with many upright, straight, slender, reddish-brown stems and suckers from the root, three or four feet high ; garnished with spear-shaped, obtuse, serrated, naked leaves ; and the stalks terminated at top by doubly-branching racemous spikes of numerous pale-red flowers.

This is the most common sort of *Spiræa*, is in high estimation as a flowering shrub ; it flowering beautifully in June and July ; and frequently the same year's suckers, from the root, flower also in August.

The young shoots of this plant being straight, pliant, and tough, are often used for tops of fishing rods, and riding switches.

2. *SPIRÆA tomentosa*.

Tomentose or Downy-leaved, Red Philadelphian Spiræa.] Rises with upright, slender, branchy, purplish stems, three or four feet high ; spear-shaped, unequally-sawed leaves, tomentose or downy underneath ; and the branches terminated by doubly-branching racemous spikes of beautiful red flowers.

Variety.] With white flowers.

Both the varieties flower in June and July, and are very beautiful.

3. *SPIRÆA hypericifolia*.

Hypericum-leaved Canada Spiræa, commonly called Hypericum frutex.] Rises with slender brown stems, branching numerously and slender almost from the bottom, five or six feet high ; garnished with small oval entire leaves, and numerous small white flowers all along the branches, to the very ends of the twigs, in small close-fitting umbels.

This shrub has singular beauty when in flower, as every branch and twig is closely covered with flowers their whole length ; flowering in May and June, continuing very ornamental about a fortnight.

4. *SPIRÆA opulifolia*.

Guelder-Rose-leaved Virginia Spiræa.] Rises with many shrubby stems branching six or seven feet high, having a brown loose bark, falling off in winter ; garnished with lobated or lobed leaves, like the guelder-rose and currant leaf ; and numerous white flowers in

corymbose bunches at the ends of the branches.

5. *SPIRÆA forbifolia*.

Sorbus-leaved Siberian Spiræa.] Rises with shrubby slender stems and branches, three or four feet high; pinnated leaves of four or five pair of folioles uniformly serrated; and white flowers in panicles at the ends of the branches, in July.

6. *SPIRÆA crenata*.

Crenated-leaved, Siberian and Spanish Spiræa.] Rises with shrubby slender stems, and numerous slender, brownish branches, four feet high; having oblong leaves serrated at the end, and white flowers in corymbose bunches laterally from the sides of the branches in May.

7. *SPIRÆA chamædrifolia*.

Germander-leaved Siberian Spiræa.] The leaves ovate, cut-sawed, smooth; and with peduncled flower umbels.

8. *SPIRÆA triloba*.—Three-lobed leaved Spiræa.

9. *SPIRÆA argentea*.—Silvery wedge-form-leaved Spiræa.

All these shrubby *Spiræas* flower here very ornamentally, from May till July, in different species; but rarely ripen seeds in perfection in England; they however are all easily propagated, some by suckers, and all of them also by layers and cuttings. See their *Propagation*.

Herbaceous Kind.

Consists of four floriferous perennials of the fibrous-rooted tribe, rising with herbaceous annual stalks, from one to three or four feet high, garnished with pinnated, ternate, and decompound leaves, and terminated by cymose bunches, and panicles of flowers; they are all perennial in root, but renew their stalks annually in spring, arriving to a flowering state in June and July, produce ripe seed in autumn, and the stalks soon after decay.

There being four species of these kinds, the two first grow naturally in England, in pastures, &c. and the others are foreigners, but are both very hardy.

10. *SPIRÆA Filipendula*.

Filipendula, or Drop-wort.] Hath a fibrous root hung with numerous small oval tubers, and crowned at top with a large tuft of pinnated leaves, of many reniform, sawed lobes spreading over the ground; and upright herbaceous stalks a foot or more high, terminated by cymose bunches of white flowers.

Varieties.] Common single-flowered *Filipendula* of the pastures, &c.—Double flowered of the gardens.

The single sort grows wild in England, in pastures and chalky grounds, but is also re-

tained in gardens as a flowery plant, in assemblage with the double sort, which is very ornamental.

They flower in June and July, and the seeds ripen in autumn.

The root of this plant, consisting of many thready fibres, hung with small oval knobs, it obtained the name *Filipendula*.

11. *SPIRÆA Ulmaria*.

(Ulmaria regina prati)—*Queen of the Meadow, or Common Meadow-Sweet.*] Hath a thick, fibrated, spreading root, upright, reddish stalks, three or four feet high; garnished with large pinnated leaves, of two or three pair of indented lobes, and an odd one, which is the largest of all, and lobated; and the stalks terminated by large cymose bunches of white sweet-scented flowers, in June.

Varieties.] Common single flowered of the meadows—Double-flowered of the gardens.—Variegated-leaved.

The common single sort grows wild in moist meadows in England, but is often allowed garden-culture along with the double and variegated-leaved sorts; the flowers of all the varieties being very conspicuous, and agreeably scented; but the double sort in particular makes a fine appearance: they flower in June, and the seeds ripen in autumn.

12. *SPIRÆA trifoliata*.

Trifoliate or three-leaved Virginia Meadow Sweet.] Hath a fibrated root, upright, branchy stalks a foot high; garnished with almost equally ternate or trifoliate serrated leaves; and terminated with loose panicles of white flowers in July.

13. *SPIRÆA Aruncus*.

(Aruncus)—*Greater Meadow-Sweet, or Austrian Spiræa.*] Rises with upright firm stalks, three or four feet high; garnished with supra-decompound leaves; each division consisting of three or four pair of folioles, and an odd one; and the stalks terminated by paniculated spikes of dioecious white flowers in July.

All the above species of *Spiræa*, both shrubby and herbaceous kinds, are very hardy, succeed in any common soil and situation, and are of long duration; the shrubby kinds being durable in root, stem, and branches, and deciduous in leaf; but the herbaceous kinds are durable only in root, and renew their stalks every spring; all the sorts, both shrubby and herbaceous, flower abundantly every summer; the flowers separately are small, composed universally of five small petals each, but being numerous and closely placed, are conspicuous to view; but are rarely succeeded by seed in England in the shrubby

shrubby kinds, though most of the herbaceous kinds furnish tolerable plenty in autumn.

As to the merit of all the sorts in gardening, they are all proper furniture for ornamenting the shrubbery, and other parts of the pleasure-ground occasionally.

The shrubby kinds particularly have great merit as deciduous flowering shrubs, for embellishing the principal shrubbery compartments, placing them somewhat forward, in assemblage with other shrubs of equally moderate growth; and here they will exhibit a proper variety, and flower very ornamentally every summer.

And as to the herbaceous kinds, considered as flowery plants, all the sorts, not omitting the doubles, are proper for adorning the common borders, &c. where they will flower every summer, and increase the variety.

Propagation, &c. of the Shrubby Kinds.

The method of propagating all the shrubby kinds is very easy; by suckers, by layers, and cuttings.

By Suckers.—Several of these shrubby *Spiræas* are productive of many suckers annually from the root, which being taken off in autumn, commence good plants; but the first species in particular, *Spiræa salicifolia*, *Willow-leaved Spiræa*, or *Common Spiræa fruticosa*, is remarkably prolific in suckers, that in one summer grow as high as the parent plant, and generally terminated by spikes of flowers the same year in autumn, and should always be cleared off from the old plants every year or two in winter; as should also the suckers of all the other sorts: and as most of which suckers will readily rise with roots, they immediately commence proper plants; and the largest may be planted at once where they are to remain, and the others in nursery-rows, to have one or two years' growth, and will then be fit for the shrubbery.

By Layers.—All these sorts will grow freely by layers, but is a more particularly eligible mode of propagation for any of the sorts that do not readily afford a sufficiency of suckers; for almost every branch or twig being layed down in the earth, in autumn or winter or spring, will be well rooted, fit for transplantation, by the autumn following.

By Cuttings.—Any of the shrubby sorts will likewise grow by cuttings, though not to be depended upon like layers; however, in October or November, chusing cuttings of the strongest young shoots of last summer's growth, planting them in a shady border, many of them will grow, and, in two or three years, commence good plants for the shrubbery.

Propagation, &c. of the Herbaceous Kinds.

All these sorts may be propagated by seed, and by parting the roots.

By Seed.—This may be sown either in autumn soon after it is ripe, for the greater certainty of having them come up freely in the spring following, or may be sown early in the spring, as they will also often rise the same year; keeping the plants thin, and clear from weeds till autumn, then planted out either in nursery-rows for a year, or at once where they are to remain.

By parting the roots.—All the herbaceous kinds may be propagated by this method in autumn, and is the only method of propagation for continuing the double-flowered and striped varieties; observing, of all the sorts, it may be performed either in autumn when the stalks decay, or early in spring before new ones begin to shoot forth.

SPONDIAS, Brazilian Plum.

This genus comprehends for our stove collection, two species of tree-like exotics of America and India; growing ten or twelve to fifteen or twenty feet high; adorned with winged or pinnated leaves, composed of four, five, or six pair of folioles, terminated by an odd one; and numerous small pentapetalous flowers along the sides of the branches; having each a five-parted deciduous calyx, five oblong, spreading petals, ten filaments, oval germen with five styles; succeeded by a roundish, oval, plum-shaped, pulpy fruit, containing a five-celled nut.

Class and order, *Decandria Pentagynia*.

The species are,

1. *SPONDIAS Mombin.*

(*Mombin*)—or *Brazilian Plum*.] Rises with an upright stem, and branchy head; pinnated leaves, having the common foot-stalk compressed; and purple flowers and fruit.

2. *SPONDIAS Myrobalanus.*

(*Myrobalanus*)—or *Yellow American Plum*.] Grows upright and branchy: with pinnated leaves, having round foot-stalks; glossy shining folioles; and yellow flowers and fruit.

These trees being tender exotics from the hot-parts of South America, require a hot-house in this country; and are retained accordingly to diversify curious collections in that department, in which they form an agreeable variety; and are propagated by sowing the stones of the fruit in pots plunged in the bark-bed, and by cuttings and layers of young shoots, assisted by the same means; keeping the plants always in pots, and continued in the stove; and treated as other woody plants of the same repository.

SPROUTS.

Sprouts are small young shoots or suckers, emitted from the sides of the stem and heads of certain vegetables; being in many instances a compendium of the plant that produced them; and, when detached from the parent and planted, although then destitute of roots, they often, in the process of vegetation, emit fibres, shoot at top to mature growth, and exhibit leaves, flowers, and seed, like the parent plant.

Likewise, in some herbaceous esculents, young Sprouts are excellent eating, such as in cabbages, broccoli, &c. proving a very profitable after-crop.

But the term Sprouts is more generally applied to the lateral shoots or suckers of certain herbaceous vegetables; such particularly, as most of the *brassica* tribe, comprehending all the sorts of cabbages, favoys, coleworts, borecole, purple broccoli, &c. which, after the main head is gathered for use, the stalks remaining, shoot forth abundance of Sprouts, that often form heads like the principal one, but smaller; and, may be gathered for use as esculents, and will prove equally good, and often superior to the main head for eating. Sometimes young Sprouts of cabbages, being detached as slips, and planted, will strike root and grow.

These Sprouts, however, of the cabbage-tribe, have merit chiefly as esculents, and very little in the work of propagation.

For, although they will grow if planted while young, they are only proper to be used occasionally in particular cases; as for example, in planting cabbages for seed in any particular good sort, which having the main-head gathered early in summer for use, and the stalk having produced a quantity of good Sprouts soon after, we sometimes slip off a quantity of the best of them towards autumn, plant them in rows two feet asunder, giving occasional waterings, will grow and shoot up to seed next spring. See BRASSICA.

However, the Sprouts of all the cabbage-tribe are to be considered principally as esculents; and are admirable fine eating, generally boil exceeding green and tender; but those Sprouts produced from the forward cabbage stalks in summer and autumn, are always larger and finer than the winter and spring Sprouts, as sometimes the Sprouts produced on the stalks of the early-cut cabbages often also cabbage into tolerable little firm heads towards autumn; the sugar-loaf cabbage particularly, and other forward kinds, producing abundance of fine Sprouts in summer, which,

being gathered while young and green, are some of the most excellent culinary greens of the season; likewise forward favoys being cut early in autumn, the remaining stalks produce fine large Sprouts the same year, fit for use in the early part of winter; later crops of the same plants produce also abundance of small Sprouts in the spring; and the borecole is remarkable for its great production of Sprouts towards spring, emitted all along the small stems from the very bottom to top; also purple broccoli never fails to produce a secondary crop of excellent Sprouts furnished with little tender heads.

Thus all these cabbage and colewort tribe, that after the main-heads being arrived to perfection and gathered for use, the stalks furnish a plenteous supply of Sprouts coming in for a second crop; those produced in summer and autumn continuing long in perfection; but the spring Sprouts run smaller, and continue but a short time before they fly up for seed; they are nevertheless very acceptable and useful, at that season of the year.

Therefore, in the culture of all the above varieties of the cabbage kind, it is proper, after gathering the main-heads, to leave a quantity of the stalks of the best and forwarder crops of the respective sorts, to produce Sprouts; and if, towards autumn or winter, &c. the ground should be wanted for other crops, the stalks may be removed and trenched in by the roots in another place, not in any shady by corner as often practised, nor placed too close, as the Sprouts would prove small and trifling, and be liable to be eat up by slugs; but being placed in an open situation, in rows a foot asunder, the Sprouts will continue their growth in much greater perfection, though probably not equally so good as if the stalks had remained undisturbed.

Thus the product of Sprouts will prove a very beneficial and acceptable supply, both for usefulness and variety at table.

The stalks of cauliflowers and cauliflower-broccoli rarely produce any Sprouts; so it is needless to leave them standing.

STAMINA, the male organs of flowers.

Stamina, consisting of the filaments and antheræ, the male organs of every-flower; being the fine chives or thread-shaped parts situated in the centre of the *corolla*, in number from one to twelve, or twenty, or more, and composed of the three following parts.

1. *Filamentum*, the filament or thread-shaped part of the stamina, elevating the antheræ. See FILAMENTUM.

2. *Antheræ*, the summit of the filaments, and

and that part which contains the *pollen* or fecundating dust or farina. See *ANTHERÆ*.

3. *Pollen* or farina, the fine dust, or fecundating male sperm contained in the antheræ, and, when ripe, dispersed upon the stigma or female organ, to effect the important office of impregnation.—See *ANTHERÆ* and *FILAMENTUM*, &c.

It is observable in most flowers, that the *Stamina* and pistillum come together; and the antheræ and stigma ripen and become of full vigour at the same time to effect the work of fecundation.

For the *Stamina*, containing the genuine male sperm of plants in the antheræ, that without its fecundatory aid no plants would be effectually prolific, but mostly abortive; at least, if they produce seeds, they would not vegetate.

In hermaphrodite plants, the *Stamina* or male organ being placed in the same flower with the female genitals, are for the most part all of equal height, generally surrounding the pistillum in such situation, as the farina or male sperm, lodged in the antheræ, may readily reach the *stigmata* of the female flower to impregnate it effectually; but in some hermaphrodite flowers, the pistillum being shorter than the *Stamina*, the flowers, though nodding before, upon opening generally stand upright, that the powder of the antheræ may fall upon the stigma; and, after conception, probably resume their drooping or pendulous posture again; and, in other hermaphrodite flowers having the style longer than the *Stamina*, it either bends back like ram's-horns towards the antheræ, or the whole flower droops, that the antheræ may drop its dust down upon the female organ. See *HERMAPHRODITUS flos*.

In monœcious plants, the *Stamina* and pistillum are, in different flowers, situated apart on the same plant, as in cucumber and melon; but many sorts have the male flowers mostly placed above the female, that the farina or fertilising powder may more readily fall on the stigma of the pistillum; or so situated as to be easily conveyed by the air, or flying insects skipping from flower to flower, sufficiently to effect the impregnation. And in some plants, such as cucumbers, growing in hot-beds at an early season, we often perform the fecundation by art, carrying the male blossom to the female, and discharge the contents of the antheræ upon the stigma; but when the warm season is advanced to admit of the plants being fully exposed, that operation is effected by the air, gentle breezes of wind, bees, &c. conveying the prolific dust of the antheræ

to the female blossom. See *CUCUMIS* and *MONÆCIA*.

And in the diœcious plants the *Stamina* and pistillum are, in separate flowers, situated on different plants, species of the same genus, as in spinach, hemp, hops, &c. but so wonderfully contrived by the great Author of nature, that the male dust of the antheræ is conveyed to the female flowers by the gentle breezes of air, &c. and impregnates them. See the Class *DICÆCIA*, under the head *CLASSIS*. See also *SEXUS*, *PISTILLUM*, *STIGMA*, and *STYLUS*.

STANDARD Trees.

Standard-trees are to be considered as all trees with upright single stems, and stand detached without being trained to any wall, &c. or other support.

The name Standard-trees is applicable both to all sorts of fruit and forest-trees, and all other tree and shrub kinds that, having upright stems, stand detached erectly without aid of support: though the word Standard is more generally understood of such trees as grow with tall erect stems, six or eight feet high, or more, before they branch out to form the head; such as the common Standard apples, pears, and other fruit-trees in orchards and gardens, and the common forest-trees of the woods and fields; in gardening, however, we commonly distinguish three sorts of Standard trees; namely, Full Standards, Half Standards, and Dwarf Standards; fruit-trees particularly, being occasionally trained in all these ways; but forest and tall ornamental trees rarely in any other than Full Standards; though, in the shrub tribe, they are occasionally formed both into Half and Dwarf Standards, according to their natural stature of growth. See each as below.

FULL STANDARDS.

Full Standards.—These are such trees that are trained with tall, straight, clean stems, six or seven feet high or more, clear of branches, then suffered to branch out at that height all around to form a head, as in Common Standard apples, and pear-trees, forest-trees, &c.

All trees designed as Full Standards, should be trained accordingly in their minor state, by trimming off all lower laterals gradually as the stem advances in height, to encourage a clean straight growth to the proper height, and promote the aspiring of the top or leading shoot more expeditiously; suffering the leader always to remain entire, especially in all forest-trees; or, if it should happen to fork, take off the worst, and leave the straightest shoot to run up, to continue the prolongation of the stem; and having thus run them

up.

up with clean stems gradually six or seven to eight or ten feet or more, especially the deciduous kinds, then suffer them to branch out into a full head, and run in height as fast as possible; though in fruit-trees the stem is often topped at six or seven feet height, to force out a set of laterals in that part, to form a regular spreading head of but moderate height, for the greater convenience of gathering the fruit: however, for all kinds of forest-tree Standards, never reduce the top, but permit the leader to remain ever entire to run up in height; for the beauty and worth of such trees consists in their lofty stature.

But in several forest and ornamental Standards of the evergreen-tribe, the trimming their stems from laterals while young, as above, must be but sparingly practised; such as the pines, firs, cedars, and several others of the coniferous tribe, which, being all of a resinous nature, do not succeed if too close pruned; besides, when designed for ornamental plantations, the trimming up the under branches of these kinds would greatly diminish the beauty of their peculiar growth; for the disposition of the branches, in most of these sorts, covering the stem in circular rays to the very bottom, is thought additionally ornamental in their general appearance, so that in training all these sorts of trees, should only prune occasionally any lower disorderly stragglers.

Almost all sorts of fruit-trees may be trained for full Standards, except vines, though all sorts will not ripen their fruit effectually on Standards in this country; such as peaches, nectarines, apricots, and figs; on the other hand, all sorts of apples, pears, plums, and cherries, ripen their fruit freely on Standards.

All fruit-trees designed as full Standards are raised by grafting, &c. on the freest strong-shooting stocks, and trained with straight clean stems full five or six feet high, either the stock trained up to that stature, and so grafted or budded at the desired height, and the graft or bud branching out forms the head; or the stock may be grafted, &c. near the ground, and the first shoot from the graft or bud trained up for a stem to the height aforesaid; then suffered to send forth branches: observing, in either method, it is next to be considered whether you intend the tree shall form a spreading open head, or assume a more erect and aspiring growth; in the former case, if you top the leading shoot of the graft or bud at six or seven feet from the ground, it will force out lateral shoots at that height, and commence a spreading head open in the middle; suffering, however, the whole afterwards to take their own growth; and in the

second instance, that, by permitting the leading shoot to remain entire, it will aspire in height, and the whole head will assume a more upright and lofty stature; in both methods the heads will afterwards naturally branch out abundantly, and furnish themselves sufficiently with bearing wood, producing fruit, in some sorts, in two or three years from the grafting and budding, as in cherries, apples, &c. but pears in particular are sometimes four, five, or six years before they bear: generally permitting the whole to take their own growth without shortening, and but very little other pruning, except the regulating any very irregular or bad growths, as below.

It being expedient to train most of our principal hardy fruit-trees as full Standards, as that, when planted in continued rows, either in gardens or orchards, by having tall stems elevating the head considerably from the ground, it both admits the influence of the sun and air more freely to the head all around; and admits of obtaining crops of esculents, grass, &c. on the ground, under their spreading branches.

With respect to the general culture of full Standard fruit-trees, in regard to pruning, &c. very little is required after the first training, to form the stem to the proper height, and the first shoots advanced at top to give the head its first formation; they should afterwards generally be allowed to advance nearly in their natural order, except reducing any very irregular growths, &c. not shortening the general branches, but permit the whole to shoot both in length and branch laterally in their own way; and they will thus all naturally form fruit-spurs along their sides upward for bearing; remarking, however, when any very irregular growing branch occasionally occurs, it should be retrenched; also if the head is much crowded, some should be judiciously thinned out to keep the middle open, long ramblers reduced, and all suckers from the root, stem, and middle of the head, cleared away, and all dead wood; which occasional prunings may be performed any time in winter.—See the culture of different fruit-trees, as apples, pears, plums, cherries, &c. under their proper heads; also PRUNING.

But sometimes Standard fruit-trees, with four, five, or six feet stems, are also planted against walls, and trained as wall trees; this being frequently practised for high walls, as the Standards having tall stems elevating the head several feet, so as immediately to cover the upper part of the wall, whilst dwarfs and Half Standards cover the bottom and middle part; and thus may every part of the wall be fully

fully occupied at once; but the dwarf-trees being designed as the principal residents, and that after several years' growth having advanced considerably upwards, and the Standards having borne a few years, the latter have their under branches gradually reduced to make room for the dwarfs, and at last are either wholly transplanted or destroyed, leaving the dwarfs in entire possession of the wall, covering it effectually from bottom to top with their branches. See the different sorts of wall-trees, as peaches, nectarines, apricots, &c.—Also the article WALL-TREES.

And sometimes Standard wall-trees with tall stems are planted against the ends of buildings, such as some choice sorts of pears in particular; also sometimes apricots in a southerly aspect, or other fruits occasionally; and which, on particular occasions, are chosen principally with tall stems to elevate the head of branches five or six feet or more from the ground, especially in much frequented or exposed situations, that the fruit may be more out of the reach of being illegally plucked; and the trees having good space of wall above, they will spread their branches accordingly, and yield large productions of fruit in the best perfection.

HALF STANDARDS.

Half Standards.—These are trees trained with short stems only three or four feet high, then suffered to branch out at that height to form heads; being practised for many sorts of fruit-trees, sometimes both as detached Standards by way of variety; and by having low heads, the fruit is more easily gathered; and likewise are often trained with fanned spreading heads, designed as wall-trees for high walls, that, as observed of the full Standards, they may cover the middle or upper part of the wall, whilst dwarfs occupy the lower part.

As to the method of raising these Half-Standard fruit-trees, it is nearly the same as observed for the full Standards; only, they being grafted, or budded upon lower stocks, training them with upright single stems only three or four feet high, either the stocks on which they are to be grafted trained up to that height for a stem; or being grafted or budded low in the stock, and the first main shoot of the graft, &c. led up for a stem, and so top it at the aforesaid height to force out branches to form the head; suffering the head, in all those designed as detached Standards, to branch out all around, and permitted to run up to a full spread, nearly according to their natural mode of growth, except just reforming any ill-growing branch, as hereafter noticed; for

shortening the branches should be very sparingly practised, which would force out numerous useless shoots, and prevent the formation of bearing wood, especially in the apple, pear, plum, and cherry kinds.

But when Half-Standards are intended for walls, they should have the head trained in a somewhat fanned manner, to spread to the wall like a common wall-tree; and as to the after-pruning, the same is to be observed, as hinted in the general culture of the respective sorts under their proper genera, whether in detached Standards or against walls.

It may sometimes be proper to have these Half Standards so trained as to form heads of as moderate growth as possible, especially the detached Standards, when designed for small compartments; in which case they are grafted or budded upon the more dwarfish sort of stocks, as apples upon codlins, and pears upon quinces, and so of other fruits; in which the head will always shoot moderate, and never ramble wide or grow high. See STOCKS.

But although a few Half Standard fruit-trees may be eligible as detached Standards for variety, they are not so proper for any general plantation in the open quarters of the garden; because their branches coming out low may impede the growth of under-crops; may however have a range thinly planted along the boundary or division of any wide compartment, especially those worked on dwarf stocks, that they may branch more moderately in a less spreading growth; and in this order may also have a good portion of the common codlin, as being naturally a moderate shooter and plentiful bearer; and, in the whole, their heads suffered to run mostly in their natural growth, except a little occasional regulating pruning, as hinted for the Full Standards.

For walls, however, that are eight or nine feet high, it would be proper to have a sufficiency of Half Standards to plant between the dwarfs or principal residents, to cover the middle or upper half of the wall, whilst the dwarfs occupy the lower space, as remarked of the full Standards.—See WALL-TREES.

Half Standard fruit-trees of cherries, apricots, &c. are also proper to plant in forcing frames to produce early fruit. See FORCING FRAMES.

The culture of detached Half Standards, in respect to pruning, is nearly as the full Standards; that, having shot out at top to form the head, permit them to branch both in length and laterally nearly in their own way, except just pruning to order any considerable irregularity, crowding branches in the middle, long ramblers, and detaching all suckers from the

the root, stem, and head, and to cut out casual dead wood; and thus the regular branches remaining at length, will emit fruit-spurs abundantly in every part for bearing.

And as to the Half Standards against walls, they are to be pruned and managed as other wall-trees, each according to its nature, as directed under their proper heads.

Forest-trees, and the taller ornamental tree kinds, are rarely ever trained as Half Standards, but mostly always suffered to run up in height to their full stature, unless any particular sort may be required to form bushy Half Standards for some particular purpose.

Many of the shrub kind in their natural growth assume the appearance of Half Standards, though some are often branchy to the very bottom, or rise with several stems; but might readily be trained with a single clear stem, three or four feet high, and then suffered to branch out into a full head.

DWARF STANDARDS.

Dwarf Standards.—They are trained with low stems only one or two feet high, being then topped to force out branches at that height to form the head.

Sometimes several sorts of choice fruit-trees are trained as Dwarf Standards, with stems seldom more than one foot high, branching out at that height, forming proportionably low heads; being occasionally planted round the borders of the kitchen or pleasure garden, &c. instead of espaliers, and the heads either kept down low by close pruning, whereby they never produce much fruit; or suffered to branch upward nearly in their natural growth, and they will bear in much greater abundance; all of which Dwarf Standards being raised by grafting, &c. upon the most dwarfish stocks, such as apples on codlin, or paradise-stocks, and pears on quinces, &c. in order to dwarf them as much as possible in their growth (see STOCKS); and as they shoot in height, each year's shoots are either generally pruned short, whereby to keep the head down, and confine it within a small compass; but, by this severe pruning, they are forced into numerous useless shoots annually, and seldom form a sufficiency of bearing wood; so that they never answer the end effectually; or the general branches permitted mostly to shoot in length, except just reducing casual ramblers, and disorderly growers; and they will generally shoot more moderately, and sooner form themselves into plentiful bearers in greater perfection; though these kinds of Dwarf Standards are not so generally introduced now since espalier fruit-trees have been brought to a proper degree of perfection in training and bearing.

However, for the sake of variety and curiosity, a few Dwarf Standards of all sorts of fruit-trees might be admitted, one here and there; and by a judicious moderate pruning, according to their nature, as directed for the respective sorts, under their proper heads, and the article DWARF TREES, they will bear abundantly in proportion to their size.

Likewise may have some Dwarf Standard fruit-trees in pots, for the purpose of forcing in hot-houses, forcing-frames, hot-beds, &c. particularly early May and May-duke cherries, plums, peaches, nectarines, apricots, figs, vines, gooseberries, currants, &c. which being placed in the above departments at the proper season, i. e. January or early in February, they will often ripen a few fruit very early in tolerable perfection, some of which might be brought to table growing on the trees in the pots. But Dwarf Standard fruit are also proper to plant fully in the borders in forcing-frames. See FORCING FRAME.

For the particular method of raising and training the different sorts of these Dwarf Standards, see DWARF TREES.

Numbers of the upright shrub tribe naturally form themselves of the Dwarf Standard kind, as rising with low, erect, firm stems, perhaps but half a foot, or a foot or two high, branching out near the ground into bushy heads, such as the gooseberry, currant, and numerous flowering shrubs and evergreens; though great numbers of the shrub kind are apt to rise with several stems immediately from or near the root, forming a bushy growth quite from the bottom; which, in many cases in the shrubbery way, may be allowable: in others, it may be proper to train them with one stem; which is easily effected by retrenching the superfluities and trimming away low stragglers; forming a clear single stem half a foot, or a foot or two high, according to their nature, then suffered to branch out into a full head.

For many of the low Standard flowering shrubs and evergreens appear to the best advantage, when trained as Standards to a single stem a foot or two high, terminated by a branchy full head.

Likewise all the fructiferous shrubs, such as all the varieties of currants and gooseberries, should generally be trained with a single stem a foot or more high, then permitted to branch out at that height into a regular head, keeping the internal part always tolerably open, and the branches moderately thin; and shorten them but sparingly, particularly the gooseberry.—See RIBES.

STAPELIA. (Stapelia.)

For

For the stove this genus furnishes two or three species of curious succulent perennial plants, singular in their protuberant branches, being mostly destitute of leaves; are of spreading and upright growth, in different species; producing large, monopetalous, stellated, variegated, yellow and purple flowers of singularly-curious appearance.

Class and order, *Pentandria Digynia*.

Characters.] CALYX, monophyllous, small, five-parted and persistent. COROLLA, monopetalous, large, flat, cut halfway into five acute segments, and containing a starry, five-pointed nectarium, with its lacerated points surrounding the parts of generation. STAMINA, five plane, broad, erect filaments, with linear antheræ attached to their sides. PISTILLUM, two oval, plane germens, without styles, each having an obtuse stigma. PERICARPIUM, two oblong, subulated, cylindric, single-celled, univalvular pods, filled with compressed downy seeds.

The species are,

1. *STAPELIA variegata*.

Variegated Lesser Stapelia, or Fritillaria Crassa Minor.] Grows with many spreading succulent branches, having several denticulated, spreading protuberances on their sides, rising about six inches; no leaves; and from the sides of the branches arise the large, spreading and starry, yellow flowers, variegated and spotted with purple, having in the centre the five-pointed coloured nectarium, including and surrounding the fructifications.

2. *STAPELIA hirsuta*.

Hairy greater Stapelia, or Fritillaria crassa major.] Grows with upright succulent, angulated branches, with erect, denticulated tubercles; and at the sides of the branches large stellated hairy flowers, variegated with purple stripes, running across the petal.

3. *STAPELIA mamillaris*.—Mamillary or Warty Stapelia.

These are plants of curious singularity, both in their leafless, protuberant and warted, succulent branches, and in the beauty of their large, stellated, variegated, spotted, and striped flowers, produced, in successional order, great part of summer and autumn, but which are of a very fetid scent.

They being tender succulent exotics, must always be kept in pots of light poor earth, and placed in the stove upon the shelves or top of the flues, &c. and continued constantly in that department, in which give them but very little water in the winter, and moderately in summer; managing them, in respect to other culture, in common with other hot-house exotics.

All the sorts are easily propagated by cuttings or slips of their succulent branches in summer; laying the cuttings or slips for a few days in the sun to heal over the moist wound occasioned on the separation from the parent plant; then plant them in pots of dry light earth, and plunge them in the tan-bed, where they will soon strike root and grow.

STAPHYLÆA, Bladder nut.

Two hardy deciduous flowering shrubs are the principal species in this genus, both of which are proper furniture for the shrubbery, being of largish upright growth, generally obtaining eight or ten feet stature, adorned with pinnated and ternate, five and three-lobed leaves; and long slender bunches of pentapetalous flowers, succeeded by bladder-like capsules; whence the name Bladder-nut.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX is roundish, concave, coloured, and almost as large as the corolla. COROLLA, five oblong erect petals, nearly like the calyx, and a pitcher-shaped nectarium at the bottom. STAMINA, five oblong erect filaments, crowned with simple antheræ. PISTILLUM, a thick three-parted germen, and three styles, having obtuse stigmas. PERICARPIUM, three inflated bladder-shaped capsules, joined together by a longitudinal suture or seam, having acuminate tops, and open inwardly, inclosing two almost globular, hard, nut-like seeds.

There are only two species, both very hardy deciduous shrubs, the first of which is a native of England and other parts of Europe, the other is from America; are distinguished by the names of five-leaved and three-leaved Bladder-nut.

The species are,

1. *STAPHYLÆA pinnata*.

Pinnated five-lobed European Bladder-nut.] Rises with upright, shrubby, smooth, brownish stems, branching eight or ten feet high or more, with very pithy shoots; garnished with pinnated leaves of two pair of large, oblong, oval lobes, and an odd one; and at the axillas along the sides of the branches, long pendulous bunches of white flowers, succeeded by large, inflated, or swollen, bladder-shaped capsules, containing roundish hard seeds or nuts, ripening in autumn.

This sort grows wild in England, and many other parts of Europe, and is cultivated in gardens, to increase the variety in ornamental plantations, where it flowers and ripens seed annually.

The seeds or nuts are in some countries eaten, but have a very unpalatable relish.

2. *STAPHYLÆA trifoliata*.

Three-leaved Virginia Bladder-nut.] Rises with upright, shrubby, smooth, greyish stems, branching eight or ten feet high; garnished with ternate or trifoliate leaves, being composed each of three large oval lobes; and at the sides of the branches, long, hanging bunches of white flowers, succeeded by large inflated capsules, containing roundish hard seeds, ripe in autumn.

Both the species flower annually in May, numerous in pendulous bunches, each flower having five oblong petals; and the seeds ripen in autumn, proper to sow for propagation.

These shrubs are very eligible furniture for diversifying any of the hardy ornamental deciduous plantations, but particularly the larger shrubbery compartments, where, being planted in assemblage with other shrubs, principally of the deciduous tribe, they will agreeably multiply the variety with their pentaphyllous and ternate foliage, long pendulous bunches of flowers, and bladder-shaped capsules, which have a singular appearance in autumn.

Method of Propagation.

The propagation of both these shrubs is most easily accomplished by three or four different methods, viz. by seed, suckers, layers, and cuttings.

By Seed.—This ripens plentifully in autumn, when it should be sown soon after it is ripe, in a bed or border of any common earth, either in drills or promiscuously on the surface, covering them an inch deep; and being thus sown early in autumn, they will come up the following spring, though probably not all of them till that time twelvemonth; keeping them clean from weeds; and if, in the early part of summer, very dry weather prevails, refresh them with frequent waterings, repeating those operations during summer as occasion may require; and by autumn or spring following, the largest plants will be fit to plant out in nursery-rows; or at least in the second autumn they may be wholly planted out, placing them in rows two feet asunder, and one foot distance in each row; here to have two or three years' growth, or till wanted for the shrubbery, &c.

By Suckers.—The plants of a few years' standing generally send up suckers from the bottom in tolerable plenty, which may be easily taken up in autumn, winter, or spring, with roots, and planted in nursery-lines, to have one or two years' growth, then transplanted into the shrubbery, when required.

By Layers.—In autumn or winter choosing the younger branches, lay them either by slit or twist-laying (see *LAYERS*), and they will be

properly rooted by the following autumn; when they should be planted off in nursery-rows for a year or two, to gain due strength for the shrubbery.

By Cuttings.—In October or November procure a quantity of young shoots of the former summer's growth, choosing principally the lower part of the shoots; plant them in a shady border, giving occasional waterings the following spring and summer in dry weather, and they will be mostly well rooted by the following autumn.

STATICE, Thrift or Sea Pink, and Sea Lavender.

Consists of low, hardy, herbaceous, and under-shrubby plants for ornament and variety; some of which being flowery perennials are employed in the decoration of the pleasure ground; they rising, some sorts with very low, close, tufty heads, of numerous small, narrow, grassy, evergreen leaves close to the earth, and very slender single flower-stalks but half a foot, or a little more or less high; others having much larger, broad, radical leaves, and stronger stalks dividing into branches; all the stalks and branches of the sorts in general terminated with globular and spiked aggregate heads, of numerous small, infundibuliform; pentapetalous flowers.

Class and order, *Pentandria Pentagynia.*

Characters.] CALYX, an aggregate of florets collected into globular or spiked heads, included wholly in one common cup of divers structures in the different species, each floret having also its proper calyx, which is monophyllous and funnel-shaped. COROLLA is funnel-shaped, consisting of five small petals, narrow at the base, but broad, obtuse, and spreading above. STAMINA, five subulate filaments that adhere to the unguis or claws of the petals, and incumbent antheræ. PISTILLUM, a small germen, and five filiform distant styles, crowned with acute stigmas. PERICARPIUM, none; the seeds, one in each floret, are lodged in the general calyx, each seed coronated by its own proper cup.

Since to this genus has been added the *Limonium* or Sea Lavender, the species are multiplied considerably; the first of which is the common Thrift or Sea Pink, a small, hardy, herbaceous evergreen, well known for its use occasionally as an edging to borders, &c. comprehends several varieties, all very low, close-growing, grassy-leaved plants: the other species, being mostly of the Sea Lavender kinds, are of larger growth, with broadish leaves; and consist of herbaceous and under-shrubby perennials and annuals; but for general garden culture, one species, common Thrift,

Thrift, and varieties, are very commonly cultivated: and also some of the most material of the Sea Lavender kinds are introduced for variety.

Common Thrift Kinds.

One species only comes under this head, comprising, however, several varieties; some of which were formerly considered as distinct species, but prove all varieties only of *Statice Armeria*, or common Thrift, differing somewhat in their size and colour of the flowers, as noticed below.

1. *STATICE Armeria.*

Armeria, Common Thrift or Sea Pink.] Hath a thick, fibrated, spreading, perennial root, dividing into heads at top, closely crowned with thick tufty heads of numerous linear, grassy, evergreen leaves close to the ground; and among them numerous slender single stalks, from five or six to eight or ten inches or more in the different varieties; each crowned with a globular aggregate of small red and other coloured flowers in the varieties, appearing in June and July.

Varieties.] Common smaller Thrift with pale-red flowers—With scarlet flowers, and with white flowers—Greater Thrift with red flowers—Greater Thrift with white flowers—Least Sea Pink with small flesh-coloured flowers—all of which flower profusely from the end of May until July or August.

Remarking, as to the difference in size and growth of these varieties,—the common smaller Thrift is distinguished by its leaves being more narrow, grassy, and of lower growth, and the flower-stalks only five or six inches high, being the sort most commonly used for edgings; the greater Thrift having longer and broader leaves, and flower-stalks near a foot high; and the least Thrift have exceeding narrow, short leaves, flower-stalks only three or four inches high, and very small heads of flowers.

All the sorts are inhabitants of plains and meadows, chiefly near the sea in most countries of Europe and North America; but have been long admitted into gardens as flowery plants, and are in great estimation to plant for edgings to beds and borders, as being of very low close growth, and always green; and also to plant in tufts about the flower-borders and other compartments of the pleasure ground, as they succeed in any soil and situation, and flower very abundantly in June and July, making a good ornamental appearance, more particularly the red and scarlet sorts; and for all of which purposes they are very expeditiously raised by slipping the heads and roots together, at almost any season, but

principally in autumn and spring.—See their *Propagation.*

However, for edgings in particular is the principal merit of these plants; and as they grow very close, low, and continue in verdure all the year, they form the most useful and eligible edging, next to box; and in some particular situations in gardens, are sometimes preferred to box edgings, especially as they flower very ornamentally for two months in summer; but are not however so proper for general edgings as box, as being rather apt to spread soon out of bounds, and require to be reduced, either by cutting them inconsiderably on each side, or by taking up and re-planting them afresh every three or four years.—See *EDGINGS.*

Sea Lavender Kinds, &c.

These sorts assume a different appearance from the common Thrift kinds, both in their foliage and mode of flowering; their leaves not being so small and grassy, but mostly plane and broadish, and the stalks generally dividing into panicles terminated by the flowers, not in globular heads like the Thrift, but chiefly in spiked aggregates; but their general *characters* proving the same as in the Thrift, they are all considered as true species of *Statice*.

2. *STATICE Limonium.*

(Limonium) — or common Sea Lavender.] Hath thick, reddish, fibrated roots, crowned with oval-spear-shaped, smooth leaves; and upright, firm, cylindric stalks a foot or more high, dividing into paniculated branches, all terminated by spiked heads of pale-blue flowers, in July and August.

Varieties.]—Common great Sea Lavender—Narbonne great late-flowering Sea Lavender—Olive-leaved Sea Lavender—Deep blue-flowered Sea Lavender—White-flowered Sea Lavender.

This species grows naturally on the sea-shores of England, &c. and is sometimes retained in the gardens for variety.

3. *STATICE tatarica.*

Tartarian Sea Lavender.] Hath long, spear-shaped, sharp-pointed leaves; and forked, branchy, spreading stalks six or eight inches high, terminated by spiked heads of whitish alternate flowers at a distance, in August and September.

4. *STATICE reticulata.*

Netted Sea Lavender.] Hath cuneiform or wedge-shaped lower leaves; prostrate slender stalks, and retroflexed naked sterile branches netted or matted together; and the stalks terminated by panicles of pale-blue flowers, in July and August.

This is a sea-side plant of England, and most parts of Europe.

5. *STATICE cordata*.

Heart-leaved Mediterranean Sea Lavender.] Hath thick, spatulate, heart-shaped, retuse, smooth leaves close to the ground; and slender naked stalks six inches high, terminating in panicles of pale-red flowers, in August.

6. *STATICE flexuosa*.

Flexuose Siberian Sea Lavender.] — Hath oval nervous leaves from the roots; and weak, flexuose, branchy stalks eight or ten inches long, terminated by corymbose bunches of flowers, in August and September.

7. *STATICE speciosa*.

Specious-flowered Sea Lavender.] With ovate, dagger-pointed leaves; flower-stalks two-edged, two forking, terminated by aggregate heads of flowers.

8. *STATICE suffruticosa*.

Under-shrubby Siberian Sea Lavender.] Hath under-shrubby stalks, naked and branching near the top, rising near two feet high; spear-shaped variegated leaves; and close-fitting round heads of pale-blue or whitish flowers, in August and September.

9. *STATICE monopetala*.

Monopetalous Sicilian Sea Pink.] Hath under-shrubby, leafy stalks, spear-shaped, vaginant leaves; and flowers placed singly.

10. *STATICE ferulacea*.

Ferula-leaved Barbary Sea Pink.] Under-shrubby branching stalk, the branchlets chaffy and imbricated, terminated by hairy bristles.

All these species, both of the Thrift and Sea Lavender kinds, are hardy fibrous-rooted perennials, seven of them being herbaceous, and the others under-shrubby; all of which flower abundantly in summer; the flowers are numerous, but separately small, funnel-shaped, and pentapetalous; and many collected together into aggregates, within one general cup (see the *Characters*); being generally produced at the ends of the stalks and branches, in some singly, in others in panicles, as before described in each species; but are not all commonly succeeded by seeds in the gardens.

But of the above species, the last three or four sorts being rather tenderer than the others, some of each should generally be kept in pots, and placed among the green-house plants, to have protection in winter.

The first species, *Statice Armeria*, and varieties, being considerably the most material for their use as edgings, are the most generally cultivated.

The other species are not so generally common in the gardens; however, all the sorts of them that can be obtained, may with propriety

be admitted, to increase the variety, as they take up but little room, will grow in almost any common soil and situation, though, if but moderately exposed to the sun, they will probably be the more successful and durable.

All the sorts, both the Thrift and other kinds, may be planted any time in autumn or spring.

The Thrift kinds, as we before noticed, are proper both to form edgings, and to plant in detached tufts about the borders: the scarlet Thrift is the most beautiful in regard to its flowering; but, for variety, should also admit the pale-red and white kinds, all of which succeed almost any where, and may be planted at almost any season when not in flower; though the autumn and spring are the most successful seasons for planting them.

As to the method of planting Thrift edgings, a quantity of slips being obtained in the seasons above-mentioned from old plants, by slipping or dividing the off sets of their roots, not however too small, and each slip furnished with roots and top; then, having made up the edge of the bed or border even and firm, proceed to plant them either with a dibble in one range, two or three inches distance in the row; or to form at once a close edging, may plant them so near as to touch one another; or, otherwise, to perform this more effectually, may form a small trench, as in planting box edgings; so plant the Thrift in the trench quite close together, to form immediately a compact uniform edging, in the manner of a box-edging aforesaid. See *Buxus Suffruticosus*, and *EDGINGS*.

And as to the culture of these edgings, they should every summer, immediately after flowering, be trimmed with garden-shears or knife, to cut off all the decayed flower-stalks close to the bottom; likewise, to trim in any projecting irregularity of the edging at sides or top: also when it spreads considerably out of bounds, should be cut in evenly on each side, in due proportion; observing to perform those occasional trimmings generally in moist weather, and not too late in autumn, otherwise the drought of summer, or the cold in winter, may injure it when newly cut, and cause it to assume a shabby disagreeable appearance.

Observe, however, that when these edgings grow considerably out of bounds, or become very irregular, it is proper to take them up, slip the plants small, and immediately replant them again as before, in a neat regular edging.

Sometimes these edgings require replanting, as above, every three or four years.

Method

Method of propagating all the Species.

All the sorts are very easily propagated, by slipping or parting the roots, in autumn and spring.

Thrift kinds.—All the varieties of Thrift propagate abundantly by off-sets of the root and head; which, in early autumn, or in the spring, &c. may either be slipped off from any growing plants, or any large old plants taken up and wholly divided, each into as many separate slips as it admits; preserving the root and top to each slip; and plant them directly, either in an edging, or in the borders, &c.

Sea Lavender kinds.—They may be propagated by parting their roots, in autumn or spring: also some of them by slips or cuttings of their shoots in summer, planted in a shady border, or shaded and watered; and they will be rooted by autumn.

These sorts may also be raised from seeds when they can be obtained from the places where they ripen, in England and abroad; sowing the hardy sorts in autumn, or early in spring on an east border, and in warm dry weather give frequent waterings, both before and after the plants come up; and in summer or autumn, plant them out in beds or borders; and the tenderer kinds, sow in March or April, either in a warm border, or in pots under glasses, or forwarded in a hot-bed; and when the plants are a little advanced in growth, transplant them as above; and some in pots to move under shelter in winter.

STELLATA Planta, a Starry Plant.

Such as have the leaves disposed in rays or whorls round the stem at intervals, and point different ways like the figure of a radiant star; exemplified in *Rubia*, or madder, &c. likewise such as have the petals of the flower starry radiated.

STEWARTIA, *Stewartia*.

There is but one species, a hardy deciduous flowering shrub from North America, proper for the shrubbery compartments, rising several feet high, adorned with largish simple leaves, and large pentapetalous flowers.

Class and order, *Monadelphica Polyandria*.

Characters.] CALYX is monophyllous, divided into five oval, spreading segments, and permanent. COROLLA, five large, oval, spreading petals. STAMINA, many filiform monadelphous filaments, being united into a cylinder at bottom, connected to the petals at their base, and crowned with roundish incumbent antheræ. PISTILLUM, a roundish hairy germen, five slender styles, having obtuse stigmas. PERICARPium, a quinquelobate pomaceous capsule of five cells, each having an oval compressed seed.

STEWARTIA *Malacodendron*.

Stewartia or *Malacodendron*.] Rises with a shrubby stem branching irregularly on every side, eight or ten feet high, having the branches covered with a brownish bark; oval-spear-shaped, sawed, veined, alternate leaves, two or three inches long, and half as broad; and at the sides of the branches large white flowers, having numerous purple stamina surrounding the five styles; flowering early in June, but do not perfect seeds in England.

This elegant shrub is a native of Virginia, from which country it was introduced into our gardens to increase the variety in the shrubbery collection; and is raised in most of the nurseries for sale.

It is a hardy shrub, though young seedling plants of it are rather a little tender the first year or two, requiring shelter from frost, but after having acquired more strength, will stand very well in the open shrubbery the year round.

It is propagated by seed and by layers, and sometimes by cuttings.

By Seed.—This the seedsmen procure annually from abroad; sow it as soon as possible either in an easterly border of light earth, about half or near an inch deep; giving water in summer, and shelter from frost in winter; or, where convenient, it would be of great advantage to sow them in pots, and plunge them in a hot-bed, either of dung or bark, under glasses, giving occasional waterings, and moderate shade from the sun, both before and after the plants come up; being careful to harden them gradually in due time to the open air in summer; but in winter place them under a garden-frame, to remain till spring; when, in order to forward them as much as possible, may plunge them again in a bark-bed for a month or two, till towards summer, then gradually hardened, and plunged in a shady border till autumn, at which time removed again under shelter all winter; and in March following, may pot them off separately into small pots, which if plunged also in a bark-bed, it will strike them more expeditiously, bestowing proper waterings and occasional shade; not forgetting to harden them as before, and protect them with shelter another winter; and in spring following, when the weather is settled, may venture to turn them out, with the balls of earth about their roots, into the full ground.

By Layers.—Chuse the young shoots for laying, which may be performed early in autumn, generally by slit-laying; and in the following spring and summer in dry weather, do not fail to give frequent waterings; and if screened with a moderate shade in the heat of summer,

summer, they will root more freely, which they sometimes effect in one year; when, in March, pot them off separately; and if then plunged in any moderate heat for a few weeks, it will forward them considerably; removing them to a shady border all summer, to shelter of a frame in winter; and in spring after, transplant them with balls into the open ground, finally to remain.

By Cuttings.—Young shoots in spring and summer being planted in pots of good earth, and plunged in a bark-bed, some of them will probably strike and commence proper plants, which must be timely inured to the open air, and managed as the seedlings and layers.

STIGMA of the flower.

Is the extremity or summit of the pistillum, or female organ of flowers.

The Stigma forms the head or summit of the style, and is accounted the principal female organ of plants, designed for the reception of the farina or fecundatory dust of the antheræ or male organs, which being discharged upon the moist Stigma, the particles burst, and shed their fertilising seminal virtue; and being absorbed by the Stigma, its effluvia or essence is transmitted through the style or vagina, into the heart of the germen, ovary, or seed-bud, for the purpose of impregnating the seeds.—See PISTILLUM, FILAMENTUM, and STYLES.

As to figure, the Stigma is various in different plants; it being in some formed into a round or globular head; in others, it is either oval, orbicular, angular, crown-shaped, target-shaped, cross-shaped, stump-shaped, hook-shaped, petal-shaped (as in *Iris*), obtuse, depressed, concave, channeled, ribbed, streaked, feathered, hairy, downy, &c.

In respect to number, the Stigma is either single or but one, as in the generality of flowers; bifid or two, as in lilac; three, as in *carthamus*; four, as in *epilobium* or French willow-herb; five, as in some plants.

With regard to situation, the Stigma generally terminates or crowns the style, as in most plants; sometimes when there are many Stigmata, they are disposed with admirable symmetry along the sides of the style; and when the style is wanting, as in poppy and some other flowers, the Stigma rests immediately on the germen or seed-bud.

In general, the surface of the Stigma is covered with a viscous or clammy moisture, serving to attract, retain, and dissolve the particles of the fecundating powder, and thereby more easily transmit its effluvia to the seeds below.

For, in the vegetable kingdom, the genital

dust of the antheræ being carried by the air to the moist Stigmata, where the particles burst, as before observed, and discharge their exceeding fine or subtle contents, and impregnate the ovary; as is often obvious to sight in many plants when in flower, and the farina flying about, that part thereof lights upon and clings to the Stigma; which some flowers show in a most agreeable manner, such as in the pansies, in which, when the flower is scarcely opened, we shall see the Stigma like a concave globe gaping open on one side, and of a pure white colour; but, as soon as the antheræ of the five stamina have discharged their male dust, you may observe the whole Stigma filled with this dust, or fertilising powder, and covered all over with a yellowish-brown colour.

With respect to duration, the Stigma most commonly withers after the impregnation is effected, except in some few genera, such as poppy and water-lily, &c. in which the Stigmata is permanent or abiding.

STIPULA of the leaves, &c.

Is a scale or very small leaf on each side the base of the foot-stalk of some leaves and flowers.

The Stipula is defined to be one of the *fulcra* or props of plants, designed to support more firmly the bud of the leaves, &c. at their first appearance; being generally stationed one on each side; though some plants have only one, and a great many none at all.

Stipulæ are, however, common to a great number of plants, both trees and herbaceous vegetables; their situation is mostly on the outside of the leaves, and in some few plants on the inside: being of divers figures and sizes in different species; and in some plants they grow free, loose, and detached; in others, they grow close to the leaves, &c. in some plants they are deciduous, or fall off before the leaves; others are permanent, continuing till the general fall of the leaf.

Thus the Stipulæ often afford marks of distinction in discriminating the species; as, from their situation, number, size, duration, &c. on the particular species, their difference is frequently more essentially distinguished.

The Stipulæ are in many plants very distinguishable and conspicuous, such as in rose, apricot, peach, cassia, tamarind tree, tulip-tree, bird-cherry, and all the papilionaceous or leguminous plants, and many others.

STOCKS, for Grafting and Budding.

Stocks, when alluding to the operation of grafting and budding, are young trees raised from seed, suckers, layers, and cuttings occasionally, designedly for the reception of grafts

grafts and buds of other trees, of any select or approved sort, to propagate and continue them the same without variation, by their uniting with the said young trees or Stocks, shoot out into branches, and become trees in all respects like the approved parent trees from which they were taken; and they thus remain supported and nourished by the trees on which they are grafted, commonly termed Stocks.

For, as numerous trees, particularly the varieties of certain species, not continuing the same from seed, but often vary exceedingly to very different sorts,—in order to continue them of the same approved varieties with certainty, recourse is had to propagating them by the operation of grafting or budding, being the insertion of shoots or buds of the said approved kinds of trees into the Stock or stem, or even the branches of other trees, which, when intended for the purpose of grafting, &c. are always denominated Stocks, and should generally be species or varieties of the same genus as the trees with which they are to be grafted, or very nearly allied in their general *characters*, otherwise they will not grow kindly upon one another: but the Stocks and grafts being of the same family, and the grafting and budding properly executed, the grafts, &c. unite firmly with the Stock, shoot and branch out into full heads, commencing trees in every respect like the select kinds from which the grafts and buds were cut, producing shoots, leaves, flowers, fruit, and seed, exactly the same as the said parent trees, whether fruit-trees, forest-trees, shrubs, &c. always retaining their respective properties distinct from the Stock; the Stock also continuing its inferior quality distinct from the graft, not interfering with the nature or quality of the trees grafted thereon; only supporting or nourishing them as effectually as if upon their own roots; sometimes, however, particular sorts of Stocks affect some varieties of trees, so far as to render them of longer or shorter duration; also, in some sorts of trees, improve or diminish the quality of the fruit: so that it is of consequence to be acquainted with the proper Stocks on which to graft or bud the different trees for general service, not only the trees of different genera, but also those of particular species, and varieties of each respective genus, as hinted hereafter in the general list of Stocks.

So that all trees, whether young or old, designed for grafting or budding upon, from the size of a large goose's quill, to one, two, or three inches in diameter, are distinguished by the appellation of Stocks; because the graft or bud is inserted into the stock or stem, sometimes occasionally into the branches.

when intended to renew any old fruit-tree, or change the sort of fruit, or have two, three, or more sorts of flowers, fruit, &c. on the same tree; in all of which cases, the part receiving the graft or bud is styled the Stock.

Remarking, that Stocks for general use may be used as such either for grafting or budding, when from the size of a good large goose-quill, to half an inch, or not more than an inch thick, in the part where the graft, &c. is to be inserted; likewise, on some occasions, Stocks of two or three inches diameter, either the stems or branches, are also occasionally grafted or budded with success, not proper, however, for general practice; for the small young Stocks, of from two to three or four years' growth in the nursery, &c. and from about near half an inch to an inch thick, or but a little more or less in the part to be grafted, whether dwarf or standards, are generally the most successful for general grafting or budding in the nursery plantations, to raise any considerable quantity of trees for transplantation, either for private or public supply.

Observing likewise, Stocks for grafting and budding are employed both principally for most kinds of fruit-trees, and occasionally for some varieties of forest and ornamental trees, and many of the shrub kind, as is generally intimated in the culture of the respective sorts in their proper genera.

Remark also, that Stocks, almost in general, when intended for grafting and budding, should be species or varieties of the same genus as the trees with which they are to be ingrafted; for most of the tree and shrub kind, whether fruit-trees, forest-trees, &c. succeed principally upon Stocks of their own family only, or such that are very near kindred by the *characters* of their flowers; such as in some similar cases as follow; for example, the peach, nectarine, and almond, being all of the genus *Amygdalus*, will take upon one another, and on Stocks of the *prunus* or plum, generally succeeding best upon that kind of Stock; that though of two distinct genera, are all icosandrious plants of the drupaceous stone-fruited tribe, nearly allied in their general *characters*; the same is also observable of the pear, which will take upon some species of the *Mespilus* and *Sorbus*, also on some of the species of *Crataegus*, such as white-thorn or haw-thorn Stocks; and all of those upon one another: but neither of these, nor the pear, however, are equally successful as upon Stocks of their own family; and even all the species of the same family do not succeed equally well upon one another, some sorts requiring Stocks principally of their own species, others those of some particular species or variety in the same genus.

For

For it being also remarkable, that although all the species of any particular genus grow by grafting or budding upon Stocks of one another, yet most sorts succeed best upon their own Stocks, that is, Stocks of some varieties and the same species; except in a few instances; for example, the apple, pear, and quince, being three distinct species all of the genus *Pyrus*, and will take upon Stocks of one another as above observed, but improper for general practice, as the apple always succeeds best upon its own species, i. e. any kind of apple or crab Stocks raised from the kernels of the fruit; the pear upon pear Stocks raised in the same manner, and will succeed upon quince Stocks, when intended occasionally to form dwarf-trees; and the quince grows free enough on their own, or pear Stocks; again, the plum, cherry, and apricot, being all species of the genus *Prunus*, and the grafts and buds of all three species will grow upon Stocks of one another, yet not all equally prosperous; for the cherry is always the most thriving upon cherry Stocks, and plums and apricots best upon plum Stocks.

And in several instances some sorts are the most thriving on some particular variety of their respective favourite Stocks, exemplified in the peach and nectarine, which being generally more thriving and durable on plum Stocks than their own, yet on one particular variety of plum, namely the muscle-plum-Stock, they are generally the most prosperous in a moderate and fruitful growth; the same is also observed of some other trees, both fruit and forest-tree kinds, as hereafter hinted in the list of Stocks.

Likewise, some sorts of fruit-trees are prosperous on crab Stocks, others succeed well only on free Stocks, and some require dwarf Stocks, to dwarf them more or less, either for walls, espaliers, or forcing-frames, &c. See Crab Stocks, Free Stocks, &c. below described.

Of the different Kinds.

For the various kinds of Stocks may for distinction sake, be divided into three classes, agreeable to their different natures, viz. Crab Stocks, Free Stocks, and Dwarf Stocks; each of which comprehending various sorts, both of the same and different genera, species, and varieties; and those of each class, although they may prove species or varieties of the same genus, yet often assume different properties requisite to be known previous to their being grafted or budded, as described below, each under its own head.

Crab Stocks.—The sort of Stocks generally considered as crabs, are all such that are raised

from seeds, &c. both of any natural or ungrafted trees, particularly of the fruit-tree kind; such as the crab-apple of the woods and hedges, any kind of wild thorny uncultivated pears, plums, wild black and red cherry, &c. and also of such trees as have been grafted or budded; and, as to the merit of these wild Crab Stocks, some sorts being strong shooters and hardy, are preferred, on which to graft some particular species, as supposed to improve the size and duration of the trees; for example, apples are very commonly worked upon the common wild Crab Stock, and cherries on the great wild black and red cherry Stock, as tending to promote a large, hardy, and durable growth proper for common standards, and the larger kinds of dwarf trees; remarking, however, in using Crab Stocks for general use, on which to graft any sorts of fruit-trees, it is proper to reject such of them as assume a very wild crab-like growth, or of a stunted, thorny nature, preferring those that are the freest clean growers.

However, the appellation of Crab Stocks is also often given to all Stocks indiscriminately, before being grafted; whether raised from the seed, &c. of wild or cultivated trees, being very commonly all denominated crabs until worked with grafts or buds; though probably with some distinction, as wild crabs, and free crabs.

Free Stocks.—The name Free Stocks is commonly applied to such as are raised from the kernels of the fruit, layers, &c. of any of the cultivated garden and orchard fruit-trees and others, which, as they often prove in general more free clean shooters than the generality of wild crabs, have the appellation of Free Stocks, and in several instances, when proving free clean growers, are more eligible Stocks than the wild crabs, particularly for choice apples, pears, peaches, nectarines, apricots, and plums, both to improve the growth of the trees and quality of the fruit, as is observed below in the List of Stocks, and in the culture of the respective sorts under their proper head; observing, however, that as also, in these seedling Free Stocks, some may appear of a wild crab-like growth, or of a stunted thorny nature, as aforesaid; which, when the real Free Stock is intended, should be all eradicated, reserving only the free clean shooters of a cultivated-like growth for grafting and budding.

But, as we noticed above of the crab Stocks, all Stocks raised from seed particularly, both of the wild, and cultivated garden fruits, are, before they are worked, very commonly termed crabs; either wild crabs or free crabs, as before

before observed, and with some propriety; since all seedling Stocks, though raised from the finest fruit, vary so greatly from the original, many of them often assuming a wild crab-like growth, and if permitted to stand long enough without grafting to bear, it is probable the fruit would prove also of the crab nature, intolerably hard and austere; hence the necessity of grafting and budding: but, on the other hand, many of them assume a free, cultivated-like growth; and if trained up without grafting to a bearing state, some out of a great many may produce tolerable good fruit, though probably not above one or two in a hundred or more; which, however, is the method by which all our fine varieties of fruit were first obtained, and the sorts afterwards increased and continued the same by grafting and budding them upon proper Stocks; so that for experiment, might select a few of the most promising of any of these seedling Free Stocks if thought convenient, transplanting them by themselves, to try to gain new varieties; but allotting, however, the general supply to remain for Stocks, for the reception of grafts and buds of the choicer kinds of the already-acquired fruits, for farther propagation.

Dwarf Stocks.—These are raised from low-growing trees, some nearly of a shrub-like nature, and others of but a very moderate tree-growth, being occasionally employed as Stocks on which to graft and bud trees, intended as the lower and middling sorts of Standards, and to form dwarfs, either for walls or espaliers, or as dwarf standards in small gardens, and any others occasionally for variety; and to plant in forcing-frames, or to pot for forcing, or curiosity, &c. such for instance, the paradise apple and codlin Stock, for dwarfing apples, the quince Stock for pears, the bird cherry, morello, and small May cherry Stock for cherries, the bullace and muscle Stock for dwarfing apricots, peaches, and nectarines, and sometimes dwarf-almond Stocks for the two latter, when designed to have these trees of a very dwarfish growth, either to pot for curiosity, or for forcing in small forcing-frames.

Observing, the most dwarfish kinds of Stocks of the above are, the paradise Stock, bird-cherry, black bullace, and dwarf almond; all of which being of very moderate growth, when used as Stocks, they dwarf the trees grafted thereon exceedingly, the head remaining within very small compass, and shooting moderately into wood, soon forms for bearing abundantly in proportion to their size; they, however, are not so proper for any

general culture as common dwarf-trees, as they never attain a large growth, sufficient to produce any considerable quantity of fruit, but continue fruitful of equal duration; so that a few only are proper for variety, or for small compartments of borders, &c. and small gardens, or to pot, or for forcing as aforesaid.

But as to the codlin dwarf Stocks, quince Stock, morello cherry, and muscle-plum Stocks, they being but moderately dwarf, are proper Stocks for the middling, or larger kinds of dwarf trees, either for walls or espaliers, or dwarf and half-standards.

All of which dwarf Stocks, both of the most dwarfish growers, and middling growth, are generally raised either from suckers, layers, and cuttings, as hereafter directed.

But we now proceed to give the list of all the principal sorts of Stocks comprehended in the above three kinds; crab Stocks, free Stocks, and dwarf Stocks, under the names of the respective genus, species, &c. in which they are used for grafting and budding.

List of the various Sorts.

As it is therefore of importance to know all the different sorts of Stocks eligibly adapted for the reception of grafts and buds of the various genera, species, and varieties of trees usually propagated by grafting and budding, particularly all the fruit-tree kinds, and some others, we will exhibit under this head a list of the principal sorts in general use, arranging them separately under the name of the species or variety to which each sort is peculiarly adapted as Stocks, for the reception of their respective grafts and buds.

For apples (*Pyrus malus*).

The Stocks for all kinds of apples, are their own kind, raised from the kernels of any of the cultivated apples or crab for common standards, and the larger kinds of dwarfs; though the wild crab Stock is often esteemed preferable to the free Stock for its hardy and durable nature, on which to graft common standards, and sometimes dwarfs for espaliers; and for lower dwarfs, the codlin, Siberian crab, and paradise Stock are occasionally used; the former for middling dwarfs, and the latter for the smallest dwarfs, as may be occasionally required.

All these Stocks for apples are easily raised, the free Stock and crabs from the kernels of the fruit, and the codlin and paradise Stock, also from suckers, layers, and cuttings. See *PYRUS MALUS*.

For the pear (*Pyrus Communis*).

The pear-tree is grafted and budded principally on pear Stocks for general use, and occasionally on quince Stocks for dwarfs;

raised, the former chiefly from the kernels of any sort of pears; and the latter freely by suckers, layers, and cuttings.

Though the pear Stock is always to be preferred for the general supply of larger trees of the pear kind raised from the kernels of the best summer and early autumn pears, being the most eligible Stock on which to graft or bud for all common Standards, and the larger dwarf pear trees for extensive walls and espaliers.

But to raise either standards or dwarfs of a more moderate growth, they are occasionally worked on quince Stocks, generally raised either from seeds, suckers, layers, or cuttings as aforesaid; for the quince-trees being low moderate growers, when used as Stocks for any kind of pears, they dwarf the trees pretty considerably, rendering them more proper for small compartments and for moderate extent of walls and espaliers, or dwarf standards; and the trees often commence a bearing state sooner than on strong-growing pear Stocks: but this sort of Stock is in more estimation for the melting pears, than the hard breaking kinds, being supposed to improve the fruit of the former, and harden the pulp of the latter; though this is not general: and the quince Stock, at any rate, is estimable principally for its dwarfing property, or at least in being productive of moderate shooting trees for walls, espaliers, or middling standards, sooner arriving to a bearing growth; as, however, pear Stocks are productive of larger trees, more extensively branching, they, when advanced to a settled growth, yield a larger production of fruit in proportion.

Sometimes also, to form dwarf pears, white-thorn Stocks, raised from seed, were formerly in repute, but are very improper, as the trees are rarely prosperous.

Therefore the pear Stock is preferable to use for grafting or budding all the sorts of pears for the general supply of large trees as before intimated; observing, however, as the goodness of a pear is often improved or diminished by the nature of the Stock on which it is grafted, so it is of importance to use principally free Stocks, raised from the kernels of the best summer and autumn pears; and being raised, if any among them assume a wild crab-like appearance, reject them, especially for the prime pears, which should be worked always on the finest free-shooting Stocks of the most cultivated-like growth.

And sometimes, to improve the quality of any particular choice kind of pears as much as possible, some double work them, i. e.

graft the best sorts into free Stocks in the spring, which shooting the same year, then about midsummer or soon after, bud the young shoots of the graft with buds of the prime sorts of pear, suffering only the shoots from the second budding to run up to form the tree: thus the breaking kind of pears are often rendered less hard and stony, and the melting property of others considerably improved; but this double working is not intended for general propagation.

Both the sorts of Stocks for pears are easily raised by the methods above noticed, and as hereafter directed.—See *Pyrus Communis*.

For quinces (*Pyrus Cydonia*).

Two sorts of Stocks are occasionally used for this tree, viz. that of its own kind, and the pear Stock raised, the quince Stocks from seed, suckers, and cuttings, &c. and the pear kinds from the kernels of any sort of pears: but as all the varieties of quinces are so expeditiously raised the same with certainty by layers and cuttings, renders the raising of Stocks for grafting or budding them on almost unnecessary. See *Pyrus Cydonia*.

For plums (*Prunus domestica*).

This tree is worked only upon plum Stocks, raised from the stones of any sort of cultivated plum, and likewise by suckers and layers thereof, as the most certain methods whereby to obtain any particular variety of free plum Stock when required; such, for instance, as the muscle-plum Stock, which many prefer as the best Stock of all on which to work the finer kinds of plums, as generally producing very thriving moderate-growing, fruitful trees; raising it, not from seed, which would vary exceedingly, but principally by suckers from the root of real muscle-plum trees, or of those worked upon the true muscle Stock; or from layer Stocks also of the muscle-plum tree: observe, however, plums almost in general succeed equally well on any kind of free plum Stock; and therefore, the general supply may be raised from any sort of plum, either by seed or suckers, &c. as may be convenient; as directed hereafter.

The plum will also grow upon the apricot and cherry Stock, but not thrivingly for any great duration.—See *Prunus domestica*.

For cherries (*Prunus Cerasus*).

The proper Stock for this tree is that of the cherry kind only; viz. the great wild cherry Stock for large trees, the cultivated garden cherries for more moderate growths, and the bird-cherry Stock for small dwarfs; raised, the two former from the stones of the fruit, and the latter also by seed, or by layers and cuttings.

But

But as for general use, the wild black and red cherry Stocks, being strong free growers, are preferable, on which to raise all common large standard cherries particularly; also the larger dwarf-trees for extensive walls and espaliers; as these Stocks being of strong hardy growth generally produce larger, more hardy, and durable trees than the cultivated cherry Stocks; though in default of these wild Stocks, may use Stocks raised from any of the cultivated garden cherries, to raise common moderate standards and dwarf-trees; it is however of importance to raise the general supply of large trees on the wild cherry Stock, for the reasons above mentioned.

Sometimes Stocks of the morello and May cherry, as being moderate growers, are used, on which to raise the smaller cherry-trees, either in dwarfs for low walls and espaliers, or for small or moderate standards, but remarking of the morello Stock, that if raised from layers you will be more certain of having the real fort in its naturally moderate growth.

And Stocks of the common bird-cherry (*Prunus padus*), being a very moderate grower of the cherry kind, is used, on which to raise dwarf cherry-trees, either to plant in borders, pots, forcing frames, or to pot for forcing, &c. are raised plentifully from seed, cuttings and layers; and have the effect of dwarfing trees worked thereon, exceedingly, so as to bear fruit when but one or two feet high; and they shooting very little to wood, generally bear abundantly for their size.

Cherries will also grow upon plum, apricot, and laurel Stocks, as being all of the same genus, but not proper for general propagation, only by way of curiosity or experiment.

All the varieties of cherry Stocks are raised with great facility by the methods above hinted and hereafter exhibited.—See *PRUNUS Cerasus*.

For apricots (*Prunus Armeniaca*).

The apricot proves the most durable on Stocks of the plum kind, viz. common plum Stocks of any variety for all common wall, espalier, and standard trees; and the bullace Stock for small dwarfs; raised, the plum Stocks from the stones of any kind of cultivated plum, or by suckers from the root; and the bullace from seed, suckers, and layers.

But always chuse the plum Stock on which to raise the general supply of apricots for common use, in general, wall-trees and occasional standards, which succeed almost equally well upon Stocks of any kind of plum, though they probably may prove the most successful on the muscle-plum Stock, like peaches, &c. in being

of a more moderate regular growth, and most prolific nature; but as the difference is not always very material, we may use any kind of plum Stocks that can be the most readily obtained, on which to raise all our principal apricot-trees, for walls, espaliers, and standards.

And the bullace Stock is only used occasionally on which to raise moderate small dwarfs for low walls, or to plant in pots, or in forcing frames for forcing.

Note, the apricot will grow on its own, and on peach and almond Stocks raised from the stones, but never so prosperous for any duration.—See *PRUNUS Armeniaca*.

For peaches (*Amygdalus Persica*).

Several sorts of Stocks are occasionally used for peaches; viz. almond Stocks, peach, nectarine, apricot, and plum Stocks, all raised from the stones of the fruit, and the latter also by suckers and layers; but the plum Stock being the most hardy, is the most eligible for general use.

For the peach is not equally successful and durable on all those kinds of Stocks, on those of the almond, peach, nectarine, and apricot, although they take freely, shoot fair and promising for some years, yet are frequently apt to prove but of middling duration in a prosperous growth: so that the free plum Stock is preferable for all the sorts of peaches and nectarines, as being productive of the most hardy, thriving, and durable trees; though it is remarkable, one sort of plum Stock in particular is generally preferable on which to work peaches, which is that of the muscle-plum, formerly hinted, as producing the most prosperous trees, generally of a more moderate, regular, and fruitful growth, as before observed, and the fruit of superior quality, provided the said Stock is raised genuine; not from the stones, for, as observed before, the seedlings are apt to run into many varieties materially different from the original; but to obtain it more certainly real, is occasionally raised from suckers or layers of the true muscle-plum-tree, or by suckers from the roots of such peach, nectarine, plum, &c. as are worked on muscle-plum Stocks, which generally send up plenty from the roots annually; planting them off at one year's growth into the nursery to train for use: however, for want of a sufficiency of this particular Stock, recourse must be had either to seedling Stocks raised from the stones of the muscle or any other kind of plum, or suckers, Stocks of any of the plum varieties.

Double Stocks or double working, is sometimes used for the more delicate peaches, to improve their bearing and flavour of the fruit; and consists of first budding in the com-

mon way, by inserting buds of any strong shooting peach, almond, or apricot into a plum Stock; and the buds shooting out strongly next summer, then upon the main shoot from the bud, perform the second or final inoculation with buds of the approved sort intended for propagation, suffering the shoots from the second budding only to grow up and form the tree; and by this practice the more prosperous fruitful growth of the trees of the above particular sorts, and the delicate flavour of some sorts of peach fruit is more certainly preserved, and sometimes improved.

For nectarines (*Amygdalus Nucipersica*).

The nectarine is worked upon the same Stocks as the peach, viz. almond, peach, nectarine, apricot, and plum; all raised as observed above for the peach-tree: preferring, however, the plum Stock for general propagation, as for peaches.—See the Stocks for peach trees above.

For almond-trees (*Amygdalus communis*).

The almond-tree when raised for its fruit, the approved varieties may be budded into Stocks of any sort of almond, peach, nectarine, apricot, or plum, raised from the stones, and the latter also from suckers, &c. but the trees are generally the most hardy and durable on plum Stocks.

For medlars (*Mespilus germanica*).

About three or four different Stocks are occasionally used, on which to raise the approved varieties of eatable medlars, viz. medlar Stocks, white-thorn, pear, and quince Stocks, raised, the three former from seed, and the latter expeditiously from suckers, layers, and cuttings; the medlar seedling-raised Stocks are very proper, whereon to graft the approved varieties; and the white thorn and quince Stocks are only used occasionally; but free Stocks, raised from the kernels of medlars or summer or autumn pears, are preferable to the two last-mentioned for all the varieties of common medlar, which either on their own or pear Stocks, generally assume a more free growth, and produce the fruit in greater perfection.

For sweet Service-trees (*Sorbus domestica*).

The domestic or sweet service, when designed as a fruit-tree, have the approved varieties grafted or budded upon proper Stocks: either principally their own Stocks raised from the seed, or occasionally on pear or quince Stocks raised as mentioned just above for medlar and other trees; though either any of the Sorbus, or the pear Stock are preferable to the quince on which to work this tree to have it large and durable, or may use quince Stocks

to have trees of smaller growth, for low standards, espaliers, &c.

For the wild maple-leaved Service berry-trees (*Crataegus torminalis*).

This tree being sometimes cultivated in the garden and orchard for its eatable berries, and to obtain or continue any particular good variety with certainty, they are occasionally raised by grafting or budding, and the proper Stocks are either their own kind, or hawthorn Stocks raised from the seed; they will also take upon pear Stocks, &c.

For hazel nuts, filbert nut, &c. (*Corylus avellana*).

Any approved variety may be continued the same with certainty, by grafting and budding upon Stocks of the common nut-tree, raised either from the nuts, or by suckers from the root; though as all the varieties may be readily increased, and continued the same by layers, &c. with great facility and abundance, the grafting or budding is not commonly practised in their propagation, only in particular cases, in default of layers or suckers of any particular good sort of nut, and that probably cuttings or buds for grafting or budding, can be more readily obtained from neighbouring trees of the sorts intended; and having raised a few trees by this method, they, in two or three years, furnishing plenty of branches to raise a more plentiful supply of layers; and these layer-raised trees, being wholly the same top and root, suckers from the bottom are equally eligible as grafting and budding, for continuing any approved variety.—See *CORYLUS avellana*.

For orange-trees (*Citrus Aurantium*).

The orange-tree is worked upon Stocks of their own kind only, viz. either any kind of orange, lemon, or citron Stocks, raised from the kernels of the fruit; though of the orange kinds, the Seville orange, as being a very free strong shooter, is generally preferred for orange Stocks; but the lemon and citron being also free growers form very proper Stocks on which to raise any variety of orange. See *CITRUS Aurantium*.

For lemon and citron trees (*Citrus Medica*).

Both these varieties are also budded or inarched upon lemon, citron, or orange Stocks, raised from the kernels of the fruit, as observed above for oranges. See *CITRUS Medica*.

Thus far is principally all the sorts of Stocks commonly used for fruit-trees, that are either generally, or occasionally raised by grafting and budding.

For the several other sorts of fruit-trees, not mentioned in the above list of Stocks, such as the

the vine, fig, mulberry, currant, gooseberry, berberry, walnut, chesnut, &c. they in their several varieties, in the first six sorts particularly, being raised and continued the same with great facility either by layers, suckers, or cuttings, according to the different sorts, and some of them by all those methods occasionally, which renders the propagation by grafting and budding unnecessary; and the walnut and chesnut not succeeding perfectly by these methods to become large thriving trees, are raised from the nuts: however, any approved variety thereof, or of most of the above-mentioned sorts, may also be tried occasionally by grafting and budding upon proper Stocks by way of experiment; and the eligible Stocks are principally those of their own kind, raised some from suckers, layers, and cuttings; others also from seed, as exhibited in the culture of the respective sorts, under their proper genera.

For forest and ornamental trees, flowering shrubs, &c.

As to the Stocks proper for such forest-trees, ornamental trees, and flowering shrubs, &c. that are occasionally raised by grafting and budding, either to improve or continue any particular variety, they are for the general part each worked on Stocks of their own kind, as observed above for the generality of fruit-trees; but, as in these kind of trees, the variation of the seedlings being not so numerous and material as in the fruit-tree kind, they do not require to be so generally raised by grafting or budding, only for some particularly valuable variety, or any of peculiar property, such as variegated-leaved, or other remarkable kinds, double flowering variety, or other curious flowering sorts, &c. that cannot be continued the same by seed, but only either by grafting or budding, or by layers and cuttings: though, as the two latter methods are not convenient in all sorts, recourse is had to grafting and budding to increase the above varieties with certainty of the kinds intended, without farther variation; working the respective sorts principally each upon Stocks of its own kind, chusing the strongest free shooters, raised either from seed or suckers, &c. as mentioned in their culture, each sort under its proper genus as observed on former occasions.

General Hints for Experiment.

Sometimes for variety and curiosity in any sort of fruit-trees and others, the same Stock is made to support two, three, or more different varieties of fruit, grafted or budded, either all into the Stock, being previously trained with branches forking off for that purpose one for each graft, or by cleft, or crown-grafting sin-

gle large Stocks, with two or more different sorts; or in smaller single Stocks, by inserting two or more different buds by inoculation; likewise any Stock being singly grafted or budded, may insert different sorts into the shoots arising from the said graft or buds; and thus may have two, three, or more sorts of apples, on the same root for curiosity; the same of pears, plums, cherries, and most other fruits, &c. that are chiefly species or varieties of the respective sorts in the same genus, or that which is very nearly allied, as we have already exhibited; and in several instances, by the same rule and method, may have different sorts of fruit upon the same Stock, as plum, cherries, and apricots all on a plum Stock, or peaches, nectarines, and apricots on the same, or on Stocks of their own kind; and pear, medlars, and quinces upon the pear Stock; also red and white currants, or currants and gooseberries, both on a currant or gooseberry Stock; or white and red grapes on any vine Stock; likewise red and white roses, or other different sorts, upon any common rose Stock; and the same of numerous other trees and shrubs, species and varieties of one genus; remarking, however, this is not recommended for any general practice, but only for a tree or two of any particular genus or species, by way of experiment, variety, and curiosity.

Method of raising the Stocks in general.

With respect to the method of raising all the different sorts of Stocks, it is occasionally by seed, layers, suckers, and cuttings, as hinted above in the list for each particular sort.

By Seed.—Numerous sorts of Stocks are easily raised from seed, consisting of the kernels and stones of the fruit, of the respective trees, such as the kernels of all the apple kinds; kernels of all the sorts of pears and quinces; and the stones of plums, cherries, apricots, peaches, nectarines; the seeds or stones of medlars, services, &c. also nuts, when designed for Stocks; all of which are to be obtained in autumn from their respective fruits when fully ripened: previously laying a sufficiency of the common pulpy fruits together in an heap, and bruise them; suffering them to lie some time to decay as the different sorts may require, in order that the pulp may be more readily cleared from the kernels and stones proper for sowing; or, the kernels of apples and pears may also be procured from any of the accidentally rotten fruits in the fruitery; and sometimes for large supplies, both apple, pear, and crab kernels are occasionally obtained from the cyder presses after the fruit have been pressed for cyder, perry, verjuice,

verjuice, &c. but the stones of plums, cherries, apricots, and the like, must be procured from the fruits as above, as soon as they are ripe; which, together with all the other sorts, may be sown as soon as possible, each sort separate.

All the sorts, both kernels, stones, and other seeds, are to be sown in beds of common earth in the nursery, either directly in autumn, or preserved in sand till February, and then sown.

Observing, however, that for the general part, it is eligible to sow them principally in autumn or early part of winter, as October, November, or December, unless the ground proves of such a wet cold nature, as to endanger their rotting in winter; and that it shall seem necessary to preserve them in sand in a dry apartment until February, as before observed.

However, in any common moderately dry soil, it is advisable to sow them at once in autumn, or as soon as they can be obtained, as it will be both less trouble, and may prove more successful in forwarding their germination; and, if the winter should prove severe, the beds of the more tender kinds, as almonds, and peaches, &c. may be covered with dry litter to defend the seed from the frost.

The method of sowing all the sorts is in beds of any common light earth in the open nursery or seminary, sown either by bedding-in, or in drills, as below.—See NURSERY.

Having, however, previously digged the ground, then if intended to bed in the seeds, divide the ground into four-foot-wide beds, with foot-wide alleys between; and then with a rake or spade trim the earth from off the top of the beds evenly, into the alleys from about an inch, to an inch and half, or two inches deep, according to the size of the different seeds; this done, sow the seeds all over the surface moderately thick, and after pressing them all evenly down into the earth with the back of the spade, cover them in with the earth from the alleys evenly, the depth as above; the kernels of apples, crabs, pears, &c. near an inch deep, the smaller stones about an inch and a half, and the larger sorts full two inches deep. But if it is designed to sow them in drills proceed thus: having digged the ground, and formed it into four-foot wide beds as above advised, then draw drills with an hoe, either lengthways or cross the bed, from one to two inches deep, and six inches asunder at least, sowing the seeds, &c. in the drills, and directly cover them in with the earth the depth of the drills. See SOWING OF SEED.

After having performed the sowings as

above, if the ground is much infested with mice or other destructive animals, which often attack these kind of seeds in winter, it is advisable to set different sorts of traps and baits for their destruction.

The different seeds being thus sown, they will all germinate freely in the spring, and soon come up the same season; observing previous to the sprouting or appearance of the seedlings above ground, that if in those sown in autumn, &c. the surface of the bed proves mossy, or that the top is hard bound or caked, it is beneficial culture to stir the surface lightly with a small iron rake; also if very dry weather prevails, to give frequent moderate waterings both before and after the plants are up; repeating the waterings occasionally in dry weather all spring and early part of summer, to encourage a free strong growth; being likewise careful to keep the beds very clean from weeds by diligent hand-weedings; and by thus giving every encouragement of culture, the seedling Stocks will grow so freely all summer, as by autumn or spring following will be mostly of proper size to plant out into nursery lines in the open quarters, in rows two feet asunder, to remain for grafting and budding; though, if they have made but middling progress this first summer in the seed-bed, and are rather small and weakly, may plant out only the strongest, leaving the rest growing until next autumn, when they will be all of full size for planting out wholly into the nursery quarters.

Therefore, when the Stocks are of due size for removal from the seed-bed, choose for their reception some of the open quarters of the nursery, preparing the ground by trenching two moderate spades deep; then forking the seedlings up out of the seed-bed, shorten any perpendicular tap-root and long stragglers, but leave all their tops entire, and then proceed to plant them in lines, either by trench-planting, slit-planting, or dibble-planting, as the size of the plants admit (see PLANTING), marking out the rows two feet or two and a half asunder, and set the plants one foot or fifteen inches apart in each row, all in an upright position; and having planted one row, then tread the earth gently all along close to the roots of the plants, to fix them firmly in the earth all evenly in a straight range and erect posture; and so proceed row and row till all is planted, levelling the surface of the ground between all the rows with your spades.

As to their future culture till grafted or budded, it consists in occasional waterings the first spring, hoeing the ground every summer to kill weeds; digging between the rows annually

nually in winter or spring; and of training the Stocks each to one stem; preserving their top always entire; but trimming off strong laterals below, to encourage the strength of the main stem, and the aspiring of the top as fast as possible; whereby they will be fit for grafting or budding, in from one to two or three years after planting.

They are generally of proper size for working, when from about the size of a large goose-quill, already observed; or half an inch diameter, to the thickness of a man's little finger, or a little more; but the sooner they are worked after having obtained due size, the better they will succeed, and the sooner you will have them form trees of the sorts intended. See GRAFTING and INOCULATION.

But supposing the Stocks to have shot freely the first summer after planting out from the seed-bed, many of them will probably be of due size to graft the following spring and summer, at five or six inches height, to form dwarfs for walls and espaliers, &c. or even, in some sorts, for full or half Standards; provided the first main shoot from the graft or bud is trained up singly, two or three years to form the stem, of from four or five to six or seven feet stature: however, if the Stocks have grown but moderately the first and second season, and that they are not generally in a condition for the operation of grafting or budding, let them have another year's growth, or till arrived to the before-mentioned size, which may be sufficient for dwarf-trees; also occasionally for standards, when the graft or bud is to form the stem, as above observed; but when designed for standards, and the Stock to form the stem, they must be permitted to stand two or three years longer, trimming off strong shoots below, and still preserving the leading top shoot entire to continue the elongation of the stem to an eligible stature, to receive the graft or bud at five or six feet height for full standards, and three or four for half standards; so that these standard Stocks being arrived to about seven feet height for full, and five or six feet for half standards, and of the before-mentioned thickness at top in the place where the graft or bud is to be inserted, they are of due size for working.

By Suckers.—Several sorts of fruit and forest trees, &c. furnish many suckers from the root annually, very proper to be transplanted for Stocks; such for instance, as codlins, plums, and quinces; also peach, nectarine, and apricots, that are worked or growing on plum Stocks, pears on quince Stocks, any sort of apples on codlin Stocks: likewise most sorts of elms, and many other forest and ornamen-

tal kinds. And the suckers of all these trees being planted off at one year's growth in autumn, winter, or spring, is a very expeditious and eligible method of raising several sorts of Stocks; as that after being transplanted into the nursery, they often in one or two years' growth commence proper Stocks for the reception of grafts and buds; and sometimes many of them will be fit for budding in the summer following at the proper budding season, or for grafting the spring after.

Likewise, in some instances, suckers afford an opportunity of raising Stocks of any particular variety required, with certainty, such as the muscle-plum for peach Stocks, codlin for dwarf apples, and the like particular kinds; for when the trees productive of the suckers are either wholly top and root of the variety intended, or that they form Stocks to other trees, the Stock and root still remaining of the intended sort; and in either case, all the sucker Stocks prove invariably the same as the parent-tree; but this is only to be particularly regarded when any particular variety of Stock is required; in other cases may use suckers of all other fruit-trees, &c. indifferently for Stocks.

They are generally fit to take up for the purpose of Stocks when of one year's growth, about the size of a tobacco-pipe or but little bigger, and should be collected in autumn or early part of winter; taking them up as well rooted as possible, cutting off all knots or knobbed woody parts of the old roots that may adhere to their bottom, trim straggling fibres, and cut off all side-shoots from the stem, then plant them in rows two feet asunder, and one foot distant in the lines; treading the mould gently to their roots, and finish the work by levelling the surface between the rows: thus they will readily take root, and in spring soon show signs of free growth.

Then as to culture till grafted or budded, it is nearly the same as the seedling Stocks, keeping them clean from weeds in summer by hoeing; and probably some of the strongest shooters may be fit to bud in July or August following; though the general part will require two years' growth before they are proper for working; still continuing them all to one stem, by timely displacing strong laterals; and preserve their top or leading shoot generally entire until grafted, &c. which may be performed when they are of the sizes before-mentioned.

By Layers.—Some sorts of Stocks, both of fruit and other trees, may also be raised occasionally by layers; and when any particular variety of Stock is required, such as the paradise

dise Stock for apples, muscle-plum for peaches, &c. they may be obtained of the real sort always with certainty, by layers of the shoots of such trees as are of the intended sort; but as this method of raising Stocks would be attended with great trouble for general grafting and budding, it is only practised occasionally when a sufficiency of any particular sort of Stock intended cannot be obtained, the same with certainty by seed, or suckers, &c. so that in autumn or winter, chusing the young shoots either of such trees whose branches naturally grow near the ground, or the stems have been cut down low while young, to force out branches near the bottom, furnishing shoots properly situated for laying; which being slit-layed in the common method, they will be rooted by autumn following, and fit to plant into the nursery; managing them as directed for the seedling and sucker Stocks.

By Cuttings. — As some sorts of trees proper for Stocks, grow freely by cuttings; such as codlins, quinces, bird-cherry, paradise Stock, &c. a supply of Stocks of these sorts are sometimes raised by this method; chusing cuttings of the year's shoots in autumn, plant them in the nursery in a somewhat shady border, giving occasional waterings the following spring and beginning of summer in dry weather, and they will be well rooted by next autumn, then transplanted in nursery-rows two feet asunder, managing them as the others.

Remarking of the Stocks in general, raised in either or by all the above methods, that as we formerly observed they must always be continued to one upright stem, with their top entire, except any should assume a stunted or crooked growth, in which case, head them down to the ground in spring, they will push out strong from the bottom the ensuing summer, training them to one stem, and with their leading top-shoot entire as abovesaid; and according as all the sorts advance in growth, divest them of strong lateral shoots below, repeating it particularly in the taller standard Stocks to encourage their upright direction more expeditiously to the proper grafting and budding height.

With respect to the different methods of grafting and budding the several sorts and sizes of Stocks, the grafting them is occasionally performed different ways according to the size of the Stock; and the budding them is performed only by one general method to all sorts; remarking as to grafting, the method called whip-grafting is consider-

ably the most eligible for general practice in nursery plants, and especially for small and moderate sized Stocks: likewise budding is also the most successfully performed upon Stocks of similar growth; for example, young Stocks, from about half an inch, to the thickness of the little finger, or but little more in the part where the graft or bud is to be inserted, are of the most eligible general size for all nursery Stocks, either by whip-grafting, or by inoculation, as the different trees may require: though cleft-grafting is also occasionally performed on small Stocks, but not so successfully as whip-grafting, so is more commonly practised for such Stocks as are too large for that method; but large Stocks of an inch or more diameter, succeed very well by cleft-grafting; also sometimes tolerably by budding, but not in general so effectually as smaller Stocks, &c. above mentioned. And such Stocks as have stood to grow very large, perhaps two inches or more in diameter, may also be grafted occasionally with tolerable success, but do not succeed by inoculation: and crown-grafting is generally the best method for such large Stocks; sometimes also cleft-grafting is practised by making several clefts round the top of the Stock, and insert one graft in each, though the working of these very large Stocks is the most generally, and successfully practised when they are growing in the places where they are finally to remain; but, for the methods of performing the operations of grafting and budding the various sorts of Stocks for raising the several kinds of dwarf and standard trees, see GRAFTING and INOCULATION; also the several sorts of trees raised by these methods, as apples, pears, plums, peaches, &c. each in its respective genus.—Also DWARF TREES, STANDARD TREES, WALL and ESPALIER TREES.

After grafting and budding the several sorts of Stocks, they may be then said to commence new trees of the respective sorts with which they are worked, especially after the graft and bud begins to shoot, which growing up into branches, forms the said new tree of the sort intended.

STOOLS, to furnish layers.

Stools are headed-down young trees and shrubs in the nursery, appropriated for the production of an annual supply of lower shoots or branches near the ground, eligibly situated for effecting the propagation of the respective sorts by layers. See LAYING.

Such trees and shrubs as are designed for Stools to furnish layers for the work of propagation, are generally headed down to the bottom

bottom in the nursery, &c. in order to force out more effectually a plenteous supply of branches near the ground, to afford layers conveniently situated for laying down in the earth as aforesaid; which being layed in autumn, winter, or spring, they striking root in a year or two; and each layer commencing a distinct plant, are planted off into the nursery in autumn following; the Stools remaining, send out a farther supply of lower shoots the following summer for laying as before; and thus the remaining Stools continue affording a plentiful supply of branches from the bottom, fit for laying annually, or every other year at least; and hereby propagate the sorts intended with great facility and abundance.

Therefore, as many sorts of trees and shrubs are principally propagated by layers, a sufficient number of the respective sorts in the nursery, &c. should be appropriated for Stools, in proportion to the supply required of the sorts intended; chusing for this purpose some strong young trees and shrubs, which being planted in the nursery, &c. at from five or six, to eight or ten feet distance, according to their size or nature of growth, and after having remained a year or two till firmly rooted, and acquired some substance, then all those of the tree kind, or such others as run up with stems, without affording lower branches near the ground for laying, should, in autumn, winter, or early in spring, be headed down within a few inches of the ground; by which operation they, in summer following, will push out from the bottom plenty of strong young shoots commodiously placed near the ground for laying, which may be performed the succeeding autumn, winter, or spring; or, if you wait till the second autumn, the first shoots sending out many lateral or side shoots the ensuing summer, and thereby probably furnish an additional supply, of a proper growth for laying; and these small laterals are often better adapted for rooting, than the first vigorous shoots that rise immediately from the Stool, and each of which layed will form a new plant; however, you will order this as it shall seem convenient, as some sorts may afford a sufficiency for laying the autumn after they are produced; others may require to grow till the second or third autumn before they are eligible for laying.

As to the method of performing the operation of laying, it being fully explained in all the various ways in practice under its proper head, we will not repeat it here, so refer the reader to the article LAYING.

In most sorts of Stools where the laying is performed in autumn, about October, or November, or early in the spring, the layers are for the general part well rooted in one year, commencing proper plants fit for separation from the Stools in the autumn following, in order for planting out in nursery rows to be trained for the purpose intended; though some very hard-wooded sorts require two summers growth in the layer-bed before they are sufficiently rooted; on the other hand, some sorts being laid in summer in the young shoots of the year, often effect their rooting freely the same season, fit for planting off the following October.

However, in all sorts it is proper to examine the layers in the autumn after they are layed; and all those sorts that are rooted should then be taken off, separating them with a knife from the Stools, with as much root as possible; and directly planted in nursery-rows a foot or two asunder; and the more tender sorts plant in pots for moving under shelter in winter, as directed for each sort under its respective genus; then, when the layers are all thus planted off, let the remaining Stools be trimmed and dressed as below, for providing a fresh supply of layers the succeeding year.

Every year, soon after the layers are separated from the Stools, the latter should be dressed, which consists of trimming the head by cutting off all parts of old branches and scraggy stumps within an inch or two of the main Stool; and then dig and level the ground neatly about and between the whole, and in spring and summer, give occasional hoeings in dry weather to destroy weeds; thus, repeating the same work of dressing, digging, and hoeing every year; and the Stools still remaining, supply you with plenty of layers for years to come.

But sometimes Stools for layers are formed occasionally of trees, &c. that are considerably grown up, not having been headed down to form low Stools, but whose branches are of some considerable height from the ground; and in which case, the branches, if flexible and long enough, are bowed down to the earth; or, if inflexible and too stubborn to bend, are plashed by making a gash or cut on the upper side; or if too large for plashing, or that the nature of the wood will not bear that operation, the tree or shrub is sometimes thrown on its side by opening the earth about the roots, loosening or cutting those on one side to admit of lowering the head sufficiently for laying the branches in the ground.

Sometimes also, Stools being formed of

grown-up trees, whose branches are too high for laying in the full ground, a temporary stage or scaffold is erected on which to place pots or tubs of earth for the reception of the layers.—See LAYING.

STOVE, or Hot-house.

Stoves in gardens are ranges of buildings constructed with brick walling behind on the north, and fronted and roofed wholly with glass sashes next the south, full upon the sun; furnished internally with a pit, or long, wide, and deep cavity for a bark hot-bed; and with flues round the inside of the walls for fires: the whole calculated to produce a certain temperature of heat at all seasons, peculiarly adapted to the culture of the tenderest exotic plants, from the hot parts of the world; also for forcing various plants, both hardy and tender, into flower and fruit, &c. at an early season.

Formerly, before the use of bark-beds was introduced, all Stoves or Hot-houses were worked by fire-heat only, hence they obtained the name of Stoves.

These Stove departments are generally constructed in an oblong manner, ranging in a straight line lengthways nearly east and west, with the glass front, and top, full upon the south sun, or inclining a little to the south-east; and in dimensions, may be from fifteen or twenty, to fifty or an hundred feet long; by twelve or fourteen, to sixteen feet wide in the clear, and from ten to fourteen feet height commonly in the back wall, by five or six in front, including the parapet wall, and upright glass-work together; and with the whole roof over-head sloping to the south entirely of glass-work, supported on proper cross bearers.

Observing, however, as to its general structure, a wall of brick-work is first formed all round, raised behind from ten to twelve, or fourteen feet height, as just observed; and only two or three feet in the front and both ends, on which to support the upright glass-work, and from the top of which, in front, are arranged the sloping glasses to the coping of the back wall; but previously, in erecting the walls, set out and construct the furnace, or fire-place of the flues near the foundation of the back wall outward, at one or both ends according to the length of the building, or may be in the back part of the end walls; the flues, for conducting the fire-heat, to be ranged internally close along the inside of the back wall, &c. above one another: but, as before noticed, the front and end walling is raised only about two or three feet height, for the support of the timber framing for the upright front glasses nearly head high, including the wall, both ends corresponding with the front

and top framing: a door-way for entrance being formed at one or both ends near the back wall; finishing the timber framing of the top glasses, over-head in one continued slope, from the top of the back wall to that of the crown timber of the front, erecting cross bars for the support of the slope sashes, which should be in two tiers sliding one over the other, the uppermost carried quite home to the crown timbers behind; having no dead roof or cieling in the back part as sometimes practised, but wholly of glass to admit the rays of light, &c. equally in every part; all the glass-work, both front and top sashes being made to slide open occasionally to admit air, &c.

Within side is formed the pit or cavity for the bark bed, and flues for the fire-heat; the pit-being ranged nearly the length of the building, six or eight feet wide or more, and three deep; either the lower part sunk a little or raised the greater part above ground, nearly equal to the outer front walls, and formed by a surrounding thin wall of brick:—and in which is made the bark hot-bed, both to assist in warming the internal air, and for the reception of some of the more tender or particular sorts of exotics, plunged therein to have the beneficial moist heat of the tan-bark immediately about the roots, such as is always indispensably necessary for the *ananas*, or pineapple plants in particular: next to the bark-pit wall, is a path or walk eighteen inches or two feet wide generally continued all round; then along against the inside of the main walling are continued the flues constructed of brick-work on edge; each flue about seven or eight inches wide in the clear, by two or three bricks on edge deep, and ranged horizontally one over the other the whole length of the back wall, in three returns or ranges communicating with each other; continued also along the end and front walls in one or two ranges, to be used either generally or occasionally; furnished with a regulator accordingly, to slide open and shut as required; and generally have the flues detached one or two inches from the walls, that the heat may arise from the back as well as the front, which is of very beneficial advantage, the whole proceeding from the first lowermost flue, which communicates immediately from the furnace or fire-place, without side, behind, in the bottom, either of the back wall at one end, or in the back part of the end walls as before hinted, and as the situation admits; or if very long stoves, more than forty or fifty feet length, two fire-places are requisite, one at each end, or both in the middle: each having its set of flues ranging half way; each set of flues terminating in an upright chimney.

chimney at the ends of the back wall without, to discharge the smoke after having spent its heat in its passage through all the returns, for the purpose of heating the whole sufficiently to warm the air within; for, in winter and early spring, fires being made in the furnaces every night, the smoke and heat passing immediately into the first bottom flue, thence quickly transmitted through all the others in their several returns, heating them in its passage so effectually, as to diffuse a proper heat sufficiently to warm the internal air in the most agreeable manner, which, together with the bark-bed heat, produces a temperature of warmth proper for the growth of all sorts of tender exotics, both woody, herbaceous, and succulent, from the hottest parts of the globe; as some succeed principally in the bark-bed, others best upon the flues and shelves, &c. or the greater part in any situation in the Stove; as is generally noticed in the culture of the respective sorts under their proper genera; hinted also in the article *STOVE PLANTS*.

The above is a general sketch of the dimensions and formation of a common Stove or Hot-house for general use, proper for the culture of pine apples, and numerous other similar tender exotics; as well as for forcing flowers, fruits, &c. but for further particulars of its construction, see the article of its *General Structure*.

But some Stoves are built considerably more lofty and capacious than the above-hinted dimensions, when intended to cultivate the taller exotics in the greatest perfection possible, according to their nature of growth; and for which purpose there are Stoves erected twenty feet high in the back wall, with width in proportion; by only five or six feet height in the front glasses, in order to suit low as well as high plants; and with the roof sloped quite from the top of the back wall to the front, and wholly of glass-work, having a capacious bark-pit within, formed mostly towards the front; behind which is sometimes a border of earth to receive tall plants in the full ground; so in this kind of Stove may cultivate exotics, &c. from the lowest to almost the highest stature, placing the shortest growth forward, and the tallest behind, according to their several gradations of height.

However, these very lofty and capacious Stoves are not recommended for general use, they being both very expensive in erecting, requiring also a great force of fire-heat to warm the internal air in winter; and not so well calculated for the growth of the general run of exotics, as Stoves of a moderate height: but persons of fortune and curiosity can in-

dulge their fancy in this respect as they think proper.

But the common Stove first described, of from ten to twelve or fourteen feet high behind, and twelve to fourteen in width, by five or six feet height in front, will prove sufficient to raise a great collection of curious tender plants of middling growth.

Thus, in these Stove departments, by the constant moderate heat of the bark-bed obtained the year round, and occasional heat of the flues in cold weather, we are able to produce such a temperature of growing warmth in the internal air equally throughout the building, as is eligible for the growth of all sorts of tender exotics from the hottest regions of the East and West Indies, &c. which, in this country, could not possibly exist, in winter especially, without the constant shelter of such a conservatory, assisted by the above artificial heats of bark hot-beds and actual fire, by which we can imitate the hot climates of Africa, Asia, and America so nearly as to raise the plants of those countries and make them flourish as in their native soil, and some of them made to yield their fruit in high perfection; exemplified in the *ananas* or pine apple particularly, which indeed is almost the only sort of our Stove exotics that afford any material useful production.

Likewise, by the aid of Stoves we are enabled to forward many of our hardy plants to early perfection, such as various sorts of curious flowers, fruits, fallads, kidney beans, strawberries, &c. probably one, two or three months sooner than they could possibly be obtained in the open ground.

Also many sorts of seeds, cuttings, and layers of exotics are made to grow freely in the bark-bed of the Stove, that without such aids would not grow at all in this country; likewise, even cuttings, &c. of many curious hardy plants that root rather reluctantly in the full ground, may be facilitated very considerably in their rooting by the Stove bark-bed.

Of the different sorts of Stoves.

There are, however, different sorts of Stoves used occasionally for different purposes, viz. a Bark Stove for common use, being accommodated both with a bark-bed and flues: a Dry Stove for some particular very succulent plants, &c. is furnished only with flues for fires, and no bark-bed: a Forcing Stove purposely for forcing hardy fruits, flowers, &c. to early perfection; being constructed, some both with bark-bed and flues, and some only with flues and no bark-bed. See each sort described below under their respective heads:

BARK STOVE, DRY STOVE, and FORCING STOVE.

BARK STOVE.

The Bark Stove is so called, as being furnished with an internal pit for a bark-bed as well as with flues for fire-heat; its general construction has already been described; and is the most universally used, as the most eligible Stove for the general culture of all kinds of the tenderest exotics, as well as for forcing several sorts of hardy plants, flowers, and fruits occasionally to early perfection; for the bark-bed being designed to effect a constant moderate moist heat the year round; and the flues are used occasionally for fire-heat in winter, or during the cold weather, to produce an additional warmth in the internal air, as may be requisite at that season; the bark-bed being formed of that useful material tanner's bark, commonly called tan, (see BARK BED) and being made the whole width, depth, and length of the bark-pit, is productive of a uniform moderate growing heat of long duration, peculiarly adapted for the immediate reception of many of the tenderest exotics, that require to be constantly plunged in their pots in the bark-bed; such as the pine-apple, &c. in order to enjoy the benefit of that durable, moist, bottom heat about their roots, peculiar to bark hot-beds only, whose heat also evaporates and warms the air of the Stove at all times; and when the cold in autumn, and winter commences, the bark-bed alone not producing a sufficient temperature of heat to warm the internal air effectually, fires are made in the furnace of the flues every night, also on days occasionally during the winter season, to produce an additional internal heat, as before observed; so as the whole may both effectually keep out frosts and the effects of cold damps, and support a constant regular temperature of heat within adapted to the nature of the plants of this department; being generally directed in this by a well graduated botanical thermometer placed constantly in the Stove, distant from the fire-place, and as much in the shade as possible, that neither the fire nor sun may affect it, and the fluid thereof only raised by the air of the house to a proper degree; supporting always such a state of heat, as to raise the spirit in the tube to the degree marked *ananas*, the standard for pine-apple Stoves, not exceeding five or ten degrees under or over that standard; which thermometers are certain guides to regulate the proper growing fire-heat requisite in winter for the culture of Stove exotics in this country.

There are hardly any exotics from the hottest parts of the world, either woody, herbaceous, or succulents, but may be cultivated in this

kind of Stove (Bark-stove) by placing them in different situations as their natures may require; and many sorts of hardy plants, forwarded in growth, both esculents, flowers, and fruits.

In the arrangement of the plants in this Stove, some require the bark-bed, others succeed in any part of the house; and others, such as the succulents, require the driest situation near the flues: many of the more tender, herbaceous, and shrubby plants, natives of the hottest countries, generally succeed best plunged in the bark-bed; though many sorts, or the greater part, both herbaceous and woody, succeed well enough in any part of the Bark Stove; as most commonly in a general hot-house, the bark-bed is principally allotted for the pine-apples; and most of the smaller succulents particularly, may be stationed mostly over the top of the flues upon shelves out of the way of moisture, as being of themselves naturally very replete with humidity. And as to any hardy plants designed for forcing, such as strawberries, kidney beans, and various sorts of flowers, &c. that being potted, may be placed upon shelves, or on the parapet wall of the bark-bed; but the nearer the glasses the better, particularly the strawberries; but may raise good early kidney beans in almost any part of the Stove; though, when intended to forward any sort of flowers, such as roses, pinks, &c. or any bulbous flowers as early as possible, may plunge some in the bark-bed, the others placed upon shelves, &c. will succeed them: thus, in this kind of Stove, besides its use for raising pines and other tender plants, may forward numerous hardy plants both for use and curiosity.

DRY STOVE.

This is called a Dry Stove, because it is furnished only with flues for fires and no bark-bed; and consequently produces a more dry heat in the air within, than the bark Stoves; intended, however, principally, for the culture of some very succulent tender exotics of parched soils, that require to be kept always dry; though this was the first invented Stove for general use, before the use of bark-beds was introduced and brought to such perfection in Stoves, where, by their moderate, durable, moist heat, we are able to cultivate most sorts of tender exotics generally in greater perfection than in Dry Stoves; in which, by the constant fire-heat all winter, night and day, the fibres of the roots are subject to dry too fast, and prove injurious to many sorts of plants that are not of the very succulent tribe; however, some persons, who cultivate full collections of exotics, erect dry Stoves in which

to deposit the most succulent plants separate, for fear of the other plants, which perspire more freely, should occasion a damp air in winter, and be imbibed by the succulents, and injure them, as being impatient of much moisture in that season particularly.

In this kind of Stove some movable stands or shelves are erected above one another, theatre ways, on which to place the pots of plants, such as the tenderer sorts of aloes, cereuses, euphorbiums, melon-thistle, and other very tender succulent plants, &c.

Though most of the tender succulent kinds of the Stove temperature above alluded to, are also occasionally cultivated in a common general Stove or Hot-house, along with other Stove exotics of different natures of growth; and mostly with a degree of desirably effectual success, in common with the other plants of that department.

FORCING STOVE

Is intended principally for forcing various sorts of hardy plants, flowers, and fruits, &c. to early perfection; some Forcing Stoves being designed principally for flowers, as is common about London, to force large quantities of early roses, pinks, and numerous other flowers for market, where they fetch a very great price at an early season. Other forcing Stoves are intended principally for fruit-trees, and some serve both for forcing flowers and fruits, and several sorts of small plants, as strawberries, kidney-beans, &c. so that these forcing Stoves consist of two kinds, viz. a bark Forcing Stove, being furnished both with a bark-bed and flues; a fire Forcing Stove, having only flues for fire and no bark-bed.

The former of which, the bark Forcing Stove, is constructed like a common Bark Stove, already described, being furnished with a pit for a bark-bed to receive the pots of some particular sorts of plants intended for forcing, in order to forward them as early as possible; and with flues for fire-heat occasionally; and sometimes is formed capacious enough in width to admit of a border of earth behind the bark-bed, next the back wall; serving for fruit-trees, to be planted in the full ground; such as cherries, peaches, apricots, &c. for early forcing; and the bark-bed being for receiving various sorts of plants in pots in winter, for forcing to maturity of growth or production in that season or early in spring; may accordingly introduce pots of roses, pinks, dwarf tulips, hyacinths, narcissuses, honeysuckles, hypericums, and many other flower plants of small or moderate growth, both of shrubby and herbaceous kinds, that may be required early in flower; also may forward any curious

tender annual flowers in the bark-bed, such as balsamines, &c. likewise may have pots of strawberries, dwarf cherries, and other small fruits plunged either in the bark-bed, or placed any where towards the glasses; also pots or boxes of kidney-beans, fallading, &c.

The season to begin forcing or fire-working this Stove, is principally from about Christmas to Candlemas, according to the earliness the flowers and fruits, &c. may be required; having the plants and trees intended for forcing in pots, previously potted either a year before or in the preceding spring or autumn, and in winter sheltered from severe frost till the forcing time arrives; though for such plants as are to be raised from seed, this should not generally be sown till the time the pots are placed in the Stove for forcing; but the shrub and tree kinds, in particular, if planted or potted the preceding year or before, that they may be well rooted and firmly established in the earth, will be of essential advantage; all of which being previously raised in the open ground till advanced to a proper growth for flowering and fruiting; and the fruit trees at the same time, trained in the requisite order; then those intended for planting in the internal border of earth behind, if any, should be planted fully therein early in autumn, without being potted; some of which, such as peaches, nectarines, apricots, &c. to be there trained as wall-trees, others as low standards, particularly cherries: and vines, planted also against the front without-side, have the stems trained in through small holes, and conducted up under the sloping-glasses; as directed below in the fire Forcing Stove.

Agreeable to these intimations, and the forcing season, as above, being arrived, having previously prepared the bark-bed, in proper time accordingly, and plunged therein the pots of plants intended; and placed pots of small plants upon the shelves and top of the flues, such as strawberries, kidney-beans, pinks, and pots of any curious or desirable low or moderate-growing flower-plants, roots, &c. in similar situations; as also any intended dwarf or small fruit-trees being some in pots, placed any where the most convenient, others planted fully in the border of earth, if any; they will all soon be set in motion by the bark-bed heat; afterwards begin also making moderate fires on cold nights, likewise on days occasionally, in very severe weather, to support a constant proper warmth to continue the plants always in growth moderately; and thus may obtain various flowers and fruits two or three months before their natural season in the open air.

The other kind of Forcing Stove, worked by

by fire-heat only, is furnished with flues and no bark-bed, but otherwise constructed like any other common Stove, having flues all round the inside walls for fire-heat; and is designed principally for forcing fruit-trees, having the whole or most part of the bottom space within formed of good rich earth full two feet deep, in order to plant the fruit-trees entirely in the ground to remain; an alley or walk being either formed next the back wall, or carried along the middle, allotting a raised border along the back part, for the reception of the choicer fruits to be trained as wall-trees; and the main middle space for small standards of moderate growth.

Here may be planted for forcing, the best sorts of apricots, peaches, nectarines, cherries, plums, vines, and figs; likewise, any small fruit plants, as gooseberries, currants, raspberries; also tufts of strawberries. All of which being first trained in the open ground to a bearing state.

For in this kind of Stove, having the bottom space formed of good rich earth as before observed, it admits of planting the trees, in the full ground; peaches, nectarines, apricots, and figs principally toward the back wall, and trained to a treillis as wall-trees: others, such as cherries, are planted as standards, both small-headed, moderate, full standards, half standards, and dwarfs, disposed in the middle space, the tallest behind and the lowest forward; and may have also pots of strawberries and low flowers, upon shelves near the glasses; and vines being also planted either within towards the front, or wholly without side, close against the front wall, and the stems or a strong shoot of each plant drawn in through a small hole made for each, either in the wall, or in the timber of the front erections; and the branches within are trained up to the inside of the slope glass upon treillis work, where they often produce abundance of fine fruit at an early time, generally observing, that in those vines planted on the outside, it is advisable to guard the stems in winter, especially some time previous to, and during the forcing season, with hay-bands wrapped closely round them, also to lay some dry mulch over the roots, to protect the whole as well as possible at that time, that the progress of the sap may not be much retarded by the external cold, and to promote its flowing more freely for the advantage of the internal growth of the vines, &c.

This kind of Stove is worked entirely by fire-heat, and the season to begin forcing or making the fires, is January or early in February, continuing it moderately every night and

morning, during the cold weather in winter and spring; to forward the different fruits to as early perfection as possible.

Some other sort of forcing Stoves for fruit-trees are contrived also with a low pit for a bark or dung hot-bed, or dung and bark together; beginning first to force the trees moderately with only the hot-bed heat; afterwards, gradually apply the fire-heat on nights, increasing its strength by degrees.

Other orders of Forcing Stoves come under the denomination of hot-walls or fire-walls, designed principally for forcing fruit trees, and worked wholly by fire-heat; being ranges of brick or stone south walling, fronted with sloping glass frames, inclosing a space of four, five or six to eight or ten feet wide, furnished with internal fire flues, and having a range of some different sorts of choice wall-fruit-trees, extending in a regular expansion along the said walling, or to a detached treillis, and trained in the wall-tree order; they, by means of the fire-heat communicated by the flues, within the glass-framing inclosure, are forwarded to early production of their respective fruits very agreeably in considerably good perfection.

In these kind of fire-wall Forcing Stoves, the flues in some are erected against the main walls, in two or three returns over one another, and the trees planted a little forward detached some small distance in front of the said flues, and the branches trained in regular order to a light treillis, continuing also a low range of flues forward along near the front and both ends, in order to have the advantage of communicating the whole benefit of the fire-heat as fully as possible, either generally or occasionally as may be required: in others, having no flues behind, the trees are trained close against the main back wall, and the flues placed forward in a low range, extending along near the glasses; and sometimes carried longitudinally along the middle space in one or two separate or distinct ranges, parallel; all the different flues communicating with each other:—and with respect to the trees, &c. for forcing herein, any of the principal sorts of the choicest wall-fruit kinds are occasionally introduced, such as those of peaches, nectarines, apricots, cherries, plums, figs, grapes, &c. generally all planted in the border within; sometimes also some small fruit plants introduced in pots, as strawberries, currants, &c. and the forcing being commonly commenced in January or early in February, by daily fires, made every evening and morning in a moderate degree, the trees are thereby forwarded to early growth, in blossoming and fruiting;

fruiting; and ripe fruit is obtained in early perfection accordingly. See *Forcing Frames* and *Hot-walls*.

In all these kind of Forcing-frame Stoves, every summer after the trees have yielded their produce, the top glasses, &c. should be removed to admit the free air, showers, &c. to strengthen and harden the shoots of the year properly, and should remain open until winter; but for more particulars in respect to forcing fruit-trees, see the article **FORCING FRAME**.

The different Structures of Stoves.

Stoves, for the various purposes above noted, are formed upon different plans, according to the fancy of the owner or inventor; though there is only one good plan we would recommend for general use.

We formerly noticed that Stoves are for the general part ranged lengthways nearly east and west, that the glasses of the front and roof may be full upon the sun; this will be found to be the most convenient and eligible plan for a common Stove for general use and good success, for the purposes before-mentioned, either for a common bark Stove for pines and other exotics; or any other kind of Stove.

There are, however, Stoves of late inventions erected on the following plans.

Some, instead of ranging lengthways east and west, are ranged directly south and north, having a double sloped glass roof, being sloped to each side like the roof of an house, sloped also at the front or south end; both sides and the south front end being of glass; which kind of Stove, as to dimensions, is from ten or twelve to fifteen or twenty feet wide, the length at pleasure; and from ten to twelve feet high in the middle, both sides nearly head height; formed by a brick wall all round, raised only two or three feet on both sides, and south end; but raised at the north end like the gable end of a house, to correspond with the above-mentioned double sloped glass roof; and upon the top of the side and south end walling, is erected the framing for the glass-work, which is sometimes formed two or three feet upright immediately on the top of the wall, and sloped glass-work above; and sometimes is wholly of a continued slope on both sides, immediately from the top of the side walls to that of the middle ridge: within, it is furnished either with one or two bark pits; but if of any considerable width, generally with two pits ranging parallel, one under each slope of the top glass; separated by a two feet path running along the middle of the Stove; and sometimes continued all round each pit; and with flues ranged along against the inside walls, the whole terminating in an

upright funnel or chimney at the north end.

Other kinds of Stoves are formed entirely square, having a ten or twelve foot brick wall behind; that of the front and both sides, only two or three feet high for the support of the glass-work, placed upright nearly the same height, and sloped above on both sides and front, also wholly of glass; and is furnished within with bark-pit and flues like the others.

And some Stoves are made semicircular, others entirely circular, formed with a two or three-feet brick wall supporting the glass framing, which is continued quite round; having the bark-pit also circular, and flues carried all round the inside of the walling, terminating in a chimney on the northern side.

However, we have in general observed, that the common straight Stoves ranging in a line nearly east and west, with the main range of glass work in front and top full upon the south, as before-mentioned, are the most commodious, as well as generally prove the most successful in the end, take summer and winter, both for the culture of all kinds of Stove exotics; also for forcing any kinds of fruits, flowers, and esculents; and is the plan we would recommend for general use, though sometimes in situations limited to room and exposure, Stoves are erected more or less inclining to an east or westerly aspect; but in general, where the situation admits, should always stand southward, as much as possible.

Stoves or Hot-houses of this plan are of different dimensions, according to the sizes of the plants they are designed to contain, though the most general Stoves for all the aforementioned purposes are but of moderate height, not exceeding ten or twelve to fourteen feet behind, and five or six in front, as in all common pine-apple Stoves; but some are built much more lofty behind, as before observed, to admit of the taller-growing exotics placed towards the back part, to grow up accordingly in a lofty stature; but Stoves of a moderate height as above, are best adapted to the culture of pines and other moderate-growing plants, as well as for forcing: for very lofty Stoves require both a greater force of heat to warm the inclosed air effectually, and the glasses being so high, the plants receive less benefit of the sun, and are apt to draw the pines &c. up too fast into long slender leaves, as they naturally aspire towards the glasses; but in lower Stoves, where the top glasses are but a moderate distance from the plants, they receive the benefit of the sun's heat more effectually, which is particularly essential in winter, and the plants do not draw so fast in a weakly stature,

stature, but become more stocky at bottom, and assume a more robust firm growth, particularly the pine apple, and thereby more capable of producing large fruit: on which consideration, a general Stove or Hot-house, intended principally for the culture of the *ananas*, and various other tender exotics, and for forcing flowers, fruits, &c. should never be built very lofty, but of the moderate height before observed, which will be found very eligible dimensions.

It may be observed, from foregoing intimations, that a Stove may be large or small, according to fancy or convenience; for even in a moderate sized Stove, a person may indulge his fancy with a great number of the more curious sorts of tender exotics, as well as forward many sorts of hardy plants, flowers and fruits to early perfection, at a moderate expence for bark and fuel; but where a more general or grander collection is required, either for pleasure or profit, the dimensions of the Stove must be enlarged proportionably; so that a common Stove for either, or all of the above-mentioned purposes, may be of any length, from fifteen or twenty to fifty or an hundred feet, as before suggested, by twelve to fourteen feet wide; ten to fourteen feet high behind, by five or six in front, including the dwarf wall, and upright glass-work together, as before observed.—See the particulars below.

Its general Structure, &c.

Having, however, determined on the size or dimensions, as to length and width, &c. of the intended Stove, the following are some further general sketches of the dimensions and construction of the different parts of the building, supposing it is designed as a common bark Stove for general use; being furnished with a bark-pit and flues, &c. which may also serve as hints for the erection of any other sort of Stove.

Proceeding to set out the foundations of the walls accordingly of brick-work, allowing also due width at bottom to support the flues a foot wide, wholly on the brick foundation; detached an inch or two from the main walls; then setting off the back or north wall a brick and half or two bricks thick; and the front and end walls nine inches, carrying up the back wall from ten to fourteen feet high; but that of the front and ends only about two feet to a yard high, upon which to erect the upright timber framing for the perpendicular glasses; previously observing in carrying up the walls, to allot a proper space for a door-way, at one or both ends towards the back part; setting out also

the furnace or fire-place of the flues in the bottom foundation, towards one end of the back-wall behind, formed also of brick-work, and made to communicate with the lowermost flue within; though if a very long Stove, of more than forty feet length, a fire-place at each end will be necessary; or if more convenient, may have them in the back part of the end walls, or both in the middle way of the back wall, as formerly mentioned; each communicating with a separate range of flues; in either case, forming them wholly on the outside of the walls, about twelve or fourteen inches wide in the clear, but more in lengthways inward; the inner end terminating in a funnel to communicate internally with the flues as above observed; fixing an iron-barred grate at bottom to support the fuel; calculated either for coal, wood, peat, turf, &c. as may be the most conveniently obtained; an ash hole being underneath, and just above it, is the mouth or fuel door, to admit the fuel, &c. being about ten or twelve inches square, having an iron frame and door fixed to shut with an iron latch as close as possible; raising the whole furnace sixteen or eighteen inches in the clear, finishing the top archways; then proceed in carrying up the main walls regularly.

Thus far observed, continue carrying up the walls of the building the thickness and height above mentioned; and within-side, erect the flues, close along the walls: but as formerly intimated, it would be advisable to have the flues a little detached from the walls, one, two, or three inches, that, by being thus distinct, the heat may arise from both sides of the said flues, which will be a particular additional advantage in more effectually diffusing the whole heat thereof internally in the house; for when the flues are attached close to the walls, a very considerable portion of the heat is ineffectually lost in that part of the wall behind: likewise, in the erection of the flues, should generally continue them also along the front and both ends, in one range at least, in the order as above; as the front and end flues, arranged near the upright glasses, are particularly efficacious, both as in conjunction with those next the back wall, the heat is more equally and effectually diffused regularly in all parts of the Stove, and being situated near the outward front and end glasses, aforesaid, the heat thereof is also more effectual in repelling the injurious effects of the cold external air, frost, damps, &c. from penetrating internally; generally raising these said flues as high as the outward front and end walls, in one or two ranges, one over the other;

other ; and on the top of which may place pots of many small plants, both of Stove exotics, and plants for forcing, as strawberries, kidney-beans, &c.

So that, agreeable to those intimations, proceeding in the construction of the flues, generally about a foot wide, in the whole including six or eight inches in the clear, formed with brick-work, on edge ; the first lower flue communicating with the furnace or fire-place without, and raised a little above it, -to promote the draught of heat more freely, continuing it along also above the intended level of the floor of the back alley or walk of the Stove ; six or seven to eight inches width in the clear, as before observed, and three bricks, on edge, deep, returning it in two or three ranges over one another, next the back wall, and in one or two along the ends, and front wall, as the height may admit ; each return two bricks, on edge, deep, and each tiled or bricked over, as mentioned below ; and in the beginning of the first bottom flue may have a sliding iron regulator, to use occasionally, in admitting more or less heat, as it may seem necessary ; being careful, as they proceed, that the brick-work of each flue is closely jointed with the best sort of mortar for that purpose, and well pointed within, that no smoke can break out ; having each return closely covered, with broad square paving tiles on the brick-work ; covering the uppermost flues also with broad, thick, flat tiles the whole width, all very closely laid and joined in mortar ; and the said uppermost or last range of flues, to terminate in an upright vent or chimney at one end of the back wall, or if two separate sets of flues, a chimney at each end, as formerly noticed ; and may contrive an iron slider in the termination of the last flue, next the chimney, to confine the heat more or less on particular occasions, either by the heat going off too quickly, or becoming of a too weakly degree.

Sometimes, in considerably wide Stoves, in erecting the flues, when thought necessary to make all possible advantage of the fire-heat, one or more spare flues, to use occasionally, are continued round the bark-pit, carried up against the surrounding wall thereof, but detached an inch or two, to form a vacancy, both for the heat to come up more beneficially, and that, by having vent, it may not dry the tan of the bark-bed too much ; and in which flues, either to use occasionally or generally, may at the beginning have a sliding iron regulator, above mentioned, either to admit or exclude the heat less or more, as it may appear expedient ; so that the smoke run-

ning through a larger extent, it spends its heat wholly in the flues before discharging in the chimney.

Should be very careful, that neither the fire-place nor flues is carried too near any of the wood-work, lest it should take fire.

Proceeding, however, within, to set out the cavity for the bark-pit, first allowing a space next the flues for an alley or walk, eighteen inches or two feet wide all round, and then in the middle space is formed the pit for the bark-bed, six or seven feet wide, the length in proportion to that of the Stove, and a yard deep ; being formed by a surrounding wall, and may either be sunk at bottom a little in the ground, raising the rest above, by means of the raised parapet wall ; or if there is danger of wet below, it should be raised mostly above the general surface ; and in either case, surrounding it wholly in width, length, and depth, with a nine-inch wall ; though a brick-wide wall is often made to do, especially that which forms the parapet above ground ; coping it all round with a timber plate or kirb, framed and mortised together, which effectually secures the brick-work.

Then the bottom of the pit should be levelled and well rammed, and if paved with any coarse materials, it would be an advantage in preserving the bark.

The path or alley round the pit should also be neatly paved with brick or stone ; this walk being very necessary for the convenience of performing the occasional operations of culture, as well as to admit of walking round, to view the plants and gather the produce of such as yield any ; as in the pine apple, and such plants as are occasionally introduced for forcing.

Next, in respect to the timber-framing and glass-work, for inclosing the whole, consisting wholly of a close-continued range of glass-sashes all along the front, both ends and roof, quite up to the back wall ; each sash being a yard, or three feet six inches wide ; and for the support of which, framings of timber are erected on the brick-wallings, conformable to the width and length of the sashes.

So that, for the reception of the perpendicular glasses in the front and ends, a substantial timber plate is placed along the top of the front and end walls, upon which is erected uprights, at eligible distances, framed to a plate or crown-piece above, of sufficient height to raise the whole front head high, both ends corresponding with the front and back ; a plate of timber being also framed to the back wall above, to receive the sloping

ing bars from the frame-work in front; proper grooves being formed in the front plates below and above, to receive the ends of the perpendicular sashes, sliding close against the outside of the uprights all the way along the front, or may be contrived for only every other sash, to slide one beside the other, as may be convenient, for admitting fresh air, &c.

From the top of the upright framing in front, are carried substantial cross-bars or bearers, sloping to the top of the back wall, where being also a timber plate, are framed at both ends to the wood-work at regular distances, to receive and support the slope glasses of the roof, placed close together upon the said cross bars or rafters, and generally ranging in two or more tiers, sliding one over the other, of sufficient length together, to reach quite from the top of the upright framing in front, to the top of the back-wall: the cross-bars being grooved length-ways, above, to carry off wet falling between the frames of the sloping lights; making the upper end of the top tier of glasses shut close up to the plate in the wall behind, running under a proper coping of wood or lead, fixed along above close to the wall, and lapped down of due width to cover, and shoot off the wet sufficiently from the upper termination of the said top sashes; though some wide Stoves, exclusive of the main slope sliding glasses, have a shorter upper tier of glass always fixed in the same place; the upper ends close to the back wall secured under a coping as above, and the lower ends lapping over the top ends of the upper sliding tier, and this over that below in the same manner, to shoot the wet clear over each upper end or termination; likewise along the under outer edge of the top plate, or crown-piece in front, may be a small channel to receive the water from the slope glasses, and convey it to one or both ends without running down upon the upright sashes; being careful that the top part behind is well framed and secured, water-tight, and finish the top of the back wall a little higher than the glasses, with a neat coping the whole length.

In every part, the bars of wood which support the glasses should be neatly formed, neither made very broad nor thick to intercept the rays of the sun; making those, however, at top, strong enough to support the glasses without bending under them. But, in wide Stoves, uprights are arranged within at proper distances, to support the cross rafters more effectually.

The glazing of the sashes should generally be in the imbricated manner, more especially

the slope sashes of the roof; so that the panes of glass should be laid in putty, with the ends lapping over each other about half an inch; the vacancies of which are by some closed up at bottom with putty, others leave each lapping of the panes open, in order both for the air to enter moderately at the imbrications, and that the rancid vapours arising from the fermentation of the bark-bed, &c. within, may thereby be kept in constant motion without condensing much; and also that such as condense against the glasses, may discharge itself at those places without dropping upon the plants; but as to the upright sashes in front, they may either be glazed as above, or the panes laid in lead work; being very careful in both places to have the glazing well performed, proof against wet.

A door way for general entrance having been formed at one or both ends of the building near the back wall, the door of which should generally have the upper half sashed and glazed to correspond with the other adjoining glass-work of the ends.

Within-side of the building, the walls should be plastered, pargeted, and white-washed; and all the wood-work, both within and without, painted white in oil colour for its preservation, and to give the whole a lively appearance, as well as to reflect the rays of light upon the plants on nights, which is supposed proves of some importance in improving their growth.

As to any necessary internal erections, there may be ranges of narrow shelves for pots of small plants, erected where thought most convenient, some behind, over the flues, a single range near the top glasses towards the back part, supported either by brackets suspended from the cross bars above, or by uprights erected on the parapet wall of the bark-pit: a range or two of narrow shelves may also be placed occasionally along both ends, above the flues; all of which shelves will serve for holding pots of many sorts of small plants, that do not require to be plunged in the bark-bed; also for pots of strawberries, flowers, &c. in winter and early in spring for forcing; which being placed near the glasses, are generally the most prosperous and successful in their respective productions.

In wide Stoves, if the cross-bars or bearers of the slope or top glasses appear to want support, some neat uprights, either of wood or iron, may be erected upon the bark-bed walling, at convenient distances, and high enough to reach the bearers above, and support them effectually in their proper position without bending under the glasses.

Without

Without side of the Stove behind should generally be erected, either a shed the whole length, or at least a small covered shed over each fire-place, with a door to shut, for the convenience of attending the fires, and keeping them regularly burning.

But if the situation admitted, a close shed, erected all the way against the north side of the back wall, would be the most advisable, as it will both beneficially defend the back of the Stove from the outward air, and if the fire places are behind, it will be convenient for attending and preserving the fires as aforesaid; serving also to stow fuel for the general use of the Stove, also for garden tools, and all garden utensils when not in use, to preserve them from the weather. As also to lay portions of earth in occasionally, to have it dry, for particular purposes in winter, and early spring.

Some stoves, or hot-houses, are furnished with top covers to draw over the glasses occasionally, in time of severe frosts and storms; sometimes, by slight sliding shutters, fitted to the width of the separate sashes; but these are inconvenient, and require considerable time and trouble in their application; others are formed by rollers of painted canvas, rolled up on long poles or rollers, and fixed lengthways all along the top of the Stove, just above the upper ends of the top sashes, which, by means of lines and pulleys, are let down all at once in a minute, and by the same means are rolled up again almost as expeditiously; though these are sometimes liable to violent winds moving and dashing them with force against the lights, and break the glasses; but many Stoves have no other covers, than occasionally using large garden mats, in very rigorous frosts, both on the top and upright glasses.

Thus far is principally all we have to say concerning the general structure of a Stove, which may serve to convey some necessary intimations; and as most builders are now well acquainted with the general plan, by giving the intended dimensions as to size, &c. to the different workmen concerned, such as bricklayers, carpenters, and glaziers, they can readily execute it, and finish the whole completely, as in other buildings.—*See the Plates.*

The above kind of Stove is calculated not only as a pinery for the culture of the pine-apple, but for all sorts of tender exotics of similar quality; some requiring to be plunged in the bark-bed, others placed on the top of the flues and shelves, and others nearer the glasses; the same Stove serves also to force

fruits and flowers, &c. as already hinted.—*See STOVE PLANTS.*

Such Stoves as are intended principally for pine-apples, and for forcing flowers, strawberries, and some sorts of small culinary esculents, &c. may be only ten or twelve feet high behind, and which generally succeed better than stoves of more lofty dimensions, for the reasons already observed.

Likewise, by raising the bark-pit within wholly above the surface, elevates the plants plunged therein nearer the glasses, and proves advantageous in their growth.

As since the insertion of the foregoing general sketches of the plans and dimensions of Stoves, it having been judged expedient to give plates of the different designs, we refer the reader thereto, for a view of the several plans.

Nursery and Succession Stove.

Besides the main bark Stove above described, it is very convenient to have one or two smaller, as a nursery-pit, and a succession Stove, particularly where large collections are required, and more especially in the culture of pine-apples; one serving as a nursery-pit, in which to strike and nurse the young off-spring crowns, and suckers of the old pines for propagation; the other as a succession-house for receiving the year old plants from the nursery-pit, and forwarding them a year to a proper size for fruiting, as succession plants, to furnish the main Stove or fruiting-house every autumn, to succeed the old plants then done fruiting.

These smaller Stove departments prove materially useful in the culture of pines, particularly to raise and nurse the young plants, until arrived to a proper age and size to produce fruit; then moved into the main Stove or fruiting-house, which being thus supplied from these smaller Stoves, with a succession of fruiting plants annually, without being crowded or incommoded with the rearing of the said succession plants, proves a particular advantage, not only in the culture of the fruiting plants, as they often require a higher degree of heat than the succession plants at particular times, in order to forward and improve the growth of fruit properly; but it is also making the best advantage of this main department, to have the bark-bed always filled with fruiting plants only, producing a full crop of proper sized pine-apples every year, which could not always be effected with such certainty and perfection without the aid of these succession Stoves; because the pine-plants in their infant state require sometimes different management

from the fruiting plants, particularly in respect to the degree of fire-heat as above said, which, in general, should be more moderate than for the fruiting plants, lest too much heat force them into fruit in their minor growth, when incapable of producing it in any tolerable perfection.

Therefore, these smaller succession Stoves may be erected as appendages to the main house, or may be detached at some little distance, as may be convenient; though if the situation admits, it may be both more convenient and ornamental to join them in a line with the main Stove, one at each end, and nearly of the same construction, but smaller both in length, width, and height, if thought proper; and sometimes are formed in the manner of a common detached bark-pit, without any upright glasses in front, having a wall all round, five or six feet behind, gradually sloping at each end, to about four feet in front, and with only sliding glasses at top, more particularly the nursery Stove, commonly called simply the pit, because the whole internal space in length and width is often allotted entirely as a pit for a bark-bed, without any walk within, or door for entrance, the necessary culture being performed by sliding open the glasses at top, and the flues for the fires being formed in the upper part of the back wall, above the surface height of the bark-bed: however, it may be more eligible to form the succession Stove particularly nearly like the main one, with erect glasses in front, and sloping sashes at top, with a door for entrance, and an alley or walk next the back wall at least, or more eligible if continued all round the bark-pit.

Observing, however, if these smaller Stoves are joined to the end of the main one, they may be divided from it only by a sliding glass partition for communication with each other, particularly the succession and main Stove, but with separate furnaces, and flues to each department, because the young pine plants do not at all times require the same degree of fire-heat as the older pines, especially those of proper size for fruiting; so that by having separate fires, the heat can be regulated accordingly.

The nursery Stove or pit may be of smaller dimensions, in respect to width and height, than the succession house, if thought convenient: and if designed wholly as a pit without any path or walk within, six or seven feet width may be sufficient, by five or six high in the back wall, and four in front, the whole internal space being filled with tan three feet deep to form the bark-bed: serving chiefly as

a nursery in which to strike and nurse the annual increase of crowns and suckers of the *ananas* or pine-plants the first year; also to raise many tender plants from seeds, cuttings, &c. without incumbering the main Stove; and when they are forwarded to such a state of growth as to require more room, they are removed to the succession-house.

But the succession-house may be nearly on the plan of the main Stove, though of smaller dimensions both in width and height; and is intended to receive the year-old pine-plants from the pit or nursery Stove, in order to plunge them at greater distances, sufficient to give the whole proper scope to take their full growth another year, when they will generally be arrived to a proper size for fruiting the year following: being previously removed in autumn to the main fruiting Stove to succeed the old fruiting plants, which generally by October have all yielded their produce, are then removed away, and their place supplied by a sufficient quantity of large plants from the succession-house, being arrived to a proper state of growth to produce fruit next summer: and the succession-house is at the same time replenished with the largest plants from the nursery pit, which next autumn will probably be also arrived to a proper size for removing to the fruiting-house to succeed the others, and the nursery-pit supplied with young crowns and suckers of the year, from the fruit and old plants, to strike and forward them in ready successions for the above occasions.

Thus, by having the different Stove departments always furnished with pine plants of three different stages of growth, succeeding one another regularly, i. e. the nursery pit containing the yearly crowns and suckers, the succession pit the one and two year plants, and the main Stove the fruiting plants, a constant succession of fruiting plants is thereby annually obtained, for the same individual plants never produce fruit but once; they, however, produce a plentiful supply of crowns and suckers which commence proper plants, attaining a fruiting state in regular succession.

However, in many places, the situation or convenience not admitting but of one common Stove to raise and forward the pines and other exotics, in their different stages of growth, or at least with probably the assistance only of a small detached bark-pit, or a bark and dung hot-bed under a large garden frame, to strike and nurse the yearling crowns and suckers of the pines, &c. of each year, until they are about a year old, then moved into the Stove, where, with the proper requisite culture, often

produce very good pine-apples, as well as raise many other curious exotics, and forward flowers to early bloom; also early fruit and some culinary esculents.

But having a main Stove with two smaller ones adjoining, nearly on the same plan as above hinted, we can always, with greater certainty, obtain a regular annual succession of fruiting pines in perfection.

As in most common Stoves the pine apples, being considered the principal useful exotics of that department, most commonly occupying the greater part of the bark-bed, or sometimes almost wholly, may also, generally in the same Stove, retain a plant or two of many other different sorts of similar tender and curious exotics, such that require aid of a hot-house in this country; some placed in the bark-bed as their nature may require, others upon the top of the flues, top of the bark-pit wall, and upon shelves; but in extensive and capacious Stoves, may have a larger or full collection of the various different sorts of principal stove exotics, a list of which is exhibited below, being collected into one point of view under the head *Stove Plants*; showing at once all the principal Stove or Hot-house plants, from the hot parts of Africa, Asia, America, and southern parts of Europe, now inhabitants of the English gardens, with hints for their general culture, referring to their proper genera for particulars; likewise, a list of such hardy flowers, fruits, and culinary esculents, as may be forwarded to early perfection by the assistance of these departments.

Supposing, however, the Stove or Stoves are now erected, and ready for the reception of the various plants intended; then observing of the bark Stove, that preparations must be made early in autumn, to fill the bark-pit thereof with tanner's bark to form the bark hot-bed, for the immediate reception of the tenderer kinds of plants, to be plunged therein, each in its proper pot; this kind of hot-bed being the most eligible for all kinds of Stoves or hot-houses, as by its moderate and durable fermentation, no material yet known equals it for a hot-bed; it effecting an uniform lasting heat, of a temperature peculiarly adapted to the growth of pine-apples, and many other tender exotics of similar quality.—See BARK-BED.

The autumn, about September or early part of October, is the general season for filling or replenishing the bark-pit with fresh bark or tan, that the bed may support a constant lively heat during the winter: however, the work may also be performed occasionally

in spring, or any time of the year, as occasion may require.

But for the general management of the Stove or Hot-house, and the plants thereof, see STOVE PLANTS below, in the article of their *General Culture*.

STOVE PLANTS.

Having exhibited in the foregoing head general hints of the form, dimensions, and construction of the different sorts of Stoves, and their respective uses in the culture of plants, we now proceed to a list of the principal Stove plants, or such tender exotics from the hot parts of the world, that require the aid of a Stove to preserve them in this country; and although they are separately treated of under their respective genera, yet by collecting them under one point of view, each genus, under its generical name, with the names of many of the principal species, distinguishing which are shrubby, herbaceous, and succulent, will, we presume, assist the memory in making a collection, and in referring to their respective genera for the particulars of their description and culture.

ABROMA, (*Abroma*)—Maple-leaved. (*Tree kind.*)

ABRUS, Jamaica Wild Liquorice. (*Shrubby.*)

ACANTHUS, Bear's-breech. — Shrubby, holly-leaved *Acanthus*. (*Under-shrubby.*)

ACHRAS, Sapota or Mammee-tree.—Common Sapota.—Mammee Sapota. (*Trees.*)

ACHYRANTHES, Bloody or Red Indian *Achyranthes*.—Woolly-cupped Indian *Achyranthes*.—Prickly-cupped shrubby Indian *Achyranthes*. — (*Mostly herbaceous, and the last shrubby.*)

ADANSONIA, Æthiopian Sour Gourd. (*Tree.*)

ADENANTHERA, Bastard Flower Fence.—*Pavonina*.—*Falcataria*. (*Trees.*)

ÆSCHYNOMENE, Bastard Sensitive plant.—Tree *Æschynomene*.—Grandiflorous *Æschynomene*.—Selban, or Ægyptian *Æschynomene*. (*Woody.*)

AGAVE, American Aloe.—Viviparous American Aloe.—Stinking American Aloe. (*Succulents.*)

ALETIS, Guinea Aloe.—Hyacinth-flowered *Aletis*.—Ceylon *Aletis*.—Cape *Aletis*.—Fragrant *Aletis*. (*Succulents.*)

ALOE, African Aloe. Most of the species, except the *Aloe Uvaria*, may be considered both as green-house and Stove plants; for, although they may all be wintered tolerably well in a green-house, yet, if placed in the Stove, in winter particularly, they more certainly flower.

flower annually in greater perfection (*Succulent.*)

ALSTROEMERIA, two or three species. (*Herbaceous*)

AMARYLLIS, Lily Daffodil.—Jacobæan Lily.—Mexican Lily.—Zelon Lily. (*Herbaceous and Bulbous.*)

AMOMUM, Ginger.—Common Ginger, Broad-leaved wild Ginger, &c. (*Herbaceous*).

AMYRIS, Sweet Wood. (*Shrubby*).

ANACARDIUM, Acajou, or Cathew-nut. (*Tree.*)

ANNONA, Custard-apple.—Netted Custard apple.—Prickly Custard apple.—Scaly Custard apple, or Sweet Sop.—Marsh *Annona*, or Water apple.—Broad-leaved *Annona*. (*Tree and Shrub kinds.*)

ANTHOLYZA, Æthiopian Corn-flag, several species. (*Bulbous.*)

APOCYNUM, Dog's-bane.—Shrubby upright Ceylon *Apocynum*, with varieties.—Climbing Dog's-bane, with varieties.—(*Shrubby.*)

ARECA, Fausel Nut Palm, &c. (*Ligneous.*)

ARUM, Wake-Robin, &c.—Ægyptian *Arum* or *Colocasia*.—Trilobate Indian *Arum*.—Tree *Arum*.—(*Two first herbaceous, the other somewhat ligneous.*)

ARUNDO, Reed.—Bamboo Cane or Indian tree-Reed. (*Ligneous.*)

ASCLEPIAS, Swallow-wort.—American Scarlet *Asclepias*, &c.—(*Herbaceous but lig-nous stalked.*)

BANISTERIA, several species. (*Shrubby climbers.*)

BARLERIA, several Species. (*Herbaceous and Shrubby.*)

BASELLA, Malabar Nightshade.—Red Malabar Nightshade.—White Malabar Nightshade. (*Herbaceous.*)

BAUHINIA, Mountain Ebony.—Prickly *Bauhinia*.—Tomentose *Bauhinia*. (*Shrubby.*)

BEGONIA, Shining-leaved. (*Shrubby.*)

BELLONIA, Rough-leaved. (*Shrubby.*)

BIGNONIA, Trumpet flower.—Several species. (*Chiefly woody.*)

BIXA, Dying Metella, &c. (*Shrubby.*)

BONONIA, Tree-celandine. (*Shrubby.*)

BOMBAX, Silk Cotton-tree.—Thorny *Bombax*, or *Ceiba*.—Pentandrous, smooth *Bombax*.—Heptaphyllous smooth *Bombax*. (*Trees.*)

BONTIA, Barbadoes Wild Olive. (*Shrubby.*)

BROMELIA, *Ananas*, Pine-apple.—Common *Ananas* or Pine-apple.—Wild Pine-apple or *Pinguin*.—*Karatas*, or Acaulous wild Pine-apple.—Pyramidal *Bromelia*.—Lingulated *Bromelia*. (*Herbaceous, succulent.*)

BROWALIA, Spreading.—Upright. (*Annuals.*)

BRUNIA, Several species, either for the Stove or green-house. (*Shrubby.*)

BRUNSFELSIA, *Brunsfelsia*. (*Shrubby.*)

BUDDLEJA, American *Buddleja*.—Occidental *Buddleja*. (*Shrubby.*)

CACTUS, Melon-thistle, Torch-thistle, &c.—Greater Hedge-hog Melon-thistle, with varieties.—Mamillary, or Smaller Melon-thistle.—Torch-thistle, several upright sorts. Creeping *Cereus*, or trailing Torch-thistle.—Climbing creeping *Cereus*.—*Ficus Indica*, or Indian Fig.—Greater Indian Fig.—Cochineal Indian Fig.—Indian Fig of Curassoa.—Sword-leaved *Opuntia*.—*Periskia*, or American Gooseberry. (*All of the Succulent tribe.*)

CALCEOLARIA, Slipper-wort. (*Herbaceous.*)

CAMELLIA, Japan Rose. (*Shrubby.*)

CAPPARIS, Caper Bush. (*Shrubby.*)

CAPSICUM, Guinea-Pepper.—Shrubby *Capsicum*, with many varieties. (*Shrubby.*)

CARICA, Papaw or Pepo-tree.—Common Indian Papaw-tree.—Posoposa, or Branching Surinam Papaw-tree. (*Tree-like.*)

CARYOPHYLLUS, Clove-tree. (*Woody.*)

CASSIA, Wild Sena.—Purgin-tree *Cassia*.—Biflorous shrub *Cassia*. (*Tree and Shrubby kinds.*)

CATESBEA, Lily-thorn. (*Shrubby.*)

CEANOTHUS, New Jersey Tea.—Asiatic *Ceanothus*. (*Shrubby.*)

CEDRELA, Bastard Cedar. (*Tree.*)

CELASTRUS, Staff-tree, two or three species for Stove or green-house. (*Shrubby.*)

CESTRUM, Bastard Jasmine, or Jasminoide.—Nocturnal *Cestrum*.—Diurnal *Cestrum*. (*Shrubby.*)

CHAMÆROPS, Dwarf Palm or *Palmetto*. (*Frondose.*)

CHIOCOCCA, Snowberry-tree.

CHRYSOBALANUS, Cocoa Plum. (*Tree-like.*)

CHRYSOPHYLLUM, Goldy-leaf, or Star Apple. (*Woody.*)

CINCHONA, Jesuit's Bark-tree.

CITHAREXYLON, Fiddle Wood. (*Shrubby.*)

CLIFFORTIA, three species, for Stove or green-house. (*Shrubby.*)

CLITORIA, three species. (*Climbers.*)

CLUSIA, Balsam-tree.

CLUYTIA, *Elutaria*, or Indian *Cluytia*. (*Shrubby.*)

COCCOLoba, Sea-side Grape. (*Shrubby.*)

COCOS, Cocoa-nut-tree. (*Frondose Tree-kind.*)

COFFEA,

COFFEA, Coffee-tree. (*Shrub-like.*)
COTYLEDON, Navel-wort.—Cut or jagged-leaved *Cotyledon*. (*Succulent.*)
CRASSULA, Lesser Orpine. (*Succulent.*)
CRATÆVA, Garlick Pear. (*Tree-like.*)
CRESCENTIA, Calabash-tree. (*Tree-kind.*)
CRINUM, Asphodel-lily.—American Asphodel-lily.—African Asphodel-lily. (*Bulbous herbaceous plants.*)
CROTALARIA, Laburnum-leaved. (*Shrubby.*)
CROTON, Tallow-tree.
DRACÆNA, Dragon-tree.
DRACONTIUM, Dragons. (*Climbers.*)
EHRETIA, two or three species. (*Shrubby.*)
ELÆAGNUS, Wild Olive, or Oleaster.—Thorny *Elæagnus*. (*Woody.*)
ELÆOCARPUS, one species. (*Shrubby.*)
ERIOCEPHALUS, three species, for the Stove or green-house. (*Shrubby.*)
ERYTHRINA, Coral-tree.—*Coraliodendron*, or Smooth Coral-tree.—Spinous Coral-tree.—Herbaceous *Erythrina*. (*Shrubby and Herbaceous.*)
EUPHORBIA, Burning Thorny Plant.—*Euphorbia* of the Ancients.—Canary *Euphorbia*.—Oleander-leaved *Euphorbia*.—Medusa's Head *Euphorbia*.—Tithymaloide *Euphorbia*, or Bastard Spurge. (*All Succulents.*)
FAGARA, two species. (*Tree and Shrubby.*)
FERRARIA, waved-leaved. (*Herbaceous.*)
FICUS, Fig-tree.—Sacred Fig, or Indian God-tree.—Sycamore Fig-tree.—Bengal Fig-tree.—Indian long-leaved Fig-tree.—Dwarf Indian Fig-tree. (*Tree-kinds.*)
GARDENIA, Cape Jasmine. (*Shrubby.*)
GLORIOSA, Superb Lily. (*Herbaceous.*)
GLOXINIA, one species. (*Herbaceous Succulent.*)
GOSSYPIUM, Cotton-plant.—Consists of herbaceous and shrubby species. See *Gossypium*.
GREWIA, Oriental *Grewia*. (*Shrubby.*)
GUAIACUM, *Lignum vitæ*, three species. (*Trees.*)
GUETTARDA, one species. (*Tree kind.*)
GUILANDINA, several species. (*Trees and Shrubs.*)
HÆMANTHUS, Blood-flower.—Scarlet *Hæmanthus*.—Reddish *Hæmanthus*.—Carinated *Hæmanthus*.—Ciliated *Hæmanthus*. (*Herbaceous bulbs.*)
HÆMATOXYLUM, Blood-wood, or Log-wood. (*Tree-like.*)
HELICONIA, Bastard Plantain. (*Herbaceous.*)
HELICTERES, Screw-tree.
HELIOTROPIMUM, Turnsole. (*Shrubby.*)
HERNANDIA, Jack-in-a-box-tree.—Sonorous *Hernandia*.—Oriental *Hernandia*. (*Trees.*)

HIBISCUS, Syrian Mallow.—Mutable-flowered *Hibiscus*, or China Rose.—*Rosa Si-nensis*, or Rose of China.—Viscous Mallow, or Scarlet *Hibiscus*. (*Shrubby.*)
HURA, Sand Box-tree. (*Woody.*)
HYMENÆA, American Locust-tree.
HYDRANGÆA, great-flowered. (*Herbaceous.*)
JATROPHA, Cassada, or Cassava Plant.—Most of the species are Stove-plants. (*Woody and herbaceous.*)
JUSTICIA, Malabar-nut.—Hyssop-leaved *Justicia*, &c. (*Woody.*)
INDIGOFERA, Indigo. (*Shrubby.*)
IXORA, Indian Wild Jasmine. (*Shrubby.*)
KÆMPFERIA, Galangale.—Both the species. (*Herbaceous.*)
LANTANA, American Viburnum.—Trifoliate *Lantana*.—Involucrum-headed *Lantana*.—*Camara*, or Leafless-headed *Lantana*.—Prickly *Lantana*. (*Shrubby.*)
LAURUS, Bay, Cinnamon-tree, Alligator Pear, &c. (*Trees*)
LAWSONIA. (*Shrubby.*)
LIMODORUM. (*Bulbs.*)
LOBELIA, Cardinal-flower.—Plumier's *Lobelia*.—Surinam *Lobelia*.—Pine-leaved *Lobelia*. (*Shrubby.*)
LORANTHUS. (*Shrubby.*)
MALPIGHIA, Barbadoes Cherry.—All the species. (*Woody.*)
MAMMEA, Mammee-tree.—American Mammee-tree.—African Mammee-tree. (*Trees.*)
MANGIFERO, Mango-tree.
MARANTA, Indian Arrow-root.—Arundinaceous *Maranta*.—Galanga, or Indian Arrow-root. (*Herbaceous.*)
MARTYNIA.—Perennial *Martynia*. (*Herbaceous.*)
MASSONIA, Broad-leaved.—Narrow-leaved. (*Bulbs.*)
MELASTOMA, American Gooseberry. (*Trees and Shrubs.*)
MELIA, Bead-tree.—Evergreen Bead-tree of Ceylon.—*Azadirachta*, or Indian Bead-tree. (*Tree-kinds.*)
MESEMBRYANTHEMUM, (*Ficoides*) Fig Marigold.—Diamond *Ficoides*, or Ice-plant. (*Herbaceous and Succulent.*)
MESUA, Indian Rose-chestnut. (*Shrubby.*)
MICHELIA. (*Shrubby.*)
MIMOSA, Sensitive-plant.—All the species. (*Shrubby and Herbaceous.*)
MUSA, Plantain-tree.—All the three species. (*Of a Tree-like growth, and Herbaceous nature.*)
MYRTUS, Myrtle-tree.—Pimento or Allspice-tree.—Diacious Myrtle.—Brazilian Myrtle, &c. (*Tree and Shrub kinds.*)
NERIUM,

NERIUM, Oleander.—Double-flowered.—Striped-leaved, &c. (*Shrubby.*)

NYCTANTHES, Arabian Jasmine.—Sambac, or common Arabian Jasmine.—Undulate-leaved *Nyctantes*, or Malabar Jasmine.—*Arbor Triflis*, or Sorrowful-tree.—Hairy Sorrowful-tree. (*Shrubby.*)

OPHIOXYLON. (*Climber.*)

PANAX, Genseng. (*Shrubby.*)

PANCRATIUM, (*Pancratium* lily) Sea Daffodil.—Ceylon unicolorous *Pancratium*.—Mexican bicolorous *Pancratium*.—Caribbean multiflorous *Pancratium*.—Amboyna broad-leaved *Pancratium*. (*Bulbous Herbaceous perennials.*)

PANDANUS, Screw Pine. (*Herbaceous.*)

PARKINSONIA. (*Tree.*)

PASSIFLORA, Passion-flower.—Sawed-leaved Passion-flower.—Laurus-leaved Passion-flower.—Vespertilion, or Bat's wing Passion-flower.—Red Passion-flower.—Maliformous, or apple-fruited Passion-flower.—Silky Passion-flower.—Multiflorous Passion-flower.—Quadrangular Passion-flower.—Suberosous, or Cork-barked Passion flower. (*Woody, and Herbaceous climbers.*)

PENTAPETES. (*Annual and Shrubby.*)

PERIPLOCA, Virginia Silk, &c.—Indian *Periploca*. (*Woody.*)

PETIVERIA, Guinea Hen-weed.

PHŒNIX, Great Palm, or Date-tree. (*Lignous.*)

PHYLLANTHUS, Sea-side Laurel.

PHYSALIS, Winter-cherry.—*Arborescent*, or Tree *Physalis*.—Winter-cherry of *Curaçoa*. (*Woody.*)

PHYTOLACCA, American Night-shade. (*Shrubby.*)

PIPER, Pepper, several sorts. (*Herbaceous and Shrubby.*)

PISCIDIA, Two species. (*Shrubby.*)

PISONIA, Two species. (*Woody.*)

PLUMBAGO, Lead-wort.—Ceylon *Plumbago*.—Rose *Plumbago*. (*Lignous or Under-shrubby.*)

PLUMERIA, Red Jasmine.—Red *Plumeria*.—White *Plumeria*.—Obtuse *Plumeria*. (*Woody Succulents.*)

POINCIANA, Barbadoes Flower-fence, &c.—Fair *Poinciana*, or Double-spined Barbadoes Flower-fence.—Bijugated Single-spined *Poinciana*.—Spineless *Poinciana*. (*Shrubby.*)

POLYANTHES, Tuberose, or Indian Tuberose Hyacinth. (*Herbaceous.*)

PORTULACA, Purslane. (*Shrubby.*)

PSIDIUM, Guava-tree.

PTILEA, Shrub Trefoil.—Viscous Indian *Ptelea*. (*Shrubby.*)

RANDIA, Two species. (*Shrubby.*)

RAUVOLFIA. (*Shrubby.*)

RHAMNUS, Buckthorn.—*Spina Christi*, or Ethiopian Jujube.—*Oenopia*, or Ceylon Jujube. (*Shrubby.*)

RHUS, Sumach.—Cobbe, or Ceylon Sumach. (*Shrubby.*)

RIVINIA, Dwarf Tetrandrous *Rivinia*.—Climbing Octandrous *Rivinia*. (*Lignous.*)

ROBINIA, False Acacia.—Violet American *Robinia*.—Smooth Indian *Robinia*. (*Tree and Shrub kinds.*)

RONDELETIA. (*Woody.*)

SACCHARUM, Sugar-cane.—Common Sugar-cane.—Spiked Sugar-cane. (*Herbaceous, of the arundinaceous tribe.*)

SAPINDUS, Soap-berry-tree.

SCHINUS, Indian Mastic-tree.—Molle-tree of Clusius, or Peruvian Mastic-tree.—Areira, or Brazilian Mastic-tree. (*Woody.*)

SENECIO. (*Herbaceous.*)

SIDA, Indian Mallow. (*Herbaceous.*)

SIDEROXYLON, Iron-wood.—Inermous, or Smooth Ethiopian *Sideroxylon*.—Spinous, Malabar *Sideroxylon*. (*Shrubby.*)

SOLANUM, Nightshade.—Guinea Nightshade.—Fiery-thorned Nightshade.—Bahama Nightshade.—Trilobate Nightshade, &c. (*Shrubby.*)

SOPHORA. (*Shrubby.*)

SPATHLIA. (*Shrubby.*)

SPONDIAS. (*Trees.*)

STAPELIA, Variegated *Stapelia*.—Hairy *Stapelia*. (*Succulent and lignous.*)

SWIETENIA, Mahogany-tree.

TABERNÆMONTANA. (*Shrubby.*)

TAMARINDUS, Tamarind-tree. (*Tree.*)

THEOBROMA, Chocolate nut-tree.—*Cocuo*, or Chocolate-nut-tree.—*Guazuma*, or Bastard Cedar of Jamaica. (*Shrub and Tree-kind.*)

TINUS. (*Tree.*)

TOLUIFERA, Balsam of Tolu-tree.

TOURNEFORTIA, Shrubby *Tournefortia*.—Volubillate, or Twining *Tournefortia*.—Fœtid, or Stinking *Tournefortia*.—Hairy *Tournefortia*.—Serrated *Tournefortia*.—Cymose *Tournefortia*. (*Shrubby.*)

TRIUMFETTA, Lappula, or Burry-capuled *Triumfetta*. (*Lignous.*)

TULBAGIA. (*Herbaceous.*)

TURNERA, Elm-leaved. (*Lignous.*)

VERBENA, Vervain. (*Herbaceous.*)

VINCA, Periwinkle.—Rose Periwinkle of Madagascar. (*Shrubby.*)

VITIS, Vine.—Indian wild Vine.—Trifoliate Indian Vine. (*Shrubby.*)

VOLKAMERIA, Prickly *Volkameria*.—Unarmed or Smooth *Volkameria*. (*Shrubby and Under-shrubby.*)

URENA, Angular-leaved *Urena*.—Sinuated *Urena*.—Procumbent *Urena*. (*Woody.*)

WALTHERIA,

WALTHERIA, American *Waltheria*.—Indian *Waltheria*.—Narrow-leaved *Waltheria*. (*Ligneous*.)

XIMENIA, American Prickly *Ximenia*.—Unarmed Jamaica *Ximenia*. (*Trees*.)

XYLOPHYLLA Love-flower.

ZAMIA, Dwarf American Palm. (*Fron- dose*.)

Of the above list of Stove plants, some of the sorts are also inserted in the green-house list; because, in default of a Stove, they may be preserved tolerably well in a good green-house, though probably brought to greater perfection in a Stove, as is generally noticed in the culture of the respective sorts, each in its proper genus.

General Management.

As to the general management of the bark Stove and culture of the plants; the pit of the Stove must always be filled with tan-bark to produce a continual heat, making fires only in winter, &c. and all the plants must be kept constantly in pots, in order to move to different situations in the house occasionally, some in the bark-bed, others on the shelves, top of the flues, &c.

But to prepare the Stove for the reception of the plants, the bark-bed must be formed by filling the pit with new tanner's bark early in autumn, or any time else when the most convenient to obtain the plants.

The tan-bark for this purpose is procured from the tan-yards, after having been used in tanning, and cast out of the tan-pits; choosing that which is fresh, not having lain long to exhaust itself, or become black and earthy; but the fresher it is from the tan-pits the better, especially after having lain a short time to drain off the grossest wet, preferring the larger or middling sort to the small-cut bark, which soon becomes earthy and declines its fermentation; but the larger sort will retain its heat several months: having however obtained the proper quantity, generally observe, previous to applying in the pit, if it happens to be very wet, it is advisable either to spread it abroad, or dispose it in small heaps or ridges, two or three days in dry weather, to drain and dry moderately: or if copiously wet, may be formed into a general heap to drain off the redundant moisture more effectually, and promote its fermentation; and in a few days, or perhaps a week or more, it will be in good preparation for use; then fill it into the bark-pit, being careful as it is thrown in, to shake it up well together with the bark fork equally in every part, not beating or treading it down, raising the whole half a foot above the top of the pit to allow for settling, suffering it to set-

tle gradually of itself; and thus the fermentation will come on regularly, perhaps in a week or ten days; though may probably be a fortnight or more, before it becomes of a due temperature for the reception of the plants; having some long sticks thrust into the bed, drawing them up daily, and feel them with the hand, you will more easily discover the progress of the fermentation, and proper degree of heat; observing, if the heat should prove violent, to defer plunging the plants till it is become of a more moderate temperature.

When therefore the bark-bed is ready, prepare to plunge the plants, such as pines and other exotics that require the aid of the bark-bed; and the other less tender kinds, to be placed in different parts of the house as their nature may require; all the sorts being previously planted in pots.

In potting the different kinds, allot proper sized pots according to the size and nature of the plants, not too large at first, for as they advance in growth they may be shifted into others a size larger, &c.

Being careful also, to pot them in proper earth adapted to the nature of the respective sorts; though most of the shrubby or woody kinds, and the common herbaceous tribe, succeed in any common rich light earth; but all the succulent plants should be planted in a dry, sandy, or rubbishy soil, on account of their humid quality; however, as to the different soils requisite for any particular sort, it is exhibited in their culture under their respective heads.

In proceeding to plunge the pines and other sorts intended in the bark-bed, it is proper to have a broad plank or board to lay across the bed, on which to stand or kneel without treading the bark hard; likewise a hand-fork for opening apertures more expeditiously to plunge the pots, which may be plunged to their rims, if the fermentation is not too violent; otherwise only about half-way at first; afterwards, when the heat is moderate, plunge them wholly down; arranging the plants regularly in respect to their different gradation of height, the tallest behind, gradually down to the lowest in front; and if disposed in the quincunx way, they will receive the advantage of more room, and benefit of the air and rays of the sun more equally; plunging the whole as above observed; and at the same time, let all the other less tender kinds of plants, not requiring to be placed in the bark-bed, be disposed in different parts of the house, as their temperature may require: many of the woody and herbaceous kinds succeed well enough any where within the Stove; but most

of the succulent tribe succeed best in the driest part near the flues, distant from moisture, especially in winter, being placed either on the top of the flues, or on shelves ranged above them, or in other parts where convenient; though almost any sorts of Stove plants, when intended to forward them faster in growth, or into bloom, may be plunged in the bark-bed occasionally; however, as to the *ananas* or pine-apple, although they will grow in any part within the Stove out of the bark-bed, yet never so prosperously, nor produce any but small trifling fruit, therefore require to be continued always plunged in the bark-bed the year round; several other of the more tender curious exotics, mentioned in their respective genera, are also the most prosperous if plunged in the bark-bed, where there is room enough without incommoding the pine-plants.

Observe, if, after the plants are plunged in the bark-bed, the bark should happen to heat violently, it is proper to draw up the pots half way, or far enough to save the roots of the plants from being by vehemence of the heat damaged, replunging them again down to their rims when the heat becomes more moderate.

Most of the Stove plants require to be continued almost constantly in the Stove the year round; though, if the Stove is much crowded, some of the less tender kinds will bear to be almost fully exposed to the open air, six weeks or two months in the heat of summer, in warm dry seasons; at least, may remove some into the green-house or under frames, &c. towards the latter end of June, or beginning of July, if thought convenient to thin the Stove on any particular occasion: the green-house being then vacant, and in which these hardier Stove plants may enjoy the free air more copiously to promote strength, by opening all the windows daily, yet be sheltered on nights and bad weather; which would change the colour of their leaves disagreeably; removing them however into the Stove again early in September, or as soon as the nights prove cold; however, if plenty of Stove room, the whole may be constantly retained in that department.

The Stove must always be kept nearly to a certain regular temperature of heat as marked on the botanical thermometer (*ananas*); observing that in summer, from May until October, the bark-bed heat alone, aided by the heat of the sun through the glasses, will sufficiently warm the internal air: but from October or beginning of November, to April or May, aforesaid, the additional assistance of

and support a due warmth in the internal air nearly equal to that in summer; by making fires every evening and morning in the furnace of the flues, also occasionally on days in very cold, or foggy, and damp weather, and rigorous frosts without sun.

But as a guide to regulate the degree of heat requisite for Stoves, especially in winter, a Stove thermometer should be placed in a convenient situation within, not too near the fire-place or flues, but hung up towards the centre of the house, with the back to the sun, so as the mercury or liquid spirit in the glass globe and tube may be affected only by the warmth of the air internally; thereby discovering the real degree of heat more effectually, which should always be so regulated, as not to exceed five or ten degrees over or under the mark *ananas*, which, as we noticed before, is the standard generally to be observed in regulating the temperature of Stove heat at all seasons.—See THERMOMETER.

Fresh air must be admitted into the Stove occasionally at all seasons, for the benefit of the plants in general, by sliding some of the front or top glasses open in sunny days, more or less, according to the season and temperature of the outward air, &c. observing, however, that in winter and early spring, air must be admitted but sparingly and cautiously, only at favourable opportunities in fine calm sunny days, opening only some of the glasses a little way in the heat of the day, for two, three, or four hours, as the weather permits, shutting all close timely in the afternoon, or sooner, if the air changes cloudy or very cold; but in summer admit air more freely every warm day, and in hot sun-shine weather especially, should slide some of the lights open pretty considerably, in the greatest heat of the day; being however careful at all seasons, to proportion the admission of free air judiciously, both as to time and quantity; not opening too soon in the day, before the sun has some power of heat; but in winter, or during the cold season, give air only in calm sunny days from about ten or eleven of the forenoon, till two or thereabout, or not so long if the weather changes; and in summer, from eight, nine, or ten in the morning, till three or four in the afternoon, or an hour or more earlier and later in very hot weather; remarking in general, that in giving air at all times of the year, to slide the lights open only a little at first in the morning, and as the heat increases, towards noon, admit a larger portion of air, according to the season; but when the sun or heat of the day is on the decline, shut the glasses close in proportion, having

also.

also particular attention to shut all quite close in due time, at the approach of the weather proving unfavourable, more especially in winter, &c. and always timely in the afternoon, before the warmth of the inclosed air falls too much below its due standard; generally observing the degree of heat on the thermometer.

Watering the plants in Stoves is also a material branch of culture to be performed, according as the different sorts require, which must always be applied more seldom and sparing in winter than in summer; remarking, the woody or shrubby plants, and most of the herbaceous tribe that are not succulent, require water frequently; the woody kinds require it most frequent, the herbaceous plants in a middling degree, and the succulents the least of all; so that the woody and common herbaceous plants, in this department, require watering, some perhaps two or three times a week in summer, and in winter, probably not above once a week; but you will regulate this accordingly, as you observe the plants stand in need: and, by the earth in the pots, being more or less dry, always apply the necessary waterings with due moderation, just to preserve the earth in the pots moderately moist, but never too wet; giving also at times occasional waterings all over the heads of the plants, in summer particularly, though but very sparingly in winter, especially to the *ananas*, *aloes*, and other exotics of similar growth; as the water would lodge long between the leaves of these sorts of plants, at this season: nor must it be practised to the pines when in flower. But as to the succulent tribe, they being naturally very replete with moisture, need but very little water at any season, more particularly in winter; except where the soil in the pots dry very fast, when a light watering now and then will be eligible; but in hot sunny weather in summer, frequent light waterings, to these kinds, is also necessary.

But in watering such of the woody plants, &c. as are apt to contract filth or insects, it is proper to water also all over their branches and leaves occasionally, at almost any season when the case requires it.

For the purpose of watering these plants, in winter particularly, a cistern or tub placed either in one corner of the Stove, or under cover of the shed behind, &c. near the fire-place, would be convenient to contain water some hours, or a day or two, previous to the using it, just to take off the chilling cold.

Likewise, for the convenience of watering

the pines and other plants plunged in the bark-bed, where they are crowded close, a tin pipe made with two or three joints or pieces, to join into one another to lengthen or shorten at pleasure; one of the pieces having a funnel fixed at one end, so that by pouring the water into the funnel, may conduct it to any pot in the bark-bed, &c. without wetting the hearts of the plants, which, in the pines, is to be avoided as much as possible in winter, and when they are beginning to show fruit.

The bark-bed will support a good growing heat three or four months, and if in that time the heat is much decreased, the pots being taken up, and the bark then forked over to the bottom, breaking all lumps, and mixing the parts well together, immediately replunging the pots, the bed will renew its fermentation, and continue in a proper temperature of heat six weeks, or two months longer, or more. Then about March or April, its strength being considerably exhausted, and probably have become earthy towards the top and sides, prepare to revive its declining heat by the addition of about one third at least of fresh tan, previously removing the pots, then clearing out all the most earthy or crumbly old tan at top, and a little down the outsides of the bed; then introduce as much new as will fill up the pit again, and then fork up the whole, new and old together, plunging the pots again as before; and thus by turning up, loosening and mixing up the old, and incorporating the supply of fresh tan, it will soon promote a fresh fermentation, and renew the heat so effectually, as to continue it in good order till autumn; at which time, not later than September or October, or probably, not longer than the middle or towards the latter end of July, or beginning of August, when, if the heat is much declined, it may be proper to revive it, by taking up the pots, and forking over the tan-bark again to the bottom; or previously observing that, as it may probably be necessary, on some particular occasions, to add a small refreshment of new tan, this, if thought expedient, should be provided accordingly, in proper time, applying and working it up with the old, either wholly or half-way down, which will revive the heat sooner, and more effectually to continue it in a proper temperature till October; or however, in default of fresh tan, it may be proper to fork up the old, to recruit its declining heat as well as possible; though the revival of the heat in the above season, (July or August), with some addition of new tan applied to the old bed, is then generally

rally more essentially necessary at the time of shifting the succession pine plants, in order to have a more lively or moderately-brisk heat about the roots when replunged after shifting; whereby to expedite and promote their fresh-rooting-freely and more effectually.

And thus by either or both the above methods, the bark-bed supporting a proper heat till October aforesaid, then as the general old bark will be in a manner quite exhausted, both in substance and its fermenting property, it should be almost entirely renewed with a fresh quantity of new tan; which should be provided in proper time accordingly; but previous to this augmentation, observing, if the old tan is not entirely wasted to a small earthy substance, it may be skreened, to separate the small exhausted materials from the larger unexhausted bark, clearing out all the small stuff that passes through the skreen, the larger remaining in the pit; then add to this as much fresh tan as will fill up the pit to the top, at the same time forking up the whole, new and old together; though if the whole of the old tan is become very small and earthy, it should be cleared entirely out, and fill the pit wholly with fresh new tan.

But for more particulars respecting these bark hot-beds, see **BARK BEDS**.

And as to fire-heat for the Stove, this is required only in winter and spring, as before observed, to expel the cold and damps, and support the heat of the internal air in a due temperature, as the bark-bed heat alone is not sufficient in those cold seasons; generally beginning to make the fires moderately in the middle or towards the end of October, or beginning of November, when cold or dark foggy weather commences, making gentle fires every night, and cold mornings; and as the cold increases, strengthen the fires in moderation; and in very severe, or cold damp foggy weather, continue the fires also occasionally on days, being always cautious never to make them too violent, but to as to produce nearly a uniform heat in the internal air, as marked on the thermometer; and thus continue the aid of fire-heat till about April or May, according to the temperature of the weather.

The firing for the Stoves may be either coal, wood, peat, or turf; but where coal can be easily obtained at a moderate expense, I should prefer it for general use, as being the most steady, regular, and durable fuel, requiring less attendance than any other; but in default of this, wood, peat, or turf is used in many places.

In winter, when the frost happens to prove very severe, it is advisable to cover the glasses

of the Stove every night, at top particularly, to protect the plants, either with shutters, canvas rollers, or large garden-mats, &c. as formerly mentioned, which covering may also be used in the day-time occasionally, if the frost continues extremely rigorous and no sun appears; but by no means continue the day-covering to darken the plants longer than it shall appear absolutely necessary.

And in the heat of summer in very hot sunny days, it may sometimes be proper to afford a moderate shade of mats, over the top glasses, to some particular plants, for an hour or two, during the violent heat, lest the sun, shining vehemently through the glasses, should scorch the leaves or burn them in holes, and prove detrimental to small tender plants.

Shifting the plants into larger pots, and fresh earth occasionally, must also be duly attended to.

Accordingly, therefore, as the different plants in the Stove increase in growth, and require larger pots, they should be shifted into others a size larger; which may be requisite to some plants annually, such as the pine-apples, and other free growing exotics; others once in two or three years, and some not so often; such as some of the smaller slow-growing succulents, &c. though most sorts of plants in this department will either require shifting or fresh earthing more or less every year or two; either in the same or larger pots, as their growth may require.

The general season for performing these works of shifting or fresh-earthing is either in the spring, about April or May, or early part of autumn, as August, or the beginning of September, time enough for the plants to strike fresh root, in the newly added earth before winter; though if any particular plant stand in great need of shifting, or is in a bad state of growth, the shifting may be performed almost at any season of the year, chusing however, principally, the spring or autumn, as abovementioned, for any general shifting.

In performing the shifting, generally preserve the ball of earth entire about the roots, unless the roots are supposed to be in a decayed state, when all the old earth may be cleared away, and the roots trimmed as occasion require; but those removed with the entire ball, should only have any very dry mouldy and matted roots round the sides and bottom of the ball trimmed off, together with a little of the old earth, if it can be done without disturbing the ball; then having the new pots and fresh compost ready, placing pieces of tile or oyster-shell over the holes in the

the

the pots, and some fresh earth at bottom, set in the plant; and fill up round the ball or roots with more new mould, almost to the top of the pot, giving directly a moderate watering to settle the earth close; and thus proceed, plant and plant, till finished, returning each to its proper place again; plunging all the pines in the bark-bed, and also as many of the other plants as room will admit, which will forward their striking or rooting more quickly in the new earth: after which the less tender kinds may be removed to the shelves, &c. in any part of the Stove.

Such plants, however, as do not require shifting annually, may be fresh earthed at top, &c. in spring, previously removing some of the old earth from the top, and a little way down round the sides of the pot, then replenishing with an equal portion of fresh mould, will prove very beneficial culture, finishing each with a very moderate watering to settle the earth.

It is of importance in the Stove culture to keep all the plants clear from decayed leaves, by removing all such as soon as they appear, as it both tends to preserve the beauty and health of the plants.

Likewise, it is of consequence to keep all plants confined in Stoves clean from dust and filth, which most sorts are apt to contract by such confinement, often to their great prejudice if not timely cleaned; this may sometimes be effected in some sorts, by now and then watering the plants all over their heads, which will wash off any loose dust, and give the plants a lively healthful appearance; though, where any is very foul, is advisable, in the larger broad-leaved kinds particularly, to wash the leaves thereof, leaf and leaf, with a sponge and warm water, also the stems and branches wheresoever any filth is contracted; but as to the pines in particular, and the *aloe* kinds, and others of the like growth, should not be watered all over in winter, because in that season the water is apt to lodge between their leaves a long time, so should only wash their leaves, when foul, with a wet sponge tied on the end of a small stick; for cleanliness contributes exceedingly to the prosperity of the plants; dust or any filth being suffered to increase considerably, is apt to clog and obstruct the fine necessary organs of perspiration, as well as the absorbent vessels destined to imbibite the humidity of the air; thereby cause a stagnation of the sap, and the plants assume a sickly state, and often become the prey of insects: it is therefore essentially necessary to keep all these plants as clean as possible, as it

certainly conduces very considerably to their health and beauty.

Insects often infest the plants in Stoves, and sometimes prove very destructive to some sorts, particularly the pine-apple; appearing first like mildew, or scurfy, and soon after assume the appearance of lice, &c. The causes of them are variously assigned; some impute it to uncleanness and bad state of health, others to the dry air of the Stove, unavoidably occasioned by the fire-heat, and others to the bad management of the plants; though it is certain we shall often also see plants that are seemingly healthful and well managed, suddenly attacked with insects, and more particularly the pine-apples, aforesaid: and when this happens, the plants assume a sickly appearance, requiring immediate assistance in our endeavours to clear them from the vermin as well as possible. As, however, this disaster of insects is ascribed to several causes, so are several methods proposed for the abolition of them; sometimes, previously with a small, pencil-shaped bristle brush, or a sponge, and impregnated water, as intimated below; brushing the leaves with the former, and washing them with the latter, clean to the bottom and heart of the plants, as far as they admit; the washing them is occasionally affected with the infusion of tobacco, &c. i. e. water impregnated with tobacco stalks, tobacco dust, flour of brimstone, and foot, &c. and with this wash the leaves, stalks, and branches; or sometimes also by dipping or plunging the head of the plant wholly into a tub of the above impregnated water, likewise strewing tobacco dust over the leaves and other parts: others try the effect of fumigation of tobacco, by means of a pair of bellows made for that purpose, furnished with a large tin or brass tube to screw on the nozzle of the bellows at pleasure, the extreme end terminating in a long pipe, and the tube being filled with tobacco set on fire; then by blowing the bellows, it produces a strong stream of smoke from the pipe, which being directed to the parts of the plants infested with the vermin, many of them are sometimes thereby effectually exterminated; various other remedies are also occasionally applied, such as compositions both of a powder and liquid kind, to destroy these Stove insects; also receipts to be sold for preparing such a composition, pretending to be of infallible efficacy: though I never found the application of them thoroughly effectual.

In the whole it may be said, that prevention is preferable to a cure, by endeavouring by proper culture, to preserve the plants in a healthful

healthful state of growth, which contributes exceedingly to the prevention of insects; or observing, however, that previous to the application of the above remedies to destroy the insects, it is of importance to keep the plants always clean from filth, the bark-beds always of a lively growing warmth, to continue the plants in a free growth, and keep the earth in the pots of a middling degree of moistness by due moderate waterings, sprinkling the tops also now and then as before observed; those, however, of the pines only in summer, for the reasons before given; supplying also proper share of fresh air in proportion to the season of the year, and temperature of the weather; and being particularly careful never to have the fire nor bark-bed heated too violent, which, affecting the plants, occasions a sickly stunted growth promotive of insects; applying also, if needful, any of the other remedies that may be thought the most efficacious. Likewise if, after all, any particular plant remains severely attacked, and rendered of a very sickly weak state by the vermin, it is advisable to shift it into a new pot and wholly fresh earth, and plunge it into the warmest part of the bark-bed, or other good hot-bed under glasses, still using also the other means; and thus the plant will likely assume a free growth, and recover its proper health and vigour.

Thus far is principally the general management of a Stove, and culture of the plants at large; and as to the method of propagating the various sorts, and of any peculiar culture and other occurrences of particular species, &c. we refer to their respective genera for explanations on those heads.

A list of hardy plants, &c. for forcing in Stoves, and general culture.

As we have already observed, that besides the tender exotics which require the constant aid of the Stove, many hardy plants, both herbaceous, shrub, and tree kinds, may be occasionally introduced into the Stove, in order for forcing to early perfection when required.

For instance, various hardy herbaceous flower-plants may be forwarded into bloom in the Stove, long before their natural season in the open ground; such as early dwarf tulips, hyacinths, polyanthos-narcissus, jonquils, and many other narcissus kinds; anemones, ranunculus, and almost any other of the more curious sorts of bulbous and tuberous flower-plants that may be required early in bloom; previously planting the roots in pots, or some in water-glasses, either at the time it is intended to place them in the Stove, or rather in the preceding autumn, in October or No-

vember, especially in pots, and place them in a garden frame, &c. to be sheltered only from frost till the time arrives for placing them in the Stove, which may be almost any time in winter, though, if not till towards Christmas or after, we may expect a stronger and finer bloom; placing them upon shelves towards the glasses: or if required to have some of them flower as early as possible, may plunge the pots into the bark-bed; supplying all the sorts duly with water, especially after they begin to shoot; and they will here grow freely without trouble, and produce their flowers both early, and in very good perfection.

Likewise pots of pinks, carnations, sweet-williams, wall-flowers, stock-gilliflowers, &c. being placed in the Stove in January, February, or any of the early spring months, may be forwarded considerably in flowering; also many other fibrous-rooted perennials of small moderate growth, that may be required early in flower. Likewise in the Stove may be raised many of the curious annual flowers early from seed, and forwarded to an early bloom.

Of esculent herbaceous plants, may raise early kidney beans and cucumbers in great perfection in the Stove; the seed, &c. being sown in pots or boxes of rich dry earth any time in winter or early spring, placing those of the kidney-beans any where in the house, and the cucumbers near the top glasses upon shelves, just over the back wall and flues; may also raise small sallading any time in winter, sown in boxes or large pots, &c. likewise strawberries, the plants being trained in the open ground in the garden to a bearing state, generally of the Alpine and Scarlet sorts, (see FRAGARIA) such as have either been planted young in pots singly and remained a year, or till advanced to a proper growth for bearing; or good bearing plants in the full ground, taken up and potted with balls of earth about their roots early in autumn, or even in winter whilst the weather continues open, and, in either method, the pots of plants, placed in the Stove near the glasses any time from January till March, either all at once, or at different times for succession, they will produce plenty of fine strawberries. I have also forced early asparagus in the Stove, when there has happened to be a vacancy in the bark-bed to admit of plunging the plants in the tan, as directed in forcing them by dung hot-beds, under the article ASPARAGUS.

As to flowering shrubs, if an early bloom is required, many desirable sorts of small or moderate growth may be forwarded considerably in the Stove; such as roses, honeysuckles, syringas,

syringas, Persian lilacs, hypericum, jasmynes, and various other principal sorts that have merit in the beauty or fragrancy of their flowers; the plants being previously potted, may be placed in the Stove in winter, or any time from January till February or March, &c. either in a common pine-apple Stove, or a forcing Stove; they will flower freely a long time before their natural season.

And as to the fruit-tree kinds, several sorts may be fruited very early in the forcing Stove particularly, especially most of the stone fruits, and some of the berry kinds; such as cherries, peaches, nectarines, apricots, plums, grapes, and figs; also gooseberries, currants, raspberries, &c. all of which being previously trained in the open ground to a bearing state, then planted in the Stove; or some in pots to move to the Stove occasionally, beginning to force them any time in January, or early in February; some being planted finally in the ground or border of earth formed within the Forcing Stove; others in pots, particularly some of the dwarf cherries, and peaches, &c. and smaller fruit shrubs; but the principal peaches, nectarines, apricots, plums, vines, and figs, should generally be planted against a treillis erected near the back and front, to be trained as wall-trees; also some of the early May and duke cherries; though cherries generally succeed very well in small standards, half standards, and dwarfs; pruning them generally to moderate heads, that they may not become high or spreading, to interfere with each other, or shade the other trees too much. Vines also in particular, may likewise be planted in the open ground against the outside of the front of the Stove, and their stems trained in through holes made in the wall or timber framing; and the branches within trained up thinly against the slope and end sashes, &c. to slight treillis work fixed to the bearers, so as the sashes have full liberty to slide; observing such vines as are thus trained in from the outside of the Stove, should in winter, when severe frosts prevail, have that part of their stems without, defended by a close wrapping of hay-bands; also the ground over their roots, especially towards the time the vines begin to shoot within-side of the Stove.

Remarking, as to the time to begin forcing by fire-heat the above hardy plants and fruit-trees, that, if in a forcing Stove for the purpose, January or beginning of February is the proper season; then shut all the glasses close, except giving air occasionally as hereafter hinted; making the fires moderate at first, increasing their strength gradually, though always in a moderate degree, rather under, but

never above the temperature of the pine-apple standard, continuing the fires every night and morning in the above moderate manner; also occasionally in the day time, in severe frosts or cold damp weather.

If, however, there is only a common pine-apple Stove for general use, it should be observed that its temperature of general heat is rather too strong for most fruit-trees, except vines: may, however, where room, introduce some small dwarf sorts in pots; several other kinds of hardy plants may also be admitted in this Stove for forcing, having them ready in pots, &c. in order that they may be moved into the Stove only at the proper season; or, to have a regular succession, may introduce them at two or three different times, at a fortnight or three or four weeks interval, having plants, &c. for this purpose ready potted, and in winter placed under occasional shelter from frost, till placed in the Stove.

All the plants thus forced in the Stove must be allowed the benefit of fresh air in fine days, and occasionally waterings; as to fresh air, if in a common pine-apple Stove they can only enjoy the advantage of air in common with the other plants in that department, as directed in the culture of Stove plants: but if they are in a forcing Stove by themselves, fresh air may occasionally be admitted more freely, especially after the plants have begun to shoot; chusing, however, only fine mild sunny days for this, by sliding open the lights a little in the heat of the day; increasing the portion of air as the warm season advances, shutting all close towards evening: and as to water, all the plants, both herbaceous kinds, shrubs, and trees, will require occasional moderate waterings; those in pots will require it more frequent than such as are planted fully in the ground: chusing generally warm sunny weather for this work, especially in winter and early spring; and give it always in due moderation.

As soon as these forced hardy plants are past perfection, either as to flowering or fruiting, &c. those of them you intend preserving for future use, and that are in pots, should be moved into the open air, to recover themselves, as some of them may serve for the open ground, and some also to force again after having a summer's growth in the full air, especially the shrub and tree kinds; and as to such as are planted in the full ground in forcing Stoves, should, as soon as the flowers and fruit are past, be fully exposed to the open air, by removing all the glasses, that they may receive the full advantage of the air, showers, dews, &c. all summer, and until nearly the arrival of next forcing season, that they may regain proper

proper strength and vigour to yield their produce in due perfection the following year; observing towards winter, or at the approach of sharp weather, to put on the glasses again, in order to give occasional shelter till the time to begin forcing, and then the Stove must be shut up close, and managed as before.

According as any of the fruit-trees fail, or become bad bearers, let them be removed in due time, and their place supplied with new ones from the nursery.

STRELITZIA. (*Strelitzia*.)

This genus furnishes the Stove with a singularly-curious and superbly-beautiful herbaceous perennial exotic from Africa; rising with large oval-oblong leaves, and upright flower-stems, terminated each by a long spatha or sheath, protruding several elegant orange-coloured flowers, having curiously-beautiful nectariums.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX, a terminal, monophyllous, channeled, declining spatha, involving the base of the flowers. COROLLA, deeply divided into three oval lanceolate acute segments, slightly carinated, including a triphyllous nectarium involving the fructifications. STAMINA, five filiform short filaments arising from the base of the nectarium, topped with long linear antheræ. PISTILLUM, an oblong-obtuse three-cornered germen, under the corolla; a single style the length of the stamina, crowned with three subulate stigmas, joined to the top of the nectarium. PERICARPIUM, an oblong blunt leathery capsule, slightly three-angled with three valves, and containing many seeds.

There is but one species of this magnificent flowering perennial: grows naturally in the interior parts of Africa, and towards the Cape of Good-Hope, from whence it was first introduced in this country.

The species is,

STRELITZIA *Regina*.

Queen's Strelitzia.] Hath a perennial stringy root, from whence arise a number of leaves standing upright on radical footstalks thrice their length, and furnished at bottom with a sheath; the leaves are about a foot in length, and four inches broad; they are oval-oblong, leathery, rigid, smooth, concave, entire on the edges, except on one side; towards the base they are more or less curled, the upper side is of a deep green, and the under covered with a fine sea-green meal; the midrib is yellowish and hollowed above, with veins prominent within side, and the young leaves are rolled up. The flower stem, a little taller than the leaves, is unbranched, proceeding from the sheath of one of the leaves; it is straight,

upright, and round, of a glaucous hue, covered with four or five sheaths which closely embrace it, two or more stems arising from the same root; the flower stem is terminated by a declining sheath about six inches long, of a bright purple at its base, running out to a long point, opening above the base to within an inch of the apex, and contains five or six flowers, these are of a bright orange colour, and become upright when protruded from the spatha; the corolla is deeply divided into three leaves slightly keeled with their base fleshy and white; the nectarium is of a very singular form, composed of two fine azure-blue petals, the upper one short and broad, with a whitish point, the sides of which lap over the base of the other petal; the inferior petal is about two inches and a half long, the lower half triangular, grooved on the two lowermost sides, and keeled at bottom, the keel running straight to its extremity, the upper half gradually dilating towards the base, gives it an arrow-shaped form, bifid at the apex, hollow, and containing the antheræ, the edges of the duplicature forming a kind of frill from the top to the bottom. The whole flower is succeeded by a blunt three-cornered capsule, containing many seeds.

This curious plant is raised from seeds imported from the Cape of Good Hope, as we have not heard of any ripening in England, though, when the nature of the plant is better understood, it is hoped it will be so managed as to produce ripe seeds here; the seeds must be sown in pots of rich earth, and plunged in a hot-bed to get them up, afterward must be transplanted singly in pots, and plunged in the tan-pit of the Stove; observing, when the plants are large enough for blowing, to let their roots have plenty of earth, so they can extend themselves into the rotten tan, which will greatly promote their blowing.

STROBILUS, a species of seed-vessel commonly called *Cone*.

The *Strobilus* or *Cone* (*Conus*) is the fruit or seed-vessel of the coniferous or cone-bearing trees, such as pine, fir, cypress, cedar, juniper, &c. being of a conical figure, formed of a conic *amentum*, composed of scaly imbricated calyces, becoming so many hard woody scales, laid over on one another like tiles, closely involving the seeds. See CONIFERÆ and CONUS.

This species of seed-vessel being generally of a conical form, is commonly called a *Cone*, (*Conus*.)

STYLUS, the Style of the flower.

The Style is that long slender part of the *pistillum* placed on the top of the germen, in the centre of the flower, elevating the stigma or

or summit of the *pistillum*, or female organ; and is corresponding to the vagina in animals, as being the tube through which the effluvia of the farina or fertilising male dust of the antheræ emitted on the stigma, pass to the germen or seed-bud, for the impregnation of the embryo seeds. See PISTILLUM, GERMEN, and STIGMA.

Every female and hermaphrodite flower is furnished with a *pistillum*, and consist of three parts, viz. the germen, Style, and stigma; the germen supports the Style, and the Style the stigma on its summit. Thus the Style connects the germen and stigma; and in plants apparently without, or with but a very short Style, the stigma is placed on the germen; as in *papaver*. The number of Styles vary in the plants of different genera, the greater number having only one Style, others two, three, to five, ten, or many Styles, which in each flower is generally equal in number to that of the germen or seed-bud, each germen being furnished with its own particular Style; so that flowers having but one germen have generally but one Style; and those with two, three, or many germens, have the like number of Styles. There are, however, some exceptions, as there are plants which have more than one Style for a single germen or seed-bud, as in the umbelliferous tribe; others on the contrary have a single Style common to many seed-buds, as in the verticillate tribe of lip flowers. And in another tribe of plants the Style is single at its origin, but soon divides or branches out into as many ramifications as there are divisions or cells in the cavity of the seed-bud, such as in the geraniums and mallow tribe, which have their Styles divided above into five branches, corresponding to the five divisions of the seed-bud or capsule.

From the number of Styles, and in their absence that of the *stigmata*, is founded the orders or secondary divisions of the classes in the sexual method. See CLASSES and ORDO.

The Style in most plants is erected like a column in the centre of the flower; in some, however, the Style is nodding or reclined, or in others is revolute or bent backwards; and sometimes, as in *nigella arvensis*, the five Styles being longer than the stamina, are first erect; afterwards when the flower is fully expanded, they are bent back, that the stigmas may touch the antheræ of the stamina or male organ, and having thereby received the male dust, they are again elevated, and ever after remain erect. For the most part the Style is always surrounded by the stamina, so that some of the pollen or male dust of the antheræ is blown by the wind on the stigma.

As to proportion and dimension, the Style is either of equal length with the *stamina*, as in most flowers; much longer, as in some others; and in some very short, or even wanting, as in *papaver*, &c. in which the stigma fits close to the germen; and in substance the Style in some plants is thicker than the *stamina*; in others of equal thickness, and in some slenderer.

As to figure, the Style is either cylindrical and hollow like a tube, as in most plants; angular, as in *cana*; awl-shaped or tapering, as in *geranium*; capillary or slender, like a hair; or club-shaped, being thicker above than below, as in *leucoium*, the greater snow-drop, &c.

In point of situation, the Style is situated either on the top of the germen, as in most flowers; above and below the germen, as in *capparis* and *euphorbia*; or on one side of the germen, as in rose, raspberry, and other plants of the *icosandria polygynia*; or on the base of the germen, as in *alchemilla*, or lady's mantle, &c.

In respect to duration, the Style is either deciduous, falling off with the other parts of the flower, after the impregnation, as in most plants; or sometimes permanent or abiding, as in the cruciform flowers of the *tetradynamia*.

STYRAX.

Storax, or Sweet Gum-tree.

It is a deciduous aromatic tree of the East, retained in our gardens to diversify the greenhouse and shrubbery collections; is famous for its medical gum called Storax, being a fragrant resinous fluid, which the tree imparts by incision in the trunk; the very wood also imparts a sweet odour.

Class and order, *Dodecandria Monogynia*.

Characters.] CALYX is short, cylindric, monophyllous, and quinque-dentate. COROLLA is monopetalous, infundibuliform, with a short cylindric tube, and spreading limb divided into five obtuse segments. STAMINA, about twelve or more awl-shaped filaments, disposed circularly, having oblong erect antheræ. PISTILLUM, a roundish germen below the corolla, single style, with a truncated stigma. PERICARPIUM, a roundish, unilocular, drupaceous fruit, containing two roundish nuts, convex on one side.

There are different species of Syrax, all exotics, though only one of which, the most noted sort, is commonly known in this country; generally requires the culture of hardy greenhouse plants, during its minor state; but when hardened by degrees to a more mature growth, it may be turned out into the full ground in a warm situation finally to remain.

The species is,

1. *STYRAX officinale*.

Common or officinal Storax.] Rises with a woody stem, branching on every side, twelve or fifteen feet high or more, covered with a smooth greyish bark; oval, moderate-sized, alternate leaves, hoary underneath; and bunches of white odoriferous flowers at the sides of the branches in June; succeeded sometimes by fruit, but rarely ripens in England.

This tree is a native of Syria, and most parts of the East; where it is highly valued for its fragrant medical gum; which it exudes from the trunk and branches.

It is, although an exotic of hot countries, moderately hardy, as in this country it only requires shelter of a frame or green-house from severe frost while young, for three or four winters; afterwards may be planted in the full ground against a south wall, and other sheltered situations; training some against the wall, others take their natural growth, and allow occasional shelter of mats in very severe weather.

The two following species are also retained in some green-house collections.

2. *STYRAX laevigatum*. — Smooth-leaved Storax.

3. *STYRAX grandifolium*. — Large-leaved Storax.

The common Storax is propagated commonly by seeds, obtained from abroad by the seedmen; sowing them in pots of light earth an inch deep, observing as they are of a hard stony nature, they rarely come up the first year; so it is proper to plunge the pots under a frame during cold weather, and in the shade in summer, and in the second spring; then as the seed will be ready to germinate, if plunged in a hot-bed, it will forward them exceedingly, being careful to give water, and to harden the seedlings gradually to the full air in summer, in a shady place during the hot weather, and often watered; and in winter place the pots under a garden-frame, &c. to have shelter from frost; then in spring following pot them off separately, and manage them as hardy green-house plants for three or four years, when some of them may be turned out into the full ground in a sheltered situation as already hinted, and some may be retained in pots for the green-house collection.

The other two sorts are propagated as above, but must be continued always in pots to have the culture as green-house plants.

SUCCULENTÆ, (*Succus*, Juice) Succulent plants.

Succulent Plants are such as have thick

fleshy leaves, &c. abounding with juice, being principally of the herbaceous tribe; and some become of a ligneous nature in the stem, though Succulent in leaf: and of the Succulent kind there are perennials, biennials, and annuals; but principally perennial and evergreen.

Of the Succulent tribe many are tender exotics, inhabitants of the hot parts of the world; and some are of hardy growth; are mostly inhabitants of dry barren soils, and rocky places; many of which being of singular growth, are retained in our garden collections as plants of variety and curiosity; consisting of many different genera, each comprising more or less varieties, some for the green-house and stove, and some for the open ground. The following is a list of the principal genera, and their varieties, collected into one point of view, referring to their respective articles for particulars.

AGAVE, Great Amenum Aloe. (*All the species*).

ALETRIS, Guinea Aloe. (*All the species*).

ALOE, African Aloe. (*All the species*).

ANTHERICUM, Spider-wort. — Aloe-leaved. — Mock Asphodel. — *Anthericum*, Shrubby, Onion-leaved.

CACALIA, Foreign Colt's-foot. — *Ficoides* African *Cacalia*. — *Anteuphorbium* *Æthiopian Cacalia*. — *Kleinia* or Indian *Cacalia*. — *Papillary* *Æthiopian Cacalia*. — (*All of somewhat shrubby growth*).

CACTUS, Melon-thistle, including also the *Cereus* or Torch-thistle, and the *Opuntia*, or Indian Fig. (*All the species*).

COTYLEDON, Navel-wort. (*All the species*).

CRASSULA, Lesser Orpine. (*Most of the species*).

EUPHORBIA, Burning thorny plant. — (*Most of the sorts*).

MESEMBRYANTHEMUM, Fig Marigold. (*All the numerous sorts*).

PORTULACA, Purslane. (*All the sorts*).

SAXIFRAGA, Saxifrage. — *Cotyledon* Saxifrage, &c.

SEDUM, Lesser House-Leek, Orpine, and Stone-crop. (*Most of the sorts*).

SEMPERVIVUM, Live-ever, or Common House-leek. (*All the sorts*).

TETRAGONIA. (*Both the species*).

YUCCA, Adam's Needle. (*All the sorts*).

ZYGOPHYLLUM, Bean-caper. (*Most of the sorts*).

As many of these Succulents are esteemed singular curiosities in the vegetable creation, they are cultivated as such in most of our eminent gardens; a general description of the different

different sorts, their propagation and culture, may be seen in the proper places, under the heads of their respective genera.

They are mostly of a very carnosé or fleshy nature, both in stem, leaves, &c. abounding with humidity, and mostly evergreen; and many of them assume great singularity in their general port or habit; and as to magnitude, some, when they flower, obtain thirty or forty feet stature, as the *agave Americana*; others, such as the stone-crop, &c. not above three or four inches. See each under its proper genus.

Most of the sorts being originally inhabitants of dry soils, or saxatile or rocky situations, walls, tops of old buildings, and ruins, &c. and being naturally all very replete with moisture, should therefore in their culture be mostly planted in light dry, lean earth, or dry rubbishy compost (see COMPOSTS); otherwise, on account of their great humidity, are very apt to rot off in winter, more particularly the very Succulent and tender kinds of the green-house and stove (see GREEN-HOUSE and STOVE PLANTS); and which sorts in particular are always to be kept in pots, in order to be placed among the plants of those two conservatory departments, as their nature or temperament require, and managed accordingly, as hinted under the *Culture of Green-house and Stove-Plants* afore-said: always kept from too copious moisture; for as they naturally abound in juice, they require very little water at any season; but in winter especially should have it but very seldom and sparing; and some of the most Succulent hardly any water during all that season.

And as to the hardy kinds, such as the common house-leek, orpine, stone-crop, &c. (see their proper genera) will grow in the open air, on rock-work, dry rubbishy borders, tops of walls and low buildings; and are proper plants to introduce in artificial ruins and rocks, &c. — May also be planted in pots to move to any place occasionally. With respect, however, to the general description, uses, propagation, and culture of this tribe of plants, we refer to their respective genera, where the whole is fully exhibited; but as only the principal curious sorts are here arranged under one head, serves as an intimation of the nature of these kind of plants, and to assist the memory in recurring to the principal genera containing the different sorts.

SUCCUS, Sap, or the Juices of Plants.

The main vegetable juices or fluids are drawn by the root from the body it adheres to, whether it be earth, water, or other substance; thence ascends to the stem, branches, leaves,

flowers, and the minutest part of the fructification, &c. But whether the same Sap, so diffused to the extremities of the plant, ever returns, and that there is a circulation of Sap in plants analogous to that of the blood in animals, is a question, which will probably never receive a satisfactory answer.

Though many of the eminent naturalists contend for the circulation, and that the same juice descends again to the root, yet by accurate experiments it appears, that the Sap ascends not by the bark, but by the capillaries or fibres of the wood; and the curious observation of many renders it highly probable that the fluid which ascends by the said capillary vessels of the wood, descends to the root by the larger fibres of the inner bark that are most contiguous to the woody body. In support of this, the same experiments of ligature and incision, which evince a circulation of the blood in animals, succeed in the like manner in vegetables, particularly in such as abound with a milky Sap; since if the ligature or bandage is fastened tight round them, the part above is found to swell very considerably, and that below it only a little, whence it appears there is a juice descending from the branches: and as to the experiment of incision, it has likewise been observed, that upon a transverse incision being made into the bark and trunk of a tree, the juice which is expended or flows from the wound, proceeds in greater quantities from the upper lip of the gash, where the swelling likewise is much larger than below; so that from the result of such experiments it is rendered somewhat more than probable, that the sap returns from the extremity of the branches to the root; thence into the earth again. But some contend, that instead of the same juices going and returning, there are two several juices; the one terrestrial, as being imbibed from the soil, digested in the root, and from thence transmitted to the extremity of the plant; the other is supposed to be aerial, and received from the moisture of the air entering in at the extremity of the branches, and surfaces of the leaves. So according to this conclusion, the ascending and descending juices are not the same; and indeed with respect to the aerial sap, experiments have determined that the plant derives part of its nourishment by the extreme branches, and the leaves in general, and that the leaves contribute greatly both to the abundance and motion of the sap; for it is observable of new-planted trees in particular, having many of their branches lopped, they will not prosper near so well as those trees left entire; and if a tree when

high in sap is divested of its leaves, it will be found to retard the growth, both of its shooting, and that of the flowers and fruit.

However, the first and principal sap of a plant is furnished by the earth entering the roots in form of a fine and subtle water, which, the nearer it is to the root, the more it retains of its proper nature; and the farther from the root the more action it has sustained, and the nearer it approaches to the nature of the vegetable.

But what course the sap takes after it is imbibed by the roots, is not very clear; the vessels that take it up to convey it to the plant, are too fine to be traced, and hence it remains doubtful, whether it is by the bark, or the woody part, or the pith that the plant is fed.

In this the naturalists differ in opinion. Some contend for the bark, others for the wood; though in the former case they observe, that the juice raised from the earth by the capillary tubes or pores of the wood, is here supposed to descend by the larger fibres placed in the inmost part of the bark immediately over the wood; in which descent the sap being now sufficiently prepared adds some of its substance to the contiguous wood, and thereby gradually increases its bulk, so that the bark is thus also supposed to serve divers purposes; for it not only transmits the nutritious juices to the plant, but likewise contains certain fat oily juices to defend the fleshy external parts from the injuries of the weather.

In some cases, even the whole plant is no more than bark; the pulp or woody part having been eaten or rotted out, except just the outside shell, as often occur in willow, elm, &c. yet continue growing, and live a long time in that state.

On the other hand, those who contend that the wood conveys the principal nourishment, observe, that the whole woody body consists entirely of slender longitudinal capillary tubes or fibres, running parallel to each other from the root up the trunk and branches, being proper to receive in a fine vapour or humour, in the ascent of which the fibres become open, and their substance increased. And thus the trunks of trees are said to increase in their circumference.

The motion of the nutritious juices of vegetables is found to be produced much like that of the blood in animals, by the action of the air, &c. for it is discovered that vegetables consist of two orders of vessels; 1. such as receive and convey the alimental juices, answering to the arteries, lacteals, veins, &c. of

animals; 2. the *trachea*, or air-vessels, being long fine pipes or tubes possessing principally the wood or ligneous body, and serve to receive and transmit the air, necessary for preparing and giving motion to the humours or juices.

As to the nature of the vegetable fluids, it appears, that plants contain many different juices, such as those of the root, stem, bark, &c. those of the leaves, the juices of the flowers, or genitals, and those of the fruit, the preparative of the last of which may be said to be nature's final work.

However, the principal vegetable juices are generally reduced to two; the lymph or sap; and the proper juice or blood of plants.

1. The lymph or sap is a simple fluid, being without colour or smell, and little different from water; and mounts from the root to the stem, and remote parts of the plant, as before observed, in its proper vessels, which are woody longitudinal hollow fibres, almost inconceivably fine, and always replete with sap; which, however, in spring, is found in greatest abundance, and then the bark is easily detached from the wood. On the contrary, when the sap-season is past, the bark is found closely applied, and, as it were, glued to the wood; or when a tree is in high sap, and stripped of the leaves, the bark, in a few days, will adhere as closely to the wood as in winter.

2. The other principal fluid, denominated the proper juice or blood of plants, and analogous to the blood in animals, contained in proper vessels, called likewise from their use vegetable blood, are straight longitudinal fibres, larger than the lymphatic or sap-vessels, and less numerous, which are filled with the proper juice, which is generally compound or coloured, and easily distinguished by its colour, smell, and substance, from the lymph or sap, it being either green, as in some plants, white as in spurge, fig-tree, and dog's-bane, yellow, as in celandine, red as in dragon's blood, mucilaginous or gummy, as in the jujube and mallow tribe, or resinous, as in the coniferous plants. So it is from the variety in colour and substance that the fluid in question is called the proper juice; each species of plant being supposed to contain a fluid peculiar to itself; and in this proper juice reside the smell, taste, and virtue of the plants.

SUCKERS.

Suckers are young offspring plants, arising immediately from the roots of older vegetables, and generally furnished also with roots; and being transplanted, readily grow and be-

come

come proper plants, in all respects like the mother plant that produced them, being therefore, in numerous sorts of plants and trees, very eligible for the work of propagation.

So that Suckers may be considered as a sort of vegetable spawn or progeny, emitted from the roots of certain trees, shrubs, and other plants, to propagate their respective species and varieties; and, a very considerable share of the vegetable creation multiply exceedingly by this means; for numerous sorts continue sending up great plenty of Suckers every summer, each Sucker furnished with roots or fibres, and in one season form proper plants for transplantation; thus proving a very plenteous and expeditious method of propagation, both for numerous tree and shrub kinds in particular, as well as for many herbaceous vegetables; which sending up Suckers from the root in spring and summer, will be fit for transplanting the following autumn.

In trees and shrubs, the propagation by Suckers is also, in certain cases, a sure method to continue any approved or desirable species, or variety; the same; remarking, however, of grafted and budded trees, that Suckers thereof partake only of the nature of the stock; as for example, such Suckers as arise from a codlin stock, grafted with any other sort of apple, will continue invariably a codlin, without partaking any thing of the nature of the graft; the same being also observable of all other grafted trees and shrub kinds; observing, therefore, not to mistake so far in propagating by Suckers from the roots of grafted and budded trees, worked on different stocks, to suppose the Suckers will produce the same sort of fruit, &c.

But in trees, &c. that are wholly the same sort root and top, the Suckers thereof will also prove the same invariably in every mode of growth, as certainly as is obtained by layers, cuttings, grafting, &c.

As to the season for taking up or transplanting Suckers, of trees and shrubs, it may be performed almost any time in open weather, from October till March, being careful to dig them up from the mother-plant, with as much root fibres as possible, and trim them ready for planting, by shortening long straggling fibres, and cutting off any thick-knobbed part of the old root that may adhere to the bottom, leaving only the fibres arising from the young wood; though, it is probable some will appear with hardly any fibres; but as the bottom part having been under ground, and contiguous to the root of the main plant, they will naturally be much dis-

posed to send forth plenty of fibres for rooting; observing likewise, preparatory to planting them, to trim the stems of the shrub and tree Suckers occasionally, such as cutting off all lower laterals; and if any have long, slender, and weak tops, or such that you intend shall assume a more dwarfish or bushy growth, may be shortened at top in proportion, to from about half a foot, to one or two feet in length, according to their nature or strength, and as the case may require: others that are more robust and strong, or that you design shall run up with taller stems, may have their tops left entire, or shortened but little, as it shall seem necessary for the uses intended.

Being thus taken up and trimmed, proceed to plant them in rows in the nursery; the weak Suckers plant separately in close rows; also the shortened ones by themselves, and the stronger plants likewise separately in wider rows; so that the rows may be from one to two feet asunder, in proportion to the size and strength of the Suckers.

After being thus planted out in nursery rows, allow them the common nursery culture of cleaning from weeds in summer, and digging the ground between the rows in winter, &c. and in from one to two or three years, they will be arrived to due size for final transplantation.

Though some kinds of trees, &c. produce Suckers so strong in one season as to be fit for planting at once, where they are finally to remain; such for example, as some sorts of roses, and numerous other flowering shrubs; likewise some of the strong shooting gooseberries, currants, raspberries, and the like kinds.

And sometimes many of the shrub kind in particular, having produced a quantity of Suckers from the root, and these suffered to stand and grow up, each to a large plant, the whole from one root forming a considerable bush, as may often be observed in gooseberries, currants, and many other shrubs; and in which case each such bush being taken wholly up at the proper season before mentioned, may be divided to the bottom into so many separate plants; and as each Sucker will be amply furnished with plenty of roots, and of due size for flowering and fruiting, may plant them, if required, at once, where they are always to stand.

But the propagation by Suckers is by some objected to in some particular sorts of trees and shrubs, such as currants and gooseberries, &c. for any general supply, on a supposition that the trees so raised, are more adapted to

run

run too considerably to Suckers, and over-run the ground round the mother plant, than such as are raised by any other method: however, it may generally be observed of such trees and shrubs as are naturally disposed to send up many Suckers, that by whatsoever method they are propagated, whether by seeds, suckers, layers, cuttings, &c. they commonly still continue their natural tendency to multiply by Suckers in the same abundance.

However, when it is required to have any sorts produce as few Suckers as possible, not to over-run the ground, or disfigure the plants, it is proper both at the time of separating the Suckers, or planting them off from the main plant, and at the time of their final removal from the nursery, to observe if at the bottom part they show any tendency to emit Suckers, by the appearance of prominent buds, should rub all such off as close as possible, which will prevent the production of Suckers proportionably.

As, however, many sorts of trees and shrubs are subject to throw out Suckers, considerably more than may be wanted at all times for multiplying the respective species or varieties; and that if permitted to remain, would over-run the ground, and become unsightly, as well as prejudice the parent plants; they should therefore be always cleared away annually at least: but in such as are not wanted for propagation, it is proper to eradicate them constantly as they are produced in spring and summer.

Likewise numerous herbaceous and succulent plants are productive of bottom off-set Suckers from the roots by which they are propagated, either generally or occasionally, according to the different sorts, both of the fibrous, bulbous, and tuberous-rooted tribe: as all off-sets from the root, and above-ground bottom side heads, of these kind of plants may be deemed a sort of Suckers, and of which great numbers both of the hardy and tender herbaceous and succulent tribe of plants, are very productive, and by which many sorts are most commonly propagated; and for which occasion they are generally proper to detach for planting when of one summer's growth, or two at most, which, in the fibrous-rooted kind, may be performed in autumn or spring; and in the bulbous, and many of the tuberous-rooted sorts, generally in summer and autumn, when the stalks and leaves decay.

In slipping and planting the above off-set Suckers of the herbaceous and succulent kinds, they may be planted, the smaller ones in nursery beds, pots, &c. according to the nature of growth, and temperature of the different

sorts, to have the advantage of one summer's advanced growth, proper for final transplantation; and the larger ones planted at once, where they are finally to remain, in beds, borders, pots, &c. agreeably as the different sorts are adapted.

SUFFRUTICOSUS.

Suffruticous, or Under-shrubby.

Suffruticose Plants are a sort of ligneous or somewhat woody vegetables, that are between a shrubby and an herbaceous nature, exemplified in thyme, sage, hyssop, winter-savory, and such like plants.

SUN.

The Sun is doubtless the first mover of all vegetable motion; for as the naturalists observe, the Sun qualifies the air, which otherwise by its great frigidity would stop the whole course of nature: but by the Sun's diffusive power of light and heat, it exhilarates not only the race of mankind, &c. but the vegetable creation.

Its genial chearful rays promotes the growth of all vegetables, by its influence upon the soils; warming and clearing the pores of the earth, when diluted and sodden with too much wet, and puts the fibres of plants in motion for seeking their food; and its influential power operates on the branches, leaves, and fruit.

Plants, therefore, which in their growth are more or less exposed to the Sun, are, for the most part, more prosperous, forwarder, and attain greater perfection than such as grow in any considerable shade.

Likewise most fruits in a sunny exposure are considerably more beautiful, sooner ripe, and acquire superior quality in flavour, &c. to those growing in shady places.

The Sun's attractive power is very conspicuous in the exhalation or dispelling of those crude and unwholesome vapours with which the earth is so often infested, which would otherwise make it noxious, and render the earth a miserable desert: but more particularly the Sun warms, and enriches the soil, and prepares the juices for being sucked in by the fibres of plants.

For this reason, ground designed to be sallow, should always be turned up in rough ridges, to give free access to the influence of the Sun and air. Likewise all compost heaps should generally be prepared in sunny situations, in the full air, not in shady corners, or in sheds, as often practised.

SWIETENIA. Mahogany Tree.

This genus furnishes for the Stove one principal species, a tree of singular excellence for its wood, employed for innumerable domestic

metic uses in household furniture, &c. is a native of South America and the West Indies, where the tree attains a vast magnitude; but being a tender exotic in this country, only a plant or two is retained in some curious stove collections for variety, in which it is but of moderate growth, adorned with pinnated leaves, and pentapetalous flowers.

Class and order, *Decandria Monogynia*.

Characters.] CALYX, a small monophyllous, quinquefid cup. COROLLA, five ovate, obtuse, concave, spreading petals, with a cylindric nectarium of one leaf, cut at the mouth into ten parts. STAMINA, ten very small filaments, inserted in the nectarium with oblong erect antheræ. PISTILLUM, an ovate germen, erect awl shaped style, crowned with a plane capitated stigma. PERICARPIUM, a large, ovate, woody capsule of five cells, containing many oblong compressed imbricated seeds, with foliaceous wings.

We know but of one species, viz.

SWIETENIA Mahagoni.

Mahogany Tree.] Rises with a woody trunk many feet high, with branches garnished with winged leaves, composed of six or eight pair of folioles on short foot-stalks; the flowers come out from the sides of the branches, and are succeeded by woody capsules opening in five cells at their base, containing imbricated winged seeds.

The propagation of this tree is by seeds procured from abroad, which should be sown in small pots of light earth and plunged in a hot-bed, and when the plants are come up about two or three inches high, they should be carefully taken up and transplanted into other pots and plunged in the bark-bed, shading them until they are fresh rooted, and afterwards managed as other stove plants of the like nature.

As this valuable tree cannot be cultivated in this country for economical purposes, only a plant or two, as above, in our stoves for curiosity: great quantities of this wood in vastly large blocks are imported from the West Indies, &c.

SYMPHYTUM, Comfrey.

This genus of plants consists of hardy herbaceous perennials, for variety in gardens and medicinal purposes, having long fleshy roots sending up annual stalks from half a yard to two or three feet high, adorned with oval and spear-shaped leaves, and terminated by monopetalous bell-shaped flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is upright, pentagonal, five-parted at the brim, and permanent. COROLLA is one bell-shaped petal, with a

very short tube, a tubular ventricose limb; divided at the brim into five obtuse reflexed segments, having the chaps or opening armed with five subulate rays connected in a cone. STAMINA, five awl-shaped filaments, placed alternately with the rays of the chaps of the corolla, and erect, acute antheræ. PISTILLUM, four germina, supporting a filiform style, crowned with a simple stigma. PERICARPIUM, none; four gibbous, acute pointed seeds lodged in the permanent calyx.

There are three principal species, one is an inhabitant of England, the other two are of foreign growth, and are all hardy plants.

The species are,

1. *SYMPHYTUM officinale.*

Common officinal Comfrey.] Hath long, thick, fleshy, deeply-striking roots, black without and white within; crowned with large, oval, spear-shaped, rough leaves; upright, thick, branchy, rough stalks, two or three feet high, garnished with decurrent leaves, and terminated at top by bunches of drooping flowers, of different colours in the varieties, appearing in June and July.

Varieties are,] Common white flowered—purple-flowered—blue-flowered—yellow-flowered—red-flowered: but the white and purple are the most common.

It grows wild in England, especially the white-flowered sort, by ditch sides, and other humid shady situations; but is sometimes kept in gardens for variety and medical uses, the root being the useful part.

2. *SYMPHYTUM tuberosum.*

Tuberosely-rooted German Comfrey.] Hath a root composed of many thick fleshy tubers, sending up inclined rough hairy stalks a foot and a half high; long, narrow, acute-pointed, rough, hairy leaves, alternate below, and opposite at top; and the stalks terminated by bunches of pale-yellow flowers, in June and July.—Grows naturally in Germany, France, and Spain.

3. *SYMPHYTUM orientale.*

Oriental Comfrey.] Hath a thick fleshy root; upright rough stalks, half a yard or two feet high; oval rough leaves, on short hairy foot-stalks, and the stems terminated by drooping bunches of blue flowers, in March and April. It grows by river sides in the East, near Constantinople.

All these three species are of the herbaceous tribe, and perennial in root, but annual in leaf and stalk, which rise in spring, and produce flowers and seed the same year; the first and second sort in particular ripen plenty of seed; the other not always in perfection in England:

England: and soon after the seed is ripe, the stalks decay.

As to their merit as garden plants, they may be employed in large herbaceous collections, to increase the variety in the pleasure-ground; and the first sort in particular. *SYMPHYTUM officinale* may also be introduced in gardens as an officinal plant in medicine: all the three sorts are very hardy, and will prosper in any common soil and exposure; but delight most in shady moist places; planting those designed for variety thinly, in assemblage with other hardy perennials, and those intended for medical uses plant in beds or borders together, in rows, two feet asunder.

Method of Propagation, &c.

Their propagation is effected by seed, and by parting the roots.

By Seed.—Sow it in spring in a bed or border of common earth, and rake it in: they will soon come up plentifully, and in autumn the plants will be fit to transplant where wanted, in the manner above observed.

By parting the Roots.—This may be effected with expedition, and abundance in autumn, or early spring. Almost every bit of the root will grow, planting them either in nursery beds, or at once where they are to remain; and they will soon multiply into large plants.

SYRINGA, Lilac.

Two noted deciduous flowering shrubs are comprised in this genus, each comprehending several elegant varieties; growing twelve or fifteen feet high, in the first species, the other but five or six feet, of more slender, shrubby growth; adorned with oval heart-shaped and spear-shaped simple leaves, and large bunches of small, monopetalous, funnel-shaped, odoriferous flowers, of a very ornamental appearance.

Class and order, *Diandria Monogynia*.

Characters.] *CALYX* is small, monophyllous, tubulated, four-parted at the brim, and permanent. *COROLLA* is monopetalous, funnel-shaped, with a long cylindrical tube, divided above into four narrow revolute segments. *STAMINA*, two very short filaments, with small antheræ. *PISTILLUM*, an oblong germen, slender, thread-like style, and a thick bifid stigma. *PERICARPIMUM*, an oblong, compressed, acuminate, bivalvous, bilocular capsule, having a single seed in each loculi, being oblong, acuminate, and with a membranaceous border.

There are only two species, which, and their varieties, are fine ornamental furniture for the shrubbery compartments. Are supposed to be natives of Persia, but have been

long in the English gardens as eminent flowering shrubs.

The species are,

I. *SYRINGA vulgaris*.

Common Lilac.] Rises with an upright shrubby stem, soon dividing into many branches, and grows fifteen or twenty feet high; garnished with oval-cordated, or heart-shaped leaves, placed opposite; and the flowers produced at the ends of the young shoots, in large, erect, conical bunches, of different colours in the varieties, appearing in May.

Varieties are,] White-flowered—blue-flowered—purple-flowered, or Scotch Lilac,—bloached-leaved.

This species and varieties have been long residents of our gardens, as elegant flowering shrubs, to decorate the wilderness and shrubbery clumps; are all so very hardy as to grow almost any where without trouble, exhibiting a very ornamental appearance, in the great profusion of their flowers, which also imparts a very agreeable odour.

SYRINGA persica.

Persian Lilac.] Rises with a slender shrubby stem, dividing into long, slender, flexible, brownish branches, growing five or six feet high, adorned with narrow, spear-shaped, entire leaves, placed opposite; and the young shoots, terminated by long paniculated bunches of blueish, and other coloured flowers in the varieties; appearing the end of May, and beginning of June.

Varieties are,] Common purple-flowered,—white-flowered—blue-flowered—lacinated, or cut-leaved Persian Lilac, having the leaves deeply cut into several segments. All of which varieties of this species, are most delightful flowering-shrubs, and their flowers have an agreeable fragrance.

Both these species of Lilac, and their varieties, are very hardy shrubs, of the deciduous tribe; and although originally inhabitants of Persia, grow freely in the open ground in any exposure, and resist the severest frosts; having been many years in the English gardens as ornamental flowering shrubs; all the sorts flowering profusely and ornamentally early in summer, each panicle of flowers being large and conspicuous, composed of numerous florets, or separate flowers, continuing near three weeks in beauty, and are succeeded in the first species, and its varieties, by plenty of seed; but the second sort rarely ripen any in England.

As therefore these fine shrubs are hardy, and easy of culture, they highly merit admittance into every pleasure-ground, large or small,

small, being excellently adapted both to embellish the premises, and increase the variety; and for which occasion they will succeed in any common soil and situation, in shrubberies, borders, &c. proper to assemble with other hardy flowering-shrubs; and the common Lilac also to plant separately in any particular compartment to run up in full growth, both for flowering conspicuously ornamental, and occasionally to afford shade in summer, near arbours, &c. and both of which may be obtained at the nurseries, in proper growth for flowering, the first year of their transplantation.

They may be transplanted almost any time in open weather from October to March, in any common soil and situation, and from a few plants of each sort they will soon abundantly increase, the stock by suckers, &c. and as to culture, observe of the *Syringa vulgaris*, or common Lilac in particular, that as it generally throws out numerous suckers annually, they should be taken off accordingly, otherwise they will soon over-run the ground near them, and run up in a confused thicket round the mother plant.

Method of Propagation.

The propagation of both the species, and their varieties, is most easily effected by suckers and layers; also by seed. But the first sort, in particular, throws out numerous suckers, and produces also plenty of ripe seed for sowing.

By Suckers.—Numerous suckers rise annually from the roots, though generally more abundantly from the first than second species; and by which all the sorts may be most readily propagated; taking them up any time from autumn till spring in open weather, with roots to each, and plant them in nursery-rows two feet asunder, to remain for a year or two, or till wanted for final transplantation.—See SUCKERS.

By Layers.—Layers of all the sorts will readily grow, and form proper rooted plants in one year; choosing the young pliable shoots in autumn, and lay them in the common way; they will be well rooted by autumn following, and ready for planting off in nursery-rows; as directed for the suckers.

By Seed.—The first species, and varieties, ripen plenty of seed annually in autumn; and by which all the varieties may be raised, all of which are generally tolerably permanent, in retaining their difference from seed; which should be sown in October or November, or in the spring, in a bed of common earth, either broad-cast or in drills, and covered half an inch deep: they will come up in the spring; and in spring after the seedling plants may be set out in nursery-rows two feet asunder, and one distant in the row, to have two or three years growth, when they will be fit for the shrubbery.

T.

T A B

TABERNÆMONTANA, a genus of plants, furnishing two woody exotics, for the stove, and two hardy perennials for the pleasure-ground.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX, a small pointed, connivent, five-parted cup. COROLLA, monopetalous and funnel-shaped, the tube long and cylindric, the border plain, and divided into five oblique blunt segments, with five bifid glandular nectarium. STAMINA, five very small filaments, topped with connivent anthers. PISTILLUM, two germens; style awl-shaped,

crowned with an oblong headed stigma. PERICARPIUM, two pointed, belled follicles reflexed horizontally, with two cells, containing a number of rugose, obtuse, oval-oblong seeds, immersed in a pulp.

There are eleven species belonging to this genus: those for our purpose are,

I. TABERNÆMONTANA *citrifolia*.

Citron-leaved Tabernæmo.] Rises with an upright woody stem, sending out several erect branches, garnished with thick, oval, opposite leaves; the flowers, which are sweet scented, and of a bright yellow, come out from the

wings of the stalks in glomerated umbels, and are succeeded by two swelling fruits filled with seeds, lying imbricated.

2. *TABERNÆMONTANA laurifolia.*

Laurel-leaved Tabernæmo.] Rises with a woody stem, sending out many branches toward the top, garnished with blunt, oval, opposite leaves, about five inches long, and two and a half broad, standing on short foot-stalks; the flowers terminate the branches in roundish bunches; they are white and of an agreeable odour.

Both these plants are tender, and require the assistance of a stove, and may be propagated by seeds or cuttings. By seeds sown early on a hot-bed, and, when come up, transplanted into pots of light earth, and plunged in the bark-bed, shading and refreshing them with water.

The Herbaceous Sorts are,

3. *TABERNÆMONTANA Amsonia.*

Alternate-leaved Tabernæmo.] With oval-lanceolate leaves, and a very smooth herbaceous stalk.

4. *TABERNÆMONTANA angustifolia.*

Narrow-leaved Tabernæmo.] With linear scattered leaves, and an herbaceous pilose stalk.

The two last species are hardy and perennial, the flowers are white and terminate the stalks, and are propagated by off-sets from the roots in spring or autumn.

TAGETES, African and French Marigold.

This genus is composed of noted herbaceous tender annuals, of the flowery tribe, for adorning the pleasure-ground, in summer; they rising with large branchy stems, and full heads, two or three feet high, ornamented with pinnated leaves, and all the stems and branches crowned with large, compound, radiated flowers.

Class and order, *Syngenesia Polygamia Superflua.*

Characters.] **CALYX** is simple, monophyllous, pentagonous, and quinque-dentate. **COROLLA** is compound and radiated, consisting of numerous tubular, quinquefid, hermaphrodite florets in the disk, and ligulated female florets in the radius, or circumference. **STAMINA**, in the hermaphrodite florets, five very short filaments, with cylindric antheræ. **PISTILLUM**, an oblong germen, filiform style, having a bifid reflexed stigma. **PERICARPIUM**, none; each floret succeeded by a single linear compressed seed, crowned by five acuminate, erect, unequal aristæ.

There are but three species of *Tagetes*, two

of which only are common to England, each comprehending many varieties; all of them tender annuals, and generally require the aid of hot-beds, or shelter of glasses, &c. to raise and forward them at first, planting them out afterwards in the open ground to grow to perfection; which they attain in July and August, producing a great profusion of flowers, both singles and doubles; but the latter are considerably the most ornamental, they growing large, and full to the very centre, appearing both conspicuous and ornamental, for two or three months in autumn, having different properties in the respective varieties, in respect to plenitude, colour, and variegations; but have mostly a very disagreeable odour.

The species are,

1. *TAGETES erecta.*

Upright Mexican Tagetes, commonly called African Marigold.] Rises with an erect, firm, single stem, branching erectly all around near a yard high; having large pinnated, light-green leaves, of many pair of narrow lobes; and all the branches terminated by large, erect, compound, yellow flowers, one on each peduncle, exhibiting different properties in the varieties.

Varieties are,] Lemon-coloured, or pale yellow-flowered African—Deep yellow-flowered — Orange-coloured — Sweet-scented—Dwarf, &c. — All of which varieties furnish both single and double flowers; the doubles being large, full, and swelling, rendered so by different modes of impletion, such as—Radiated doubles, rendered double by the impletion or multiplication of the plane florets of the radius.—Discous doubles, rendered full by the elongation and less profound division of the hollow florets in the disk—Fistulous, or quilled doubles, having all the florets appearing fistulous or hollow like a quill—Plane doubles, having all the florets plane or flat—Waved doubles, having all the florets waved—Common single flowered, having plane florets in the radius, and numerous small tubular florets in the disk.

All these varieties being species of the *Tagetes erecta*, they rise with erect, firm stalks and branches, as in the specific description; producing numerous flowers in regular succession, from June or July until October, succeeded by abundance of seed in autumn.

2. *TAGETES patula.*

Spreading Mexican Tagetes, commonly called French Marigold.] Rises with subdivided spreading stalks and branches, two feet high; large pinnated deep-green leaves; and at the sides and ends of the branches numerous, moderately

derately large, compound, radiated flowers, yellow, crimson, and variegated, in the different varieties.

Varieties are,] Pale yellow-flowered—Deep yellow-flowered—Golden yellow-flowered—Crimson-coloured, velvety—Variegated crimson and yellow, consisting of many beautiful variegations in different varieties—Striped, crimson, and yellow—And of each of which colours there are Single-flowered—Double-flowered—Large-flowered—Small-flowered—Sweet-scented, and dwarf French Marigold—All of which rise with subdivided stalks, of very branchy spreading growth, producing a great profusion of flowers from the sides and ends of the branches, in succession, from June or July, until November; but the double, the variegated, and the striped sorts, are the most beautiful; likewise some of the variegated and striped singles are remarkably elegant in their variegations, and richness of colours; all the sorts producing great plenty of ripe seed in autumn.

Both these species of *Tagetes*, and all their numerous varieties, are herbaceous annuals, rising from seed in spring, obtain full growth in July, flower and produce seed in autumn, and wholly perish, root and top, in October or November.

They being natives originally of foreign warm countries, are consequently of somewhat tender quality here; but have been long residents of the European gardens, as ornamental flowery plants; raising them annually from seed in spring, generally in a hot-bed; thence planted into the full ground, &c. in May or June, where they flourish in great perfection, till killed by the frost.

The flowers of both the species and respective varieties are large, and very conspicuous; but those of the first species, *Tagetes erecta*, are much the largest; and in all the sorts they are universally compound and radiated, each flower being composed of numerous smaller ones, all within one general calyx or cup; which in their common single state, the middle or disk consists of many small tubular hermaphrodite florets, and of many plain or flat-tongue-shaped female florets, forming the circumference or radius: but in their multiplied state, they are rendered double by different impletions; sometimes by the tubular florets of the disk being enlarged, lengthened, and less divided at the brim; and sometimes the impletion is effected by an increase of the flat florets, in the ray or radius, multiplying inward, and fill the disk, to the total exclusion of the tubular florets; and in some varieties the impletion consists wholly of plain florets; in

others, they become wholly fistular or quilled, as often obtain in some varieties of the first species *Tagetes erecta*.

The different varieties of each of these two species, although apt to vary in their colours, doubleness, and other peculiarities, will, with particular care in saving the seed of each respective sort, from the very finest full flowers and best colours, remain tolerably permanent, and mostly produce the like kind of flowers in return.

All the sorts, considered as ornamental plants, are eligible furniture for decorating the borders, and other conspicuous compartments of the pleasure-ground; also to plant in pots for moving occasionally, to adorn any particular compartment, in assemblage with other potted annuals: they will all grow freely in any common soil of a garden, and in an open exposure; and exhibit a very conspicuous autumnal bloom, in long succession; and being properly disposed in assemblage, will affect a very ornamental variety in the diversity of the various forms and colourings of the flowers, in the different varieties.

They therefore being all of the annual tribe, as we already observed, that being raised from seed sown annually in the spring, about March or April, in a hot-bed, or warm border, &c. as hereafter directed, they will arrive to a proper size for planting out towards the middle or latter end of May, or beginning of June, when the weather will have become settled or temperate enough to admit of their being planted any where in the full ground, finally to remain to produce flowers and seed.

They are all of very free growth, especially after being planted out finally in the full ground, where they require but very little culture.

The first species in particular, and varieties, as they always grow firmly erect, both in stem and branches, require but very little trouble after their final transplantation.

But the second sort, *Tagetes patula*, divides and spreads out widely near the ground in a rambling manner; it requires to be trimmed up at bottom to a single stem, and its branches also trimmed occasionally, to preserve the head somewhat regular, and within due bounds.

Method of Propagation.

As to the method of propagation, they are raised only from seed sown every spring in March or April, either in a hot-bed, to raise the plants to more early perfection, or in a warm border, about the middle or latter end of April, for a later bloom.

By a Hot-bed.—Towards the middle or lat-

ter end of March, or beginning of April, you may sow some seed of each sort in any moderate hot-bed either alone, or with other annuals of similar temperament, such as China aster, common balsamine, marvel of Peru, chrysanthemum, &c. See ANNUAL PLANTS. Having therefore a hot-bed ready, and sheltered with a frame and lights, or with hand-glasses, &c. or in default of either, arched over with hoops, to be covered with mats on nights, which will succeed tolerably, if not sown before the beginning of April, observing, in either method, the hot-bed being properly earthed at top, five or six inches deep; then sow the seed of each species and respective variety separate, either in shallow drills a quarter of an inch deep, or on the surface, and covered with light mould that depth; or may be sown in pots, and plunged in the hot-bed.

They will soon come up, giving occasional waterings, and admit a large portion of free air to strengthen the plants as they advance; which when about three or four inches high, prick a quantity of the best upon another moderate hot-bed four or five inches asunder, to have about three weeks growth or more to forward them as much as possible; assisting them with proper waterings, giving likewise occasional shade from the sun till rooted, and plenty of free air daily; another parcel of the same seedlings may, about the beginning or towards the middle of May, when the weather is settled tolerably warm, be planted out into the full ground, taking opportunity of showery weather; and plant them either at once where they are to remain, or in nursery-beds, in rows half a foot at least asunder; being careful to give water directly, repeating it occasionally in dry weather, together with occasional shade, where convenient, in sunny days, till the plants are well rooted afresh. And when those thus pricked out both in the hot-bed, and in the nursery-beds in the open ground, have had three or four weeks growth, or till from six or eight to ten or twelve inches high, they may be transplanted with balls of earth, without hardly any check by their removal; or some in the nursery-bed, in the full ground, may be permitted to stand till they show bloom sufficient to discover which are double and which single-flowered, and then chusing only the best sorts accordingly, removing them with a ball of earth about their roots as aforesaid, into the borders and pots, or other places intended: observing of the whole, in disposing them in the borders, to plant them at from five at least to ten feet distance from one another, and distribute the

different sorts so as to effect diversity, watering them directly, and at times till fresh rooted.

Or, if intended to plant the whole immediately out from the feed-bed into the borders, &c. finally to remain, as often practised to save time and trouble; and that if you would cultivate only the finest sorts, may plant two or three plants nearly close together in patches, about the borders, the aforementioned distance, or in pots, &c. and as soon as they show their flowers large enough to judge of their properties, may clear away the worst, and leave only one of the best sorts in each patch, or pot.

Likewise, when intended to plant any in pots, to adorn fore courts, &c. always select the very best doubles of the finest colours, from among those which have been previously pricked out in nursery-beds, and remained to show bloom, transplanting them with balls of earth into the pots, giving plenty of water, and place them in a shady border, &c. till they have taken good root; then remove the pots of plants where wanted.

Raising them in the open ground.—In default of hot-beds, &c. may raise all the varieties of these plants in the full ground, but the seed must not be sown before April, when, if convenient to cover with mats, or glasses, &c. of nights and cold weather, may sow in the beginning of that month: otherwise not generally till towards the middle: chusing some warm rich border, sow the seed either in shallow drills near half an inch deep, or all over the surface, and covered thinly with earth, or raked in evenly; observing, that if the place is defended with any spare hand-glasses, or frames and lights, or even with hoop-arches for the support of mats, it will be of much advantage in affording shelter in cold nights; however, this sowing often succeeds tolerably well without any covering, though probably not come so forward as those that have occasional shelter.

When the plants thus raised are from about three to five or six inches high, as formerly noticed in the hot-bed culture, they should be planted out either finally into the borders, or, if small, planted in nursery-beds for a little time; then transplanted where they are to remain, as before directed.

As to future culture of all these plants, after being finally planted out, give occasional waterings the first week or fortnight till they have taken root, as before advised; and after being advanced in growth, place some stakes where needful to the strongest large-headed plants, one stake to each; likewise trim off

low straggling branches near the bottom; and long ramblers of the top or head just to preserve a little regularity, more particularly in the *Tagetes patula*, which is apt to ramble considerably.

Those planted in pots will require constant watering, three times a week at least, or even every morning or evening in very dry hot weather.

Saving Seed of all the Sorts.

As to saving the seed of these plants; they ripen abundance in September; but it should be collected only from the finest double flowers, to preserve the respective varieties in as true perfection as possible, which, without this precaution, are apt to degenerate considerably; therefore gather only the prime large heads of seed; which, after being spread to dry properly, may either be beat or rubbed out, or retained in the heads; putting the whole up in bags or boxes till spring, for sowing.

Always save fresh seeds every year; for those more than one year old rarely grow.

TAMARINDUS.

Tamarind tree.

It is a large elegant tree of Indian growth, adorned with fine pinnated leaves; and bunches of tripetalous flowers; and is retained here in our stoves for variety.

Class and order, *Triandria Monogynia*.

Characters.] CALYX, four plane, oval, acute leaves, coloured and deciduous. COROLLA, three oval, plicated, equal, rising, spreading petals, the length of the calyx, with room for a fourth and lowest petal, &c. STAMINA, three awl-shaped, rising filaments in the sinus of the calyx, arched towards the corolla, and with oval incumbent antheræ. PISTILLUM, an oblong, pedicillated germen, awl-shaped, rising style, and thickish stigma. PERICARPIUM, a long, compressed, unilocular pod, having a double bark, and contains generally three angular seeds.

There is but one species, viz.

TAMARINDUS indicus.

Indian Tamarind tree.] Rises with a large trunk, dividing into a very branchy spreading head, growing fifty or sixty feet high, covered with a brown bark; long abruptly-pinnated leaves of sixteen or eighteen pair of oval lobes, not terminated by an odd one; and at the axillas of the leaves loose bunches of reddish flowers, succeeded by seed-pods full of an acid pulp, surrounding the seeds; but do not ripen in England.

The seed-pods of this tree are the tamarinds used in medicine, being of a pulpy acid nature, excellent to quench thirst, and allay heat; and

are imported hither from the West and East Indies, preserved in sugar.

This tree is a native of the East and West Indies, also of Ægypt and Arabia; and from which countries it was first introduced into the European gardens for variety; where it requires the constant protection of a stove all the year; so must be kept always in pots, and continued constantly in that department, and managed as the other woody exotics of the stove collection.

It is propagated by seeds obtained from abroad, which sow in spring, in pots of light earth, and plunged in a hot-bed or bark-bed in the stove, &c. where they will readily come up; and when the seedlings are three or four inches high, prick them out in separate small pots, giving water, and plunge them again in the hot-bed, repeating the waterings, and give occasional shade from the sun till fresh rooted; and as the plants advance in growth, shift them into larger pots, and keep them always in the bark-stove.

TAMARIX.

Tamarisk-tree.

Consists of two hardy deciduous tree and shrub kinds, for variety in the shrubbery compartments, garnished with narrow, finely-divided leaves; and numerous small pentapetalous flowers in loose spikes at the ends of the branches.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX is obtuse, divided into five obtuse, erect segments, and permanent. COROLLA, five oval, concave, spreading petals. STAMINA, five or ten capillary filaments, having roundish antheræ. PISTILLUM, an acuminate germen, no style, but three oblong feathery revolute stigmas. PERICARPIUM, an oblong acuminate triquetrous, trivalved, unilocular capsule, having numerous small downy seeds.

There are only two species in our gardens, the one somewhat of the tree kind, the other a shrub, both deciduous hardy exotics, and remarkable for one producing pentandrous, and the other decandrous flowers; and both of which are very ornamental.

The species are,

1. **TAMARIX gallica.**

French Tamarisk.] Grows fourteen or sixteen feet high, with slender spreading irregular branches, covered with reddish and brown bark; narrow, finely-divided leaves, having the indentures imbricated, or lie over one another like scales of fish; and numerous small, pale-red, pentandrous flowers in loose spikes at the ends of the branches.

2. **TAMARIX germanica.**

German

German Tamarisk.] Grows eight or ten feet high, branching erectly, covered with a yellowish bark; small, divided, scaly, light-green leaves; and numerous, larger decandrous flowers in loose spikes at the ends of the branches.

Both these species of *Tamarix* begin flowering in July, and as they are produced numerously towards the ends of all the branches in large loose spikes, they appear very conspicuous and ornamental; for though the flowers are separately small, they are very numerous, and closely placed in each spike; and which in the first species have each but five stamina, (*pentandria*), and in the second species ten stamina, (*decandria*), each flower succeeded by oblong three-cornered capsules, full of downy seed, rarely ripening in England.

These shrubs are proper ornaments for decorating the shrubbery, and all hardy deciduous plantations; as they exhibit a very conspicuous variety, both in their beautiful foliage, and fine spikes of flowers.

They will succeed in almost any soil and situation; and may be had at the public nurseries; and being in possession of a few, may soon encrease them plenteously as below.

Method of Propagation.

They are propagated most readily by cuttings; also occasionally by layers; though they generally grow very freely by cuttings.

By Cuttings.—They will readily grow by cuttings of the young shoots; and the proper season for planting them is either in autumn, any time in October or November; or in the spring, in February or March, in open weather; chusing therefore a quantity of cuttings, young shoots of the year, and plant them in a shady border, or any moist ground, in rows a foot asunder, they will be well rooted by the following autumn; when, if necessary, they may be transplanted in wider rows, and in two or three years they will be ready for the shrubbery.

By Layers.—The young shoots are the proper parts to lay, and the autumn or early part of winter is the season for laying them; which perform by slit-laying, and let them remain a year; then examine them, and plant off such as are rooted in nursery rows till wanted.

They may also be raised from seed sown in a moist border as soon as it can be obtained.

TAMUS.

Black Briony.

Two hardy, herbaceous, climbing perennials,

are the principal species in this genus, sometimes raised for variety in the pleasure-ground, and for medical uses; are volubilate climbers, rising by support many feet high, garnished with heart-shaped and trifid leaves, and bunches of apetalous dioecious male and female flowers of no beauty.

Class and order, *Diœcia Hexandria*.

Characters.] CALYX, male and female flowers on separate plants, the males having a six-leaved cup, and the females a monophyllous one divided into six parts. COROLLA, no petals. STAMINA, six simple filaments in the males, with erect antheræ. PISTILLUM, in the female flowers, an oblong germen under the calyx, cylindric style, having three reflexed emarginated stigmas. PERICARPIUM, an oval trilocular bacca, having two globular seeds.

There are but two species, one an inhabitant of England, &c. among hedges and bushes, and the other of the island Crete; are both large fleshy-rooted plants, perennial in root, but with annual stalks.

1. TAMUS communis.

Common Black Briony.] Hath a very large, thick, fleshy root, covered with a blackish-brown skin, sending up long, twining-climbing stalks, winding round any support ten or twelve feet high; heart-shaped, undivided, smooth leaves; and long bunches of white flowers from the sides of the stalks, succeeded by oval red berries.

It grows wild under hedges, &c. in England, but is sometimes admitted in gardens as a climber for variety; and is esteemed of great efficacy in medicine.

2. TAMUS cretica.

Cretan Black Briony.] Hath a large, fleshy root, twining-climbing stalks, mounting by support ten or twelve feet high; trifid, or three-lobed leaves; and bunches of whitish flowers at the sides of the branches, succeeded by red berries.

Both the species flower in June and July; the flowers are small, and without petals; and are succeeded in the female plants by berries ripening to a red colour in August; each having two seeds. See the *Characters*.

They are both hardy perennials that are abiding in root, producing new stalks annually in spring; will grow any where in the full ground under shrubs and bushes; and a few of each sort may be introduced in the herbaceous collection for variety and observation, in thickets, woods, and wilderness plantations, among other climbers; and may be there raised both from seed and roots, planted at once, where they are to remain near the shrubs

shrubs and bushes, and suffered to run and climb over their branches, and any adjacent support.

Some may also be cultivated in any place for medical use, particularly the first sort, as being the most common and the most easily obtained, either the seed to sow, or roots to plant, as below.

Both the species are easily propagated by seed, and by parting the roots.

By Seed.—The berries ripen in autumn, which should be sown soon after, that they may more certainly grow the first spring. Sowing some at once where they are to remain, in patches between shrubs, &c. four or five seeds in a place half an inch deep; others may be sown in beds, either to remain, or for transplantation.

By parting the Roots.—The old roots often furnish off-sets, which should be slipped off early in autumn or spring, and planted at once where they are to remain.

TAN, or TANNER'S BARK, for making hot-beds, called bark-beds.

Tanner's Bark, commonly called simply Tan or Bark, is the Bark of the oak-tree, peeled therefrom when felled in the woods for timber, of which there are generally great falls made every spring, when all the bark is detached for the tanner's use in tanning of leather, being previously chopped or ground to pieces; and, after being used for that purpose, and cast out of the tan-vats, becomes a valuable material in gardening, for making those kinds of hot-beds commonly called bark-beds, which are considerably the most effectual hot-beds in use, for the culture of most kinds of tender exotics, that require aid of artificial heat in this climate all the year in stoves, &c. being generally made in an oblong pit or cavity six or eight feet wide, and three deep, the length at pleasure (see BARK-BED and STOVE); and the hot-bed being, in substance, the width and depth, &c. as above, it produces a very substantial, though moderate, uniform, and durable heat, not so apt as dung hot-beds to heat vehemently, and endanger burning the plants, nor send up a noxious steam; and the heat is of three times longer duration, and more easily managed; for a Bark hot-bed will support its heat near a year, with the assistance of a little fresh Tan added every three or four months, forking up the old and new together each time. See BARK-BED and STOVE, &c.

Therefore this valuable material, Tan or Bark, for the purpose of making hot-beds, is the cast-off Tan of the tan-yards; which, however, they preserve in store with the ut-

most care for sale to the gardeners, being careful to have that which is tolerably fresh out of the tan-vats, and that of proper quality, for there are different sorts, some being chopped or ground moderately large, some middling, and some cut very small, to make it go the farther for particular purposes of tanning, though not near so proper for the gardener's purpose as the middling or larger sort; but the largest of all heats the most violently, the middling more moderate and durable, and the small sort soon becomes earthy, and declines its heat; so that the middling Tan is preferable for general use: however, as there is now such an universal demand for this article, the desired sort is not always to be readily obtained; therefore, we are often obliged to put up with a mixture of all sorts.

But for the particulars respecting the choice and preparation of the Tan or Bark, and method of forming it into a hot-bed, and management thereof, see BARK-BED, BARK-PIT, FORCING-FRAME, and STOVE.

TANACETUM.

Tansey.

This genus comprises herbaceous and shrubby perennials for the kitchen-garden, pleasure-ground, and green-house collections, all of upright growth, from two or three to eight or ten feet high, garnished with bipinnated, pinnated, and entire leaves, in the different species; and the branches terminated by numerous compound flowers, in umbellate and corymbose bunches.

Class and order, *Syngenesia Polygamia Superflua*.

Characters.] CALYX, a compound flower, having a hemispherical, imbricated general cup. COROLLA, numerous tubular, quinque-dentate, hermaphrodite florets in the disk, and trifid female florets in the radius. STAMINA, five short capillary filaments, with cylindric antheræ, in the hermaphrodite florets. PISTILLUM, an oblong germen, slender style, having in the hermaphrodites a bifid revolute stigma, and two reflexed stigmas in the females. PERICARPIUM, none; a single seed in each floret, placed on the convex naked receptacle.

There are many species of *Tanacetum*, though not above six or seven esteemed for culture in our gardens; three of which are hardy, herbaceous perennials for the full ground, and four are of shrubby growth for the green-house.

Hardy herbaceous kinds.

Under this head is comprised the common Tansey with varieties, Costmary or Alecoast, and Siberian Tansey; all hardy, fibrous-rooted perennials,

perennials, abiding in root, but with stalks rising every spring and decaying in autumn.

1. *TANACETUM vulgare.*

Common Garden Tansey.] Hath a fibrous, tough, creeping root; large, bipinnated, cut, serrated leaves, of a strong agreeable odour; and upright, channeled stalks, branching erectly, two or three feet high; all crowned with umbels of yellow flowers in July and August.

Varieties.] Common plane-leaved Tansey, —Curled-leaved. —Variegated-leaved. —Scentless Tansey.

The common sort grows wild in England, &c. by road sides, and on the borders of fields, and sides of banks, &c. but which, and its varieties, have been long employed in our gardens, both as culinary and medical herbs; and, sometimes as ornamental plants: but for latter purpose the curled-leaved and variegated sorts merit the most respect; the curled sort in particular having very large thick leaves, most beautifully curled, appearing double as it were, and is of a heightened grateful fragrance; which, therefore, together with the variegated sort, demand a place in every ornamental collection, where they will exhibit a very conspicuous diversity.

However this herb, for its oeconomic uses in the kitchen and medicine, merits culture in every garden, the leaves being sometimes used in sallads while young and tender in the spring, and for making Tansey-cakes, puddings, &c. and the leaves, seeds, and flowers, are said to be a certain remedy to destroy worms in the human body.

This herb, therefore, merits culture in every kitchen-garden, planting slips of the root in beds, in rows a foot asunder, where it will abide many years.

2. *TANACETUM Balsamita.*

Balsamita Major, commonly called Costmary or Alecost.] Hath a thick, fibrated, fleshy, creeping root; oval, entire, serrated leaves; upright, round, branchy stalks, a yard high, and the stalks and branches terminated by corymbose bunches of deep-yellow flowers in August.

It is an odoriferous plant, formerly in much esteem both as a culinary and medical herb, and as such is still cultivated in some kitchen gardens, planted as the common Tansey.

3. *TANACETUM Sibericum.*

Siberian Tansey.] Hath a thick, fibrous, creeping root; pinnated leaves, having very narrow foliola or pinna, ending in two or three points; upright branchy stalks two feet high; and at the axillas and termination of the

stalks, smooth, corymbose bunches of yellow flowers, in June and July.

All these herbaceous kinds are durable in root, but annual in leaf and stalk.

Tender shrubby kinds for the green-house.

Consists of four shrubby species, mostly evergreens, originally from Æthiopia in Africa, and require the shelter of a green-house here in winter: they rise with shrubby stems and branches from three or four to eight or ten feet high; ornamented with pinnated and pinnatifid leaves, and bunches of yellow, compound flowers at the end of the branches.

4. *TANACETUM suffruticosum.*

Under-shrubby Æthiopian Tansey.] Rises with under-shrubby branching stems, three or four feet high, pinnated multifid leaves, of many very narrow lobes, sub-divided into acute parts, and roundish bunches of bright-yellow flowers at the ends of the branches.

5. *TANACETUM frutescens.*

Shrubby African Tansey.] Rises with a woody firm stem, branching six or eight feet high; pinnatifid leaves, with spear-shaped obtuse entire segments or lobes; and roundish bunches of sulphur-coloured flowers at the ends of the branches.

6. *TANACETUM crithmifolium.*

Samphire-leaved Shrubby Tansey.] Rises with a shrubby stem, branching five or six feet high; pinnated leaves, with very narrow entire lobes, remote from one another, and corymbose bunches of yellow flowers at the ends of the branches.

7. *TANACETUM flabelliforme.*

Fan-shaped shrubby Tansey.] Rises with a shrubby stem and branches three feet high; garnished with deltoid, sawed leaves, and yellow flowers in a corymbose, terminating the branches.

All these seven species of *Tanacetum*, both herbaceous and shrubby kinds, flower very abundantly every summer, though not all esteemed ornamental; but the shrubby kinds in particular most of all: the flowers of all the sorts are separately smallish, but being collected into numerous large umbellate and corymbose bunches at the top of the stalks and branches, appear very conspicuous; and being compound, each main flower is composed of many smaller ones, all within one general cup, and are succeeded by plenty of ripe seed in autumn, more especially the herbaceous kinds.

The three herbaceous *Tanacetums* are very hardy fibrous-rooted perennials, that prosper in almost any soil and situation, and are of great duration in root, which also creeps and spreads

spreads very considerably; by which the plants, propagated abundantly, and increasing into large bunches, require trimming or cutting in all round occasionally, to keep them within moderate bounds, especially the common Tansey, and varieties. The two first species in particular, are the most common in England, and are cultivated in kitchen-gardens as culinary aromatic herbs; but more commonly the *Tanacetum vulgare*; planting slips of the root of each sort in autumn or spring, in rows a foot asunder. They may also be all employed to diversify the compartments of the pleasure-ground, among other large herbaceous perennials.

And as to culture of these herbaceous kinds, it consists principally in keeping them free from weeds, and cutting down the decayed stalks annually in autumn; and as the roots increase fast into large bunches, spreading widely round, they require cutting in, or to be slipped occasionally, which otherwise are apt to over-run the ground; and to dig between the plants annually, in common with other such-like perennials.

The four shrubby *Tanacetums* being exotics from hot countries in Africa, are somewhat tender here, but they only require shelter from frost; so must always be kept in pots, and deposited among the green-house plants, and treated as other shrubby exotics of that collection; in which they will effect a very agreeable variety at all times of the year, but more particularly all summer and autumn, when in flower. They generally begin flowering the early part of summer, and continue mostly till the end of autumn; but are rarely succeeded by good ripe seeds in England.

Propagation of all the sorts.

Herbaceous kinds.—All the herbaceous species are propagated plentifully by parting the roots; also by seed.

By parting the Roots.—All these sorts multiply exceedingly by the root, which is the most expeditious and ready method of propagating them; and is performed by slipping or dividing the roots into slips, in autumn or winter, when the stalks are decayed; or early in spring, before new stalks shoot forth, planting the slips at once where they are to remain; those for the kitchen-garden, such as the common Tansey, &c. plant in any bed or border a foot and a half asunder; and those intended for variety in the pleasure-ground, dispose singly here and there, at eligible distances, to effect a proper diversity.

By Seed.—Plenty of seed may be saved in autumn, which being sown in spring following, in beds of light earth, broad-cast and

raked in, they will soon come up, and in July the plants will be fit to prick out in beds, in rows a foot asunder; some to remain, and others to be transplanted in autumn, where required.

Shrubby kinds.—All the four shrubby sorts are easily propagated by cuttings of the branches.

The cuttings may be planted any time in spring and summer, chusing the young and most robust shoots, which cut off in proportionable lengths; and if early in spring, &c. may plant them in pots of good earth, several in each, and plunge them in a hot-bed, where they will be rooted, and fit for potting off separately in six weeks; or, if in summer, the young shoots may be planted in the full ground, in a shady border, or where they may be shaded with mats from the sun; or planted in pots, and placed in the shade, or rather under a garden frame, &c. and shaded occasionally; in all of which methods giving plenty of water, they will readily take root; but those in the hot-bed will be forwardest: they however will all be well rooted the same season, and should then be transplanted in separate pots, then managed as other shrubby green-house plants. See GREEN-HOUSE PLANTS.

TARCHONANTHUS.

Shrubby African Flea-bane.

It is a shrubby ever-green exotic of Æthiopia, for the green-house collection; adorned with oval leaves, and compound flowers.

Class and order, *Syngenesia Polygamia Æqualis*.

Characters.] CALYX, a compound flower, having a monophyllous, top-shaped, septemfid, coloured, permanent cup. COROLLA, the compound flower is uniform, of many funnel-shaped, quinque-dentate, hermaphrodite florets. STAMINA, five short filaments, with cylindric antheræ longer than the corolla. PISTILLUM, an oblong germen, a style double the length of the flower, and two gaping stigmas. PERICARPium, none; a single seed in each floret, covered with down, ripening in the permanent calyx.

There is but one species, viz.

TARCHONANTHUS camphoratus.

Camphire-scented shrubby African Flea-bane.] Rises with an upright woody stem, branching out towards the top, ten or twelve feet high; oblong-oval, downy leaves, white underneath; and purple-violet flowers, in spikes at the ends of the branches.

It begins flowering about September, and continues a succession of flowers several months, but does not ripen seeds in England.

It is an ever-green exotic from Africa, but has been long introduced into our gardens for variety as a green-house plant, as it requires shelter in winter; must therefore be always cultivated in pots, and managed as other shrubby exotics of this collection. See GREEN-HOUSE PLANTS.

The propagation of this plant is easily effected by cuttings planted in spring or early part of summer, in pots, and plunged in a hot-bed, giving occasional shade and water; they will soon emit roots the same year, and be fit to pot off separately in two or three months. Or cuttings planted in May and June, in beds of common earth, or in pots, and shaded with mats or oiled paper shelters, or covered with hand-glasses, and shaded and watered; they will also strike root: observing in either case, that when tolerably rooted towards autumn, they should be potted off separately, and managed as the other green-house plants.

TAXUS.

Yew-tree.

It is a famous hardy ever-green tree, of stately spreading growth; a native of England, and most parts of Europe; and an old inhabitant of most European gardens, employed principally for ornamental and useful hedge-work, and detached trained figures; and occasionally as a rural standard tree for ornamental and timber plantations, in its natural growth; but has been more universally cultivated for hedges, and various detached formal devices; as it branches out numerous-ly and close to the very bottom, having all the branches very closely garnished with small, narrow, ever-green leaves, as to render it remarkably well adapted for training into any sort of hedges, and detached figures, &c. hence this tree was cultivated in great abundance for that purpose in ancient gardening.—See HEDGES, PLEASURE-GROUND, &c.

Class and order, *Diæcia Monadelphica*.

Characters.] CALYX, male and female flowers apart, on separate trees, having no calyx; but a germ or bud, like a four-leaved cup. COROLLA, no petals. STAMINA, numerous filaments in the males, coalesce in a column below, crowned with peltated depressed antheræ, having obtuse octofid margins, and open on each side the base, discharging the farina or pollen. PISTILLUM, in the females, an oval, acuminate germen, no style, but an acute stigma. PERICARPIUM, a small succulent red-berry, succeeds the female flowers, lengthened below, and globular at top, covered by a proper coat below; and includes one oval seed, prominent beyond the berry.

There are several species, but not more than one common in Europe, which is,

1. TAXUS baccata.

(*Berry-bearing Taxus*)—or *Common Yew-tree*.] Rises with an upright trunk, and very branchy spreading head, thirty or forty feet high or more, very closely garnished with small, narrow, stiff, dark-green leaves, growing near together, and very small, apetalous, yellowish flowers, male and female, on different trees, in clusters, at the sides of the branches, succeeded by small, red, pulpy juicy berries, containing the seed, ripe in autumn.

The following is also retained in some gardens for variety, both in the shrubbery and in the green-house collection.

Varieties.] With very short leaves—Broad shining-leaved—Striped or variegated-leaved.

2. TAXUS nucifera.

(*Nut-bearing Japanese Yew-tree*.) Having narrow stiff-leaves placed remote, or at a distance from one another.

The Yew, in all its varieties, is of the dicious class, bearing male and female flowers, mostly on separate trees; flowering generally in March, but the flowers make an inconsiderable appearance, and are succeeded in the females by great plenty of ripe berries, serving as food for birds, and to sow for the work of propagation; as by the berries or seed only the tree is generally raised, effected in great abundance in a bed of common earth, as directed under the article of their *Propagation*.

This tree, Common Yew, and varieties, are very hardy ever-greens, whose verdure assumes a dark melancholy hue, of a malignant nature: are all hardy enough to prosper in any common soil, even often in the most barren, cold situations, as may be observed in many parts of England, where the tree grows naturally, arriving to a large size, fit to fell for timber; which being of a very hard durable nature, is valuable for many useful purposes: and it is by some affirmed, that bedsteads made of Yew, will not be approached by bugs.

But in respect, however, to its merit in gardening, it may be employed various ways as an ornamental ever-green; also as a forest tree, both for ornament and use, as before observed. Formerly it was greatly employed for hedges, and detached trained figures, in various ornamental forms, in pleasure-grounds; but now seldom used in England for these purposes, since all formal works of that nature are mostly banished our gardens, and instead thereof it is employed in its natural state, in shrubberies, and other ornamental plantations.

princi-

principally of the ever-green tribe; being there permitted to assume its natural growth, in common with other rural trees and shrubs; sometimes also planted as detached standards, in extensive distant opens of grass ground, in parks and sides of hills, &c. for variety, and suffered to grow in the order of nature; likewise is very proper to be introduced as a forest tree in timber plantations, of the ever-green kind particularly (see FOREST-TREES and PLANTATIONS); and for hedge-work, where any internal hedges are required, either for ornament or shelter, no tree is better calculated, or so proper in many cases, it forming the closest, even, moderate-growing hedge of any tree of the ever-green collection. It is also peculiarly calculated for training into any formal or fancy figure, both in hedge-work, and as detached objects, for, by reason of its branches and leaves growing exceedingly close, and shooting very moderate and regular, they may be readily trained, by clipping, into any form: and as a hedge for shelter in nursery-grounds, &c. to defend the more tender or delicate young plants, a Yew hedge is well adapted. But as an outward hedge for a fence, it is not so well calculated as a holly or hawthorn hedge. See HEDGES.

For all of the above purposes may this noted tree be most easily trained, and for which it should be proceeded with accordingly, in its minor growth in the nursery; that if for hedges or any fancy figures, suffer the plants to branch away immediately from the very bottom, and cut them with garden shears once or twice every summer, to form them for the purposes intended; and if designed for the shrubbery and other rural plantations, prune them up a little at bottom to a single stem, and suffer the head to branch out on all sides and top diffusively; likewise, if for larger detached standards, trim up the stems gradually to elevate them in proportion; and encourage the head to branch out, and spread its branches widely around according to nature.

Yew hedges, and detached fancy figures, were in so great repute formerly, when nothing but uniform designs in gardening prevailed, that, in pleasure-grounds particularly, most of the divisions or quarters were surrounded with these sort of hedges, &c. so as in a manner to shut out all other trees, shrubs, and flowers, from the sight of persons in the adjacent walks; and nothing hardly but Yew hedges were to be seen on every side: hence many such gardens being, in a manner, destitute of variety and entertainment, these and other similar hedge-work, becoming in almost general disrepute, were rooted out by degrees,

and the gardens laid out in more open rural designs, in imitation of nature, exhibiting all the various plants to open view, from the contiguous walks and lawns. So that in modern designs, hardly any Yew hedges are admitted by way of ornament, or otherwise; or even so much as a single detached Yew, trained in any uniform manner. However, sometimes, in extensive grounds, Yew hedges, and other formal Yew figures, were so judiciously arranged, and trained, as to exhibit an ornamental appearance at first entrance, especially where they were not too prevalent; though should be introduced with great moderation and caution in the internal districts, not to obstruct the prospect, or shut out from sight the view of any desirable object within the garden.

But Yew trees, in their natural growth, are eligible to introduce in any large decorative plantations to increase the variety: though some persons reject the Yew, on account of the gloomy mournful aspect of its verdure, and poisonous quality; others again admire it for its solemn appearance, which effects a remarkably good contrast with the other more lively evergreens; and as to its baneful effects, it is certain the leaves are of a poisonous nature, and it is said was formerly used in compounding poisons. Hence some authors have distinguished this tree by the name of *TAXUS lethifera*, the *death-bringing Yew*; and hereby, say they, it is looked on as a symbol of mortality, and for that reason planted in church-yards to remind people of their approaching fate. It is certain that many accidents have happened to cattle, both horses and cows, by eating the leaves and young shoots of Yew, especially the clippings of Yew hedges, which, when they have lain in the sun a day or two, and half dried, some cattle, particularly cows, will sometimes eat them very greedily; so that every one ought to be remarkably careful either to burn the clippings of these trees, or put them quite out of the way of cattle, and not carelessly cast them over the wall or hedge, into lanes, highways, or on rubbish heaps, where cattle frequently come.

Young plantable Yews for all the fore-mentioned purposes may be procured at most of the public nursery-grounds, at a moderate rate; or may easily raise them abundantly from seed, of a competent size, in a few years, for final transplantation; i. e. from two or three to five or six feet high; though this tree may be removed occasionally at seven or eight feet height, if required, to form an immediate high hedge, &c. for the root being remarka-

By fibrous, the earth adheres close in a lump, so as to admit of removing large plants readily with a ball, to the places allotted them; supplying them with due waterings.

Method of Propagation, &c.

The propagation of this tree is effected principally by seed, which ripen plentifully in autumn, and may be sown in any bed or border in the open ground, either as soon as ripe, or in spring. It may also be propagated by layers and cuttings.

By Seed.—It is most advisable to raise the principal supply from seed; which if sown in autumn it will expedite the germination so far, as some part will rise the spring following; but if not sown till spring, they generally all remain in the ground till the second year before they come up, though if the seeds or berries are preserved in earth or sand till spring, then sown, they will all rise together in equal growth, more plentiful and regular than the autumn sowings: however, every one may suit their own convenience or inclination, in the time of sowing; and having therefore procured a due quantity of the Yew berries, divested of the pulp or mucilage, sow them in beds of light earth, either in shallow drills, or scattered over the surface of the bed, and covered near an inch deep with light mould, out of the alleys, or elsewhere. Being thus sown, no farther care is required but keeping the beds clean from weeds, both before and after the plants come up; giving also occasional waterings in dry weather, in spring and summer, which will forward and strengthen the seedlings in their growth: continuing this care of occasional waterings and weeding, let the seedlings have two years growth in the seed-bed; then in autumn or spring prepare some ground into four-feet-wide beds, and here plant them out in nursery rows, a foot asunder, to remain two, three, or four years; when some may either be planted out finally for hedges, if required; others in the nursery quarters, in rows, two or three feet asunder, and there trained for the purposes they are intended, according to the hints before given.

After growing in the nursery till they obtain from half a yard to four or five feet stature, they may be finally transplanted in autumn or spring, for their intended purposes; they will rise with a large spread of roots, and sometimes with good balls of earth, if thought necessary in transplanting any of large growth; and should be planted in their allotted places, as soon after removal as possible, giving each plant a good watering.

As to future culture, those to be trained in hedges, &c. must be clipped or shorn annu-

ally, once or twice in the summer (see HEDGES); and those in shrubberies, and other rural plantations, require only some of the lower branches pruned up occasionally to a single stem; but permit the head generally to spread agreeably to its natural mode of growth, except just reducing any considerable rambling branch, &c.

Remark, as to the striped or variegated Yews and other varieties, that in order to continue them exactly the same, the propagation of them should generally be effected by layers or cuttings, as they are rarely permanent by seedlings.

By Layers.—Young shoots, not more than a year or two old, being laid in spring, summer, or early in autumn, many of them will root, and in one or two years be fit for planting off into nursery lines.

By Cuttings or Slips.—In March or April, or end of August, or early in September, slip off a quantity of the one year's shoots, divest them of the lower leaves, and plant them in a shady border thick together, in small trenches, giving water at planting, and afterwards occasionally in dry hot weather; they will be well rooted in two years, fit for transplantation into wider nursery rows.

TELEPHIUM. True Orpine.

Consists of one species, a small hardy perennial plant, of procumbent or trailing growth, with small oval leaves, and short terminal spikes of pentapetalous flowers.

Class and order, *Pentandria Trigyna*.

Characters.] **CALYX**, five oblong, obtuse, concave, carinated, permanent leaves. **COROLLA**, five oblong, obtuse, erect petals, narrowed at the base. **STAMINA**, five subulate filaments, topped with incumbent anthers. **PISTILLUM**, a trigonous, acute germen, without style, crowned with three acute stigmas. **PERICARPIUM**, a short, three-sided, trivalvular capsule, with one cell, furnished with many roundish seeds.

The species is,

TELEPHIUM imperati.

True Orpine of Imperatus, or Live-long.]

Hath a thick, hard, fibrous root, of a yellowish colour; many slender, procumbent, green stalks, trailing on the ground, eight or ten inches long, with small, oval, stiff, smooth, greyish leaves, placed alternately; and short, thick, reflexed spikes of white flowers, at the termination of the branches; appearing in July, succeeded by ripe seeds in autumn.

This procumbent plant is proper to introduce for variety in any of the principal borders, &c. of the pleasure-ground, placed towards the front, in assemblage with other perennials.

perennials for variety, and as a flowering plant; allotting it a dry light soil, in which it will both grow more prosperously, and continue of longer duration than in moist ground.

It is propagated by sowing the seed in autumn or spring, in dry light ground, either where intended the plants are to remain, or for transplanting; they will come up in the spring, and the next year will flower and ripen seed. The propagation is also sometimes effected by off-sets, and by slips and cuttings.

TERRACE, (from *Terra*, the Earth).

A Terrace-walk.

In gardening, a Terrace is a raised bank of earth, &c. regularly formed in an oblong manner to any length, broad enough to admit of a spacious level walk at top, and elevated somewhat considerably above the level of the general surface; having the sides uniformly sloped, and laid with grass, and the top formed into a flat or level, sufficiently broad for a grass or gravel-walk, of proportionable width, as hereafter noticed; designed in gardens as a high, airy walk, to command a better prospect of the adjacent places around, both within and without side of the garden occasionally, as well as to enjoy the fresh air in summer more freely; and likewise in the former style of laying out gardens, a noble Terrace was considered as very ornamental in the pleasure-ground.

As to the necessary elevation or height of a Terrace-walk, it may be more or less as the situation admits, or requires, from one foot high to one or two yards; or even three or four yards or more in particular situations, and where there are plenty of earthy materials, rubbish, &c. either acquired or natural, for its formation; allowing breadth in proportion, from five to ten or twenty feet or more, and extended to any length required, or as may be convenient: for Terraces are sometimes formed on some naturally high, rising ground, to save as much trouble as possible, in bringing stuff from a distance; and are sometimes raised wholly of forced materials.

As to the proper situation in a garden for a Terrace, this may be varied as the natural situation of the place may require; though in ancient gardening Terraces were more common than at present; some designed both for ornament and grand elevated walks, as being considerably raised with noble sloping banks, having spacious walks at top for occasional walking; others being intended only as a moderately-raised walk, sometimes extending in a line from the front of the mansion, or conducted round some grand open division, &c.

Sometimes, however, in ancient designs, a grand Terrace-walk was formed next the house, ranging either parallel to the front, or to one or both wings; or extended in a perpendicular line outward from the front of the main house to some considerable distance; and sometimes continued both ways; the latter generally much less elevated than the former.

Sometimes also a Terrace-walk was carried round the boundary of a lawn, or other open division; others, sometimes contrived at some outer verge of the ground, or at the termination of some particular compartment.

And sometimes also a moderately elevated Terrace was carried almost all round the outward boundary of the pleasure ground, to command a more advantageous prospect of the open country.

In respect to form, a Terrace is always broader at the base than the top, and extended lengthways to any distance required; having the sides regularly sloped, of more or less acclivity, as the width, height, and situation admit or require. Sometimes both sides are sloped, and sometimes only one side, the other perpendicular, and faced with a substantial wall, &c. or by being formed against the side of a hill, or some naturally rising ground; in either case is finished always broad enough at top to admit of a proper walk. Likewise, in some naturally-elevated situations in particular, terraces were sometimes formed one above another in two or more ranges, each having its separate side slopes, and elevated walk; in all of which the slopes were neatly laid with grass, and the walk at top was occasionally of grass or gravel.

The ascent of entrance to a Terrace-walk was sometimes formed by an easy acclivity of a grass or gravelled slope; and sometimes by a grand flight of stone steps.

Where a naturally-rising ground, of some considerable elevation, occurs in a proper situation, or on the side of a hill, it is an eligible opportunity for forming a grand Terrace with the least expense and trouble, by not requiring the addition of so much foreign assistance in bringing earth and rubbish, as when raised entirely on a perfect level, wholly of forced earth, brought from another place for that purpose; or where there are any excavations of ground intended to form ha-has, pieces of water, &c. the excavated earth might be employed in forming a Terrace, &c. where required.

In proceeding to form a garden Terrace, the base must be staked out wider than the intended width at top for the walk, in order to admit of the ascent of slopes being moderate.

And

And in its formation all the forced earth and rubbish must be well rammed from time to time as it is applied, in order to render the whole equally firm, that it may not settle out of form after being finished; the slopes of which may either be laid with turf, or sown with grass-seed.—See GRASS.

TETRAGONIA, *Tetragonia*.

Comprehends shrubby and herbaceous succulent perennials of Africa, for the green-house collection; of somewhat decumbent growth, with succulent stalks, garnished with small, narrow, succulent leaves, and apetalous flowers at the sides of the branches.

Class and order, *Icosandria Pentagynia*.

Characters.] CALYX, four oval, plane, deflexed, coloured, permanent leaves. COROLLA, no petals. STAMINA, about twenty or more capillary filaments, shorter than the calyx, having oblong, incumbent antheræ. PISTILLUM, a roundish, quadrangular germen, under the calyx, five awl-shaped, recurved styles longer than the stamina, crowned with long hoary stigmas. PERICARPIUM, a large leathery, tetragonous, crustaceous capsule, with four longitudinal, narrow wings, or borders; and contain one quadrilocular hard nut, with four oblong kernels.

The species of most note are,

1. TETRAGONIA *fruticosa*.

Shrubby Tetragonia.] Hath slender, ligneous, succulent, grey stalks, branching numerous and stragglingly, four or five feet long, inclining to the ground, unless supported; and full of crystalline drops; very narrow, linear, fleshy leaves, in clusters, bespangled also with pellucid glittering pimples, and greenish and yellow flowers, by two or three together, along the sides of the branches, in July and August, succeeded by large tetragonous capsules, ripening seeds in winter.

2. TETRAGONIA *herbacea*.

Herbaceous Tetragonia.] Hath a remarkably thick, fleshy root; herbaceous, weak, trailing stalks, garnished with small, oval, plane, succulent leaves, and bright yellow flowers, along the sides of the branches, in February or March; sometimes succeeded by ripe seeds in England.

Both these species of *Tetragonia* being exotics from *Æthiopia*, require shelter here in winter; so must be always retained in pots, and placed among the green-house plants, and managed like other succulents of that collection; but should be always placed in the most airy part of the green-house in winter; as they only want protection from frost, either in that conservatory, a glass-case, or garden-frame;

and should be but very moderately watered during that season.

They are both of procumbent growth, and unless supported, trail on the ground. The shrubby sort is durable in root, stem, and branch, garnished with leaves all the year; but the herbaceous kind often die down to the ground, wholly or in part, towards autumn, and send up new stalks again about the latter end of the same season, continuing in leaf all winter, &c.

Both the sorts are retained in most of our eminent green-houses, to increase the variety; and as there is a singularity in their general port or habit, particularly the *Tetragonia fruticosa*, they merit admittance in every curious collection.

They are easily propagated by cuttings and by seed.

By Cuttings.—Cuttings of the young branches may be cut off any time in summer for planting, which, as being succulent, after having lain a few days to dry up the moisture of the cut parts, may be planted either in pots, and placed either in a garden-frame, and occasionally shaded, or plunged in any hot-bed to forward them. Or cuttings planted in a bed of light good earth, in the full ground, will also readily take root, allowing shade from the sun at first, and occasional waterings: they will be rooted in six weeks, or two months, fit for potting off separately, planting each in a small pot at first, and shift them into larger as they shall require.

By Seed.—Sow it in the spring in pots, and plunge them in any moderate hot-bed, which will generally bring up the plants the same year, which otherwise are apt to remain in the ground till the second spring, before they appear. When they, however, come up, inure them by degrees to the full air; and when two or three inches high, prick them separately in small pots, placed in the shade all summer, and moderately watered and managed as other green-house succulents.

TEUCRIUM, Tree Germander, including also *Polium* and *Marum*, &c.

This genus is composed of under-shrubby and herbaceous plants, for variety in the pleasure-ground, green-house, and for medicinal use, mostly of low or very moderate growth, some upright, others with trailing stalks, garnished mostly with small, simple foliage, and small, monopetalous, ringent flowers, in verticillate clusters and spikes, at the sides and ends of the branches, in the different species.

Class and order, *Didynamia Gymnospermia*.

Characters.] CALYX is monophyllous, cnt half

half way into five acute nearly equal segments, and is persistent. COROLLA is monopetalous; ringent, with a short cylindric tube, incurved at the top, and with the upper lip erect, and deeply cut into two parts: the lower one into three, with the middle segment largest. STAMINA, two long and two short awl-shaped filaments, longer than the upper lip, and prominent between the segments, crowned with small antheræ. PISTILLUM, a four-parted germen, a filiform style, and two slender stigmas.—PERICARPIUM, none; the four roundish seeds lodge in the calyx.

To this genus is added the *Palium* and *Marum*, and some other genera, each formerly considered as a distinct genus, but now arranged as a species only of this genus, *Teucrium*, which comprehends above thirty different species; though scarcely a quarter of that number common to our gardens, or that have any definable merit for general culture, either for use or ornament; consisting of hardy, shrubby, herbaceous, and ligneous perennials, for variety and ornament in the full ground; and some tender kinds for the green-house collection.

Hardy shrubby kind.

Consists of one small, shrubby plant, hardy enough to live in the full ground in a warm, dry situation.

1. TEUCRIUM *flavum*.

Yellowish shrubby Teucrium, commonly called Tree Germander.] Rises with erect shrubby stalks and branches, a foot and a half or two feet high; having small heart-shaped, obtusely-ferrated, foot-stalked leaves, hoary underneath, with the floral leaves concave and entire; and numerous flowers by threes, in whorls, along the upper part of the branches, of different colours in the varieties.

Varieties.] Yellowish-flowered—Pale-white-flowered—Purple-flowered.

This shrub is durable in root, stem, and branches, foliated most part of the year, and produces flowers ornamentally in July, succeeded by ripe seed in autumn.

It is an exotic from Spain and Italy, long since introduced into our gardens; formerly kept as a green-house plant, but now is sufficiently naturalised to this climate to succeed in the open air all the year, in a sheltered, dry situation; though it is still also proper to keep some in pots, to move under shelter of a frame, or green-house, in severe winters, by way of a reserve, in case the fully-exposed plants should be killed by the frost.

It is easily propagated by slips or cuttings of the branches, and by seed.

By Slips, &c.—In spring or summer, slips

or cuttings of the young shoots may be planted either in pots, several in each, or in a bed or border of good earth; or, to forward them as much as possible, a quantity of slips may be planted in pots in spring, and plunged in a hot-bed; observing, in either case, to give due waterings, and occasional shade from the sun till rooted; and in autumn following, they may be transplanted in nursery-rows, for a year or two, and some in pots for occasional shelter in winter.

By Seed.—This may be sown in April, in a bed of light earth; and they will soon come up, and be fit for planting out early in autumn following.

Hardy herbaceous and ligneous kinds.

There are many herbaceous Germanders; but the most material are the following perennials, all principally of the fibrous-rooted tribe, rising mostly with herbaceous and slender ligneous stalks; both of procumbent and erect growth; seldom exceeding a foot and a half long or high; which in some are annual, and some become somewhat ligneous and abiding; are cultivated for variety and observation, and some as medical plants.

2. TEUCRIUM *Scordium*.

Common Water Germander.] Hath creeping perennial roots, sending up many square, procumbent, or trailing stalks, branching diffusely; oblong, indented, ferrated, close-fitting, opposite leaves; and small reddish flowers, generally two together, from the sides of the stalks and branches, in July and August.

This is a medicinal herb, and smells strongly of garlic.

It grows naturally in marshy places, in the isle of Ely, and other parts of England, and most parts of Europe; and sometimes admitted in gardens, in moist places, for variety, and as a medical plant.

3. TEUCRIUM *Scorodonia*.

Wood Sage.] Hath a fibrous, creeping, perennial root; upright, four-cornered stalks, a foot and a half high; heart-shaped, ferrated, foot-stalked leaves; and racemous clusters of whitish flowers, from the sides of the stalk upward, ranged mostly towards one side, appearing in July.

It grows naturally in woods and thickets in England, &c.

4. TEUCRIUM *Chamædrys*.

(Chamædrys) Smaller-creeping Germander.] Hath fibrous, very creeping, spreading roots; many four-cornered, very branchy, trailing stalks, near a foot long; oval, cuneiform, cut-crenated leaves, on short foot-stalks; and reddish flowers, growing almost in a verticillous, or whorls, round the stalk, three on each peduncle;

peduncle; appearing in June and July. Is a native of Germany, France, &c.

5. *TEUCRIUM canadense*.

Canada Germander.] Hath a fibrous perennial root; upright stalks, a foot and a half high; oval, lanceolate, serrated leaves; and white or reddish flowers, collected in racemous clusters, terminating the stalks, having six leaves under each verticillus, or whorl; flowering in July.

6. *TEUCRIUM lucidum*.

Shining Germander.] Hath a fibrous, creeping, perennial root; upright, ligneous, smooth, blackish-green stalks, branching diffusely; oval-oblong, cut-serrated, smooth, shining-green leaves; and purple flowers by pairs, at the axillas of the stalks and branches. Grows naturally in France and Germany.

The following are principally of the *polium* kind, moderately hardy, but rather impatient of severe frost; so should also keep some in pots, to move under shelter in winter.

7. *TEUCRIUM Polium*.

(*Polium*) or *Common Poley Mountain*, or *Mountain Poley.*] Hath a fibrated perennial root; herbaceous and ligneous, trailing, branchy stalks, prostrate on the ground; oblong, obtuse, crenated, downy, sessile leaves; and the branches terminated by roundish heads of yellow and other coloured flowers in the varieties; appearing in June and July.

Varieties.] There are many varieties of this species, distinguished by some little variation in their growth, having all roundish heads of flowers; consisting of yellow-flowered, white-flowered, upright blue-flowered.

It grows naturally in Spain and Portugal, &c.

8. *TEUCRIUM montanum*.

Mountain Poley, with Lavender Leaves.] Hath a fibrous, tough, ligneous root; somewhat ligneous, weak, procumbent stalks; spear-shaped entire leaves, hoary underneath; and small white flowers in a corymbus at the termination of the branches, in June and July.

9. *TEUCRIUM pyrenaicum*.

Pyrenean Mountain Poley.] Hath slender, trailing, somewhat ligneous, hairy stalks; wedge-shaped, and roundish crenated leaves; and flowers produced in a corymbus at the ends of the branches, of different colours in the varieties; appearing early in summer.

Varieties.] Purple-flowered—White-flowered—Variegated purple and white-flowered.

10. *TEUCRIUM pumilum*.

Dwarf Mountain Poley.] Hath somewhat ligneous, procumbent, slender, downy stalks, lying on the ground; linear, or very narrow,

plane leaves in quadrifarious clusters; and reddish flowers, collected into small heads, terminating the branches, in June and July.

11. *TEUCRIUM capitatum*.

Capitated Mountain Poley.] Rises with upright, somewhat ligneous, branchy stalks, a foot high; spear-shaped, crenated downy leaves; and white flowers collected into round heads at the end of the branches, standing on peduncles; appearing in June and July.

All these herbaceous *Teucriums* flower commonly in June and July; the flowers separately small, of the monopetalous ringent kind; produced generally in a sort of verticillus, or whorls, towards the upper part of the branches: in some placed at a distance, and in others in close heads or spikes; succeeded in the first three or four sorts by plenty of seed in autumn; but the others do not always ripen seeds freely in England.

They are all perennial plants, durable in root; and some of the ligneous kinds are also abiding in stalk and branches of several years duration.

All the sorts are occasionally employed in gardens for variety, and may be had at most of the nurseries.

The first four or five sorts are very hardy plants, that will succeed any where in the full ground, all of which may be propagated abundantly by slips of the roots, in autumn or winter; or of the young shoots in spring and summer; also by seeds.

But the *Polium* kinds are rather a little tender, and should therefore have generally a dry, raised, sheltered, sunny situation, as before observed; and some should also be potted for shelter in winter, under a frame, or in a green-house.

As to the method of propagating all these sorts, it is either by parting the roots, by slips of the branches, or by seeds.

The first five or six sorts may be propagated plentifully, either by slipping the roots, in autumn, winter, or spring; or by slips or cuttings of the young shoots in spring, or early part of summer, planted in a moist shady place; or by sowing the seeds in a bed or border of common earth in the spring.

The *Polium* kinds may likewise be raised plentifully from seed, and by slips or cuttings of the shoots in spring. The seed should be sown in spring in a bed of light earth, a quarter of an inch deep; where the plants will soon come up, and be fit to prick out in July or August; either in nursery-rows till autumn or spring, or planted at once where they are finally to remain. And as to the propagation by

by slips, it may be performed in April, chusing the most robust shoots, and plant them in an easterly border, giving occasional waterings and shade; and they will be well rooted by autumn for transplantation.

Tender shrubby kinds for the green-house collection.

Several of the shrubby kinds of *Teucrium*, being exotics of tenderer quality, require shelter here in winter of a green-house or garden-frame; so are commonly retained in pots and placed among the green-house plants, serving to increase the variety of that collection; and the following are the principal sorts thereof in the English gardens, being all moderate-growing shrubby plants, closely garnished with small simple leaves, mostly of a somewhat hoary or downy nature; and flowers growing in the verticillate order.

12. *TEUCRIUM fruticans.*

Shrubby or Spanish Tree Germander.] Rises with an upright, shrubby, hoary stalk and branches, five or six feet high; having oblong-oval entire leaves, smooth above, and hoary underneath, placed opposite on short foot-stalks; and blue flowers at the axillas of the branches, one on each peduncle; appearing great part of summer.

Variety.] With striped leaves.

13. *TEUCRIUM latifolium.*

Broad-leaved Spanish Tree Germander.] Rises with a shrubby downy stalk and branches, six or seven feet high; having broad, rhomboid-shaped, acute, entire, hairy leaves, downy underneath; and pale-blue flowers singly at the sides of the branches; appearing most part of summer.

14. *TEUCRIUM Marum.*

Syrian Marum or Mastick.] Rises with an upright shrubby stalk, and numerous slender hoary branches, from about a foot and a half to two or three feet high; having very small oval, entire leaves, pointed at both ends, hoary underneath, and placed opposite; and bright red flowers in clusters at the ends of the branches, generally ranged on one side, having hairy cups; appearing in July and August, but rarely any seeds in England.

This is a fine aromatic, and is an old resident of our gardens, esteemed both for its aromatic property, and to effect variety, generally as a green-house plant; though it will also sometimes succeed in the full ground, if planted in a dry sheltered situation; affording it protection of mats in very severe weather.

15. *TEUCRIUM massiliense.*

Marseilles Under-shrubby Germander.] Rises with upright, suffrutescent, or under-shrubby

stalks, about a foot high; oval, acute-crenated, rough, hoary leaves; and purple flowers in erect clusters, terminating the stalks; appearing in July, succeeded by ripe seed in autumn.

16. *TEUCRIUM creticum.*

Cretan narrow-leaved Mountain Poley.] Narrow, linear, spear-shaped, entire leaves; and spiked clusters of flowers; with the flowers by threes.

17. *TEUCRIUM coccineum.*

Scarlet Mountain Poley.

All these shrubby germanders under this head (Green-house kinds), are mostly wholly perennial, or durable in root, stem, and branches; and generally retain their leaves most part of the year, flowering abundantly every summer, but rarely ripen good seeds in England.

As all these green-house sorts are tenderish exotics, originally from distant warm countries, they require to be sheltered here in winter from frost; and therefore must generally be cultivated in pots, in order to be moved into a green-house or garden-frame, during the winter, and managed as other green-house shrubs (see GREEN-HOUSE PLANTS); but some may also be planted in the full ground, in a warm dry situation, where they will often stand through our moderate winters tolerably well; but are liable to suffer by severe frost, which renders it necessary to treat the principal part generally as green-house exotics.

The propagation of all these tender shrubby kinds, is by slips or cuttings of the young shoots of the branches in spring, and early part of summer, as directed for the first species (*Teucrium flavum*); and when rooted, plant most of them singly in pots for removing to occasional shelter in winter, and managed as before hinted; others plant in the open air, in a dry warm exposure, to take their chance.

THALICTRUM.

Meadow Rue.

This genus consists wholly of hardy, herbaceous, fibrous-rooted perennials, some of which are cultivated in gardens for variety and ornament, rise mostly with upright stalks annually, adorned with many-lobed leaves, and smallish tetrapetalous flowers, generally crowning the stalks in paniculated bunches.

Class and order, Polyandria Polygynia.

Characters.] CALYX, none. COROLLA, four roundish, concave petals, that soon fall off. STAMINA, numerous compressed filaments, broadest above, and terminated by oblong erect antheræ. PISTILLUM, numerous

roundish pedicillated germina, having thickish stigmas. PERICARPIUM, none. Numerous oval sulcated seeds in a head.

There are twelve or fourteen species, and the most noted of which in our gardens are the following, retained in the pleasure-ground for variety; all of which have perennial roots, mostly fibrated and creeping; and send up erect herbaceous stalks annually in spring, which constantly decay to the ground in autumn.

1. *THALICTRUM flavum*.

Yellowish Greater Thalictrum, or Common Meadow Rue.] Hath a thick, fibrous, creeping, yellow root; sending up several round, furrowed, leafy stalks, five or six feet high; garnished with many-lobed leaves, having most of the lobes cut into three parts; and numerous whitish-yellow flowers terminating the stalks in many paniculated bunches, standing erect.

Variety.] Montpellier yellow-flowered.

This species grows wild in meadows, and other moistish places, and by river sides in England, &c. and is sometimes introduced in gardens for variety.

2. *THALICTRUM aquilegifolium*.

Columbine-leaved Thalictrum, commonly called Feathered Columbine.] Hath a thick fibrous root; upright round stalks, three or four feet high; large leaves composed of many lobes, much like the *aquilegia* or columbine; and numerous whitish flowers, terminating the stalks in large panicles, succeeded by straight, triangular, pendulous seeds.

Varieties.] Green-stalked, with white flowers and stamina—Purple-stalked, with purple flowers and stamina.

Is an inhabitant of Helvetia, &c. but has been long in the English gardens.

3. *THALICTRUM cornuti*.

Canada Thalictrum of Cornutus.] Hath a fibrous dark-coloured root; upright, smooth, purplish stalks, three or four feet high, branching towards the top; large, many-lobed leaves like those of columbine; and numerous white flowers terminating the stalks and branches, in large panicles, each flower having five petals.

4. *THALICTRUM angustifolium*.

Narrow-leaved German Thalictrum.] Hath a fibrated root; upright stalks, two or three feet high; large pinnated leaves, of many very narrow entire lobes; and numerous small whitish flowers in panicles, at the top of the stalks.

5. *THALICTRUM tuberosum*.

Tuberous-rooted Spanish Thalictrum.] Hath

a root hung with many-knobbed tubers; upright, almost naked stalks, a foot and a half high; small obtuse leaves, three-parted at the end; and largish white flowers, in roundish bunches, at the top of the stalks; each flower having five petals.

6. *THALICTRUM minus*.

Lesser Meadow Rue.] Hath small, fibrous, creeping roots; slender branching stalks, about a foot high; leaves cut into six parts; small and whitish and yellow flowers, in a nodding position, in loose panicles, at the top of the stalks.—It inhabits moist meadows and pastures in England, &c.

7. *THALICTRUM fœtidum*.

Stinking Dwarf Thalictrum.] Hath a fibrous creeping root; slender, paniculated, branchy, leafy stalks, six or seven inches high; leaves composed of many small, indented, foliola, having a stinking odour, and small whitish flowers in loose panicles, at the top of the stalks.—Grows naturally in the south of France, and Helvetia, &c.

8. *THALICTRUM alpinum*.

Alpine Dwarf Thalictrum.] Hath a fibrous creeping root; slender, single, almost naked stalks, about six inches high; leaves having small obtuse lobes, and whitish flowers in single clusters terminating the stalks.

All these species of *Thalictrum* generally flower in June and July, except the Alpine sort, which commonly flowers in April or May; the flowers separately are small, but collected many together in paniculated bunches at top of the plants, each flower having generally four petals, and in some species five, as in their respective descriptions; and are succeeded by ripe seeds in August and September.

They are all very hardy herbaceous perennials, that will succeed in any common soil and exposure, in the full ground; though generally are the most prosperous in shady moist situations: they are esteemed, some as flowery ornamental plants, others principally as plants of variety, and botanical observation; though all the sorts may be employed to diversify the pleasure-ground in any of the open compartments, in assemblage with other herbaceous perennials; and are all easily raised from slips of the root in autumn, which will creep exceedingly, and multiply in great abundance.

But the second and third species are the sorts that are the most commonly esteemed, and cultivated in the English gardens as ornamental flower plants, they flowering more conspicuously than the others; though the first sort, and also all the other species are

eligible to assemble in the borders and other pleasurable compartments to increase the variety.

The propagation of all the sorts is very easily effected in abundance, by parting the roots in autumn, when the stalks decay, or in the spring before new ones shoot forth; planting the slips, the strongest where they are to remain, and the weakest in nursery-rows, to have a summer's growth, or to remain till wanted.

Likewise by seed sown in the spring, in a bed or border; they will soon rise, and the seedling plants will be fit to plant out towards autumn following.

THEA.

The Tea-tree.

This genus comprises those two curious and distinguished Chinese evergreens, the Bohea and Green Tea-trees; universally famous for producing the leaves of which is made, by infusion, that well-known domestic article Tea; are of moderate growth, rather of the shrubby kind with slender branches; garnished with oblong-oval, and spear-shaped, sawed, smooth, nervous leaves, two or three inches long, and large whitish-red flowers of six to nine oval petals; succeeded by tricapsular, trilocular fruits, with three seeds singly.

Class and order, *Polyandria Monogynia*.

Characters.] CALYX, small, flat, of five or six roundish, blunt, persistent folioles. COROLLA, six to nine large, roundish, concave, equal petals. STAMINA, many slender filaments, shorter than the corolla, with simple antheræ. PISTILLUM, a globose, three-cornered germen, and awl-shaped style, crowned with a triple stigma. PERICARPIUM, a tricapsular fruit of three roundish united parts, trilocular and opening at top, with roundish solitary seeds, one in each cell.

The species are,

1. THEA Bohea.

Bohea Tea-tree.] Rises with an upright shrubby stem and slender branches, having ash-coloured bark, garnished with oval, obtuse-pointed, sawed leaves, about three inches long, and two broad, placed alternately, of a dark-green colour, and rosaceous whitish flowers at the sides of the branches, having generally six petals.

2. THEA viridis.

Green Tea-tree.] Rises with a shrubby stem and branches, garnished with spear-shaped, sawed, plane leaves, three or four inches long, of a light-green colour, and whitish flowers having generally nine petals.

These two noted trees, or rather shrubs, are natives of China and Japan; introduced

in our gardens for curiosity, variety and ornament, both as green-house plants, and in the full ground in a warm situation; they being moderately hardy to stand our ordinary winters with some occasional protection from frost, especially if planted in some dry well-sheltered compartment to have the full sun in the winter season.

However, it is advisable both to have some in pots to remove under shelter either of a green-house, glass-case, or deep garden frame in winter, as a more certain protection from severe weather; and others planted in a dry, well-sheltered, warm part of some principal shrubbery compartments, conspicuous to sight; and afford them occasional defence of covering from rigorous frosts; by which they generally stand our common winters tolerably well, grow freely in spring and summer and often show plenty of blossoms in their proper season.

Both the sorts are propagated by layers of the young wood, in the autumn, spring, or early part of summer; and will be rooted to transplant in autumn or spring following: also by cuttings of young shoots in spring and summer, planted in pots, and plunged in a hot-bed: likewise by seed, assisted by the same means: and in all of which methods of propagation, the newly-raised young plants should be transplanted singly in small pots, and moved under the protection of a frame, &c. in winter to shelter them occasionally from frost, till they gain some tolerable degree of strength, of at least, one or two-feet growth; then some may be disposed in a warm situation in the full ground, as formerly intimated, and some retained in pots, to move under shelter in winter, and these shifted into larger pots according as they advance of some tolerably increased size in their general growth in the root and head.

Thus these two noted exotic shrubs are cultivated in our gardens to diversify the green-house collections, and those of principal shrubbery compartments: though, in this country, only a few plants of each sort are retained principally for those purposes, and as noted curious exotics as well as for ornamental variety in their general growth.

But in China, their native soil, they are cultivated in vast abundance in very extensive plantations, for their leaves, of which the Chinese make a valuable merchandise for the supply of all parts of Europe, &c. with which to make the Tea, now so generally used every where.

For this purpose, they pluck the leaves in three different gatherings annually: the first

gathering being of the youngest leaves, is superior to the others, and is generally called imperial Tea; the second gathering, in older leaves, is next in goodness; and the third gathering being of the oldest leaves, is inferior to the two former.

But in each gathering, the leaves being plucked promiscuously as they come to hand, care is afterwards taken, previous to their usual manufactured preparation, to arrange them into different classes, according to their size and goodness, which produces the different qualities and prices of the prepared Tea; and of the last, or third gathering particularly, when the leaves are of full growth, they being sorted into classes; the lowest of which being composed of the oldest leaves, is the coarsest and cheapest sort of Tea, much inferior in flavour to that of the others.

After the leaves are gathered and sorted, as above, they are then prepared into the form we receive the Tea from abroad, by drying them, when fresh, over a fire in an iron pan, constantly stirring them about; and then rolling them while hot, with the palm of the hand, on a mat, or canvas, till they curl up; then when cold, the Tea thus prepared is put up in some vessel or case, and kept very close from the air; either in large China jars, or canisters, or in chests lined with lead, in which latter it is commonly imported in this and other countries, from China, by shipping annually, in amazing quantities; supplying millions of people as one of the daily articles of food in its peculiar preparation.

THEOBROMA.

Chocolate Nut Tree, &c.

Comprises two exotic trees of the West Indies, retained here in some eminent stoves for variety; are adorned with large oblong and heart-shaped simple leaves, and small pentapetalous flowers, in bunches, at the sides of the branches.

Class and order, *Polyadelphia Pentandria*.

Characters.] CALYX, three oval, concave, reflexed, spreading, deciduous leaves. COROLLA, five concave, galeated or arched, quinquenervous petals, having each a bifid, horn-like bristle at top, and a bell-shaped nectarium of five oval-lanceolate, connected, spreading leaves. STAMINA, numerous awl-shaped filaments in five bodies, terminated by so many antheræ. PISTILLUM, an oval germen, awl-shaped style, and simple stigma. PERICARPUM, a woody, unequal, oblong, or roundish fruit, or nut; having many oval fleshy seeds arranged in five cells.

There are two principal species, both of the tree kind, though the first is but of very mo-

derate growth, and the second obtains some considerable stature and magnitude.

1. THEOBROMA *Cacao*.

Cocaa or Chocolate Nut Tree.] Rises with an upright, robust stem, about half a foot thick, branching ten or twelve feet high; large, oblong, entire, opposite leaves, near a foot long, and half as broad; and numerous yellowish flowers, in bunches, from the sides of the trunk and branches; succeeded by oblong, quinquangular fruit, full of seeds, of which is made the chocolate.

This tree inhabits the hot parts of America, where it is also attentively cultivated for its fruit, to make the chocolate; being made of the kernels, which are first roasted in a pan, and reduced to powder; then worked with orange water, and formed into a paste; afterwards mixed with sugar, aromatic spices, and perfume; then formed into rolls or cakes, and exported to Europe, and other different parts of the world.

2. THEOBROMA *Guazuma*.

(Guazuma), or Bastard Cedar of Jamaica.] Rises with an upright large trunk, branching numerously and spreading, thirty or forty feet high; oblong, heart-shaped, serrated, alternate leaves, four inches long; and numerous small yellowish flowers at the sides of the branches; succeeded by roundish, tuberculated rough fruit, containing the seed.

Both these trees being exotics from the hot parts of America, in this country require the indulgence of a stove; and in many of which a few plants are retained for variety: so must be kept always in pots, and placed in that conservatory, and managed as other woody exotics of similar quality.

3 THEOBROMA *angusta*.

Angustous Chinese Bastard Cedar.] With hearted seven angled leaves.

They are propagated by seed obtained from abroad, sowing it as soon after its arrival as possible, in pots, and plunged in a bark-bed, where they will soon come up; and when about three inches high, pot them off separately, and plunge them in the bark bed in the stove; and manage them as other woody exotics of this department.

THERMOMETER.

An instrument resembling a weather-glass, for measuring and demonstrating by inspection the degrees of heat and cold at all seasons, and which proves of great utility in the culture of tender exotic stove plants, by serving as a guide to regulate the proper degree of heat for stoves or hot-houses, containing such plants; particularly in winter, when fire heat is used. See STOVE.

As to the construction of a botanical Thermometer for a hot-house, it consists of a long slender glass tube, or pipe, about eighteen inches or two feet long, having a small glass ball or globe at the lower end; and is fixed longitudinally on a brass or wooden plate or frame, the same length, or longer, and four or five inches broad; the glass tube and ball being furnished with a quantity of coloured liquid spirit, which is affected by heat and cold so as to ascend higher or lower in the tube proportionably, a scale being marked on the frame along each side of the tube, divided into the different degrees of heat and cold; and the spirit ascending by the heat of the internal air of the Stove, promoted by fire, &c. points out on the scale the proper degree of heat required, having the name of some remarkable exotic, such as the *ananas*, or pineapple, wrote on the scale as a standard mark of the requisite temperature of heat, so as when the internal heat of the stove raises the spirit to that mark, or within five degrees over or under, is the proper temperature for the growth of the *ananas*, and all other tender plants from the hottest parts of the world; so that the fires requisite for the stove in winter, are to be made stronger or weaker, according to the direction in the Thermometer.

Thus a good Thermometer in Stoves is more particularly useful in winter, during the time the fires are made in the flues for warming the air internally; it being generally hung up towards the centre of the stove, so as the warmth thereof may operate moderately and equally on every side, and discover the real temperature of the general internal heat, which should be supported always nearly equal by the aid of bark hot-beds and real fire, sufficient to raise the spirit in the tube to the mark *ananas* aforesaid, or but a little over or under.

Remarking, however, the Thermometer should not only be suspended nearly towards the centre of the stove, but also out of the sun, or at least placed with its back thereto, that the glass tube and ball containing the spirit may be shaded from the sun-shine as much as possible; and also placed at some medium distance from the fire place and flues, so as neither the direct rays of the sun, or heat of the fire, darting immediately on the tube and ball, may affect the operation of the inclosed liquor, and cause it to mount considerably higher than would be effected by the real general warmth of the air of the stove, and be thereby led inadvertently into an error, in supposing the internal heat to be much stronger than it really is, when probably it is not strong enough; therefore this instrument should always be

judiciously placed as above, so as to be affected only by the real general warmth of the internal air; and by observing this, you may easily regulate the stove heat at all seasons to such proper temperature as is requisite for the culture of the plants before mentioned.

Therefore every stove ought to be furnished with a good well-regulated Thermometer, as a guide for more certainly determining, at all times, the necessary degree of heat; for in winter, when fires are requisite, it is easy to make them of more or less strength, as you shall see necessary, to warm the whole inclosed air equally, to such a temperature of heat, as to mount the spirit in the Thermometer to the degree marked *ananas*, which should be well attended to, and continued always as nearly as possible to that standard, or not exceeding five or ten degrees over or under.

Or if the Thermometer should at any time discover the fire heat in winter, &c. to be considerably too strong, let the fire be immediately lessened, and open the door of the furnace to cool the flues; also, if calm mild weather, admit fresh air moderately, if it shall seem necessary, in order to reduce the heat as soon as possible, nearly to the proper standard.

Likewise in summer, in very hot sunny weather, if the internal heat of the stove appears by the Thermometer to be much too powerful in the middle of the day, it is easily reduced to the proper temperature, by sliding open the glasses to admit free air, as you shall see convenient.

THICKETS.

Close plantations of trees and shrubs, in pleasure-grounds, parks, &c.

Plantation thickets are designed for different purposes, such as sometimes to repel the force of tempestuous and cold cutting winds, either from the habitation, or some particular district of the garden; or sometimes to form places of shade or retirement in summer, having spaces for walks, recesses, &c. under the umbrage of the trees; others occasionally to serve both to conceal or shut out from view any unsightly or disagreeable objects, either within the limits of the garden, or without its boundary; and also sometimes to form a screen or blind arranged towards some outward boundary to conceal from the sight of persons without, any particular compartments of the garden. Likewise Thickets are sometimes extended considerably along next some outward boundary of pleasure-grounds, parks, &c. both to exhibit an exterior appearance of extensive plantation, and to form a continual extent of shelter from cold or furious winds, &c. to some otherwise exposed interior parts; or also sometimes

times so arranged as to afford a large extent of shady and private walking, having walks conducted in the serpentine order between the plantations.

And Thickets are also, on some occasions, adopted in some internal parts of large pleasure-grounds, and parks, in contrast with the more open and airy plantations; and sometimes are formed on some side district, extensively in a close plantation in imitation of a natural wood; and in which to have shady wood-walks, winding variously through the plantation. They are also introduced somewhat similarly to form recesses, by environing particular spaces, rendering them retired, shady, and sheltered, by the surrounding trees and shrubs composing the said Thickets; and sometimes close Thickets of hardy trees and shrubs are disposed in detached clumps in capacious open situations to affect a diversified ornamental variety, the said clumps being distantly stationed not to obstruct the view of any desirable prospect.

In the formation of Thicket plantations, they are sometimes planted wholly of large tree kinds, five or six to eight or ten feet asunder, either some in regular lines like a close grove, or others more generally in a sort of promiscuous planting, as it were, but with some degree of order in the distances: and Thickets are also often composed of various trees and shrubs together to affect a more full, close growth below and above, and to display a greater diversity in the plantation, by disposing the various shrubs properly between the larger trees, in some order of gradation, the lowest towards the front, and the taller growths backward, in proportion, thereby forming a sort of close underwood Thicket below, while the tree kinds run up and form a thickety growth above.

Sometimes, in particular compartments of shrubberies, Thickets are formed wholly of shrubs only, of different sorts and degrees of growth, from the lowest placed forward to the tallest behind; being sometimes arranged towards some outer boundary to run up in a close natural growth to cover and hide the outward fence of paling, walls, &c. and permitted to branch spreadingly over the ground in a thickety manner.

Likewise, Thicket plantations are occasionally adopted of distinct or separate tree kinds in some extensive premises, parks and out-grounds, formed wholly each of particular sorts of trees disposed separately in distinct plantations, such as Thickets of Elm, others of Ash, Beech, Poplars, &c. each sort di-

stinct; and of Alder, Willows, and other aquatic kinds, similarly in marshy situations.

General Thickets may be composed of any of the common forest trees, and other hardy tree kinds, and the most hardy sorts of shrubs; a list of which being comprised in that of the general hardy tree and shrubby tribe, arranged under the articles DECIDUOUS TREES and Shrubs, and EVERGREENS, &c.

Thickets of forest trees designed for woods are also formed with the different sorts of timber trees in considerable extent of wood plantations; both to grow up in full Standards for timber, being planted thick, only four to five or six feet distance, to admit of thinning gradually in advanced growth; and in coppice plantations, closely planted to grow in underwood for cutting occasionally in smaller growth, in a thinning order, leaving a sufficiency of the straightest standards thereof singly, at moderate distances, to run up in full growth for timber trees; the smaller underwood between, shooting up again, affords a cutting every six, eight, or ten years for smaller purposes on different occasions.

The planting of any intended Thicket plantations should be effected with young trees of four, five or six, to eight or ten feet growth; and the shrub kinds proportionably: and in all of which the planting may be performed in the common seasons of autumn, winter and spring.

In respect to culture of Thicket plantations, very little is required, keeping them clear from large over-bearing weeds, while the trees and shrubs are in young small growth; and the whole generally permitted to run up in their natural order below and above, especially when intended merely as close Thickets for any of the purposes before intimated for designs in gardening and planting; or, as before suggested, Thickets that are formed into extensive woods of closely-planted forest-trees for timber and underwood growth, designed principally as profitable plantations; they, after some years advanced growth in some considerable degree to sell for economical purposes, may be thinned gradually in some regular manner for poles, spars, and many other light requisites, as a profitable produce accordingly.

THUYA.

Arbor Vitæ, or Tree of Life.

This genus furnishes beautiful hardy evergreen trees, of the coniferous tribe, for adorning the shrubbery and other hardy plantations, being of erect tall growth, very branchy to the bottom; with the branches spreading,

spreading, and with flat-fanned young shoots closely garnished with very small or minute leaves, placed imbricatum (over one another), and small apetalous male and female flowers separately on the same tree.

Class and order, *Monœcia Monadelphica*.

Characters.] CALYX, male and female flowers apart on the same plant; the males being collected in an oblong, oval amentum, growing opposite on the common foot-stalk; the florets having an oval concave scale for the cup; and the female flowers form an oval cone, having a scale for a cup to every two florets. COROLLA, small florets, without any petals. STAMINA, four very small, monadelphous filaments in the males, having the antheræ adhering to the base of the calycinal scale. PISTILLUM, in the females a very small germen, slender style, and single stigma. PERICARPIUM, an oblong-oval cone, opening longitudinally, composed of nearly equal scales, convex on the outside, and obtuse, each having an oblong seed, surrounded with a membranous wing.

There are only two species of *Thuja* common to the English gardens, being esteemed fine ornamental ever-greens of the tree kind; and which, although exotics, the one principally from America, the other from China, are hardy enough to flourish here in almost any common soil and exposure, and remain in verdure the year round; are therefore in great estimation for all ornamental plantations.

They are both of the very small-leaved kind, with the leaves imbricated or lying over one another like scales.

The species are,

1. *THUYA occidentalis*.

Occidental, or Common American Arbor Vitæ.] Rises with a large upright straight trunk, branching on every side irregularly, forty feet high or more, with the branches growing somewhat horizontally and straggling; being closely garnished with very small leaves, placed imbricatum, or over each other, appearing of a dark dusky-green colour; and with male and female flowers apart, at the sides of the young branches in spring, succeeded in the females by smooth cones, having smooth obtuse scales, containing oblong seeds.

Varieties.] Common American Arbor Vitæ — American sweet-scented — Variegated-leaved.

This tree grows naturally in Canada, in North America, and in Siberia, is of an aromatic and resinous nature; the leaves emit a strong odour; also the wood, which is likewise remarkably durable: hence it is said the

tree anciently derived the name *Arbor Vitæ*, or Tree of Life.

2. *THUYA orientalis*.

Oriental, or Chinese Arbor Vitæ.] Grows with a straight upright stem, branching erectly, close, and regular, thirty or forty feet high, very closely garnished with very small flat leaves, placed imbricatum, appearing always of a bright-green colour; and male and female flowers separately at the sides of the young branches in spring, succeeded by rugged cones, composed of acute-pointed reflexed scales, having ripe seeds in autumn, or towards spring.

Both these trees are natives of distant countries, the first being of North America and Siberia, as before observed, and the other a native of China, inhabitants of humid soils, where they arrive to a considerable stature and magnitude; and from which countries they were many years since introduced into the European gardens, as ornamental trees in the pleasure-ground; being hardy enough to succeed in the open air all the year, in any common soil and situation, and thrive as in their native climate; and are all easily raised from seed, layers, and cuttings, as hereafter directed.

They, in their general growth, assume a picturesque ornamental appearance, being finely branched to the very bottom, always fully adorned with leaves, which, in both species, are of a very minute size, but very closely and curiously arranged in an imbricated manner, exhibiting a perpetual verdure: and in the whole, the trees effect a very distinguishable variety at all seasons.

And as to their flowering, they flower early in the spring; but the flowers being small and apetalous (without petals), they are not ornamental; are universally monœcious, or male and female, separated on the same tree; consisting wholly of scaly calyxes, containing the fructifications, collected into oblong and conic bunches; the males being in oblong amentums, and the females in close oval cones, which become that sort of seed-vessel called a cone, furnishing ripe seed in autumn, or towards spring.—See CONIFERÆ and CONUS.

The first sort, *Common American Arbor Vitæ*, is the oldest resident in our gardens, very distinguishable from the other by the dark-green colour of its leaves; which, sometimes in winter particularly, assume a disagreeable dusky hue.

But the *Chinese Arbor Vitæ* is both of more regular growth, and its foliage continued always of a fine lively bright green, summer and winter,

winter, and is generally a more beautiful tree than the other.

However, both the sorts are in high estimation as fine ornamental evergreens, and most elegant furniture for adorning the shrubbery, and all other garden-plantations, designed for variety and ornament; have also a fine effect disposed singly in decorative borders, &c. and in open spaces of grass, in the shrubbery; in all of which situations, suffering them generally to grow rural, with their full branches, nearly in their own natural way, except reducing with a knife any low straggling or rambling branches occasionally; which is principally all the culture they require.

But these trees may also be employed as timber-trees, in the evergreen forest-tree plantations. See FOREST TREES.

The Chinese Arbor Vitæ is also occasionally planted in pots, both to place among other potted plants to adorn any particular compartment, and to assemble with green-house plants for variety: and to have shelter in winter during its younger growth.

They are cultivated in all the public nursery grounds for sale, and may be transplanted in autumn, or almost any time in open weather, from October until March or April.

Method of Propagation, &c.

The method of propagating both these trees, is by seed, layers, and cuttings.

By Seed.—Both the sorts ripen seed in England, and are also obtained in great plenty from abroad by the seedsmen; and which should generally be sown soon after they are ripe, or as soon as they can be obtained in autumn or spring; sowing them in pots or boxes of light earth, covering the seeds half an inch deep, and place the pots, &c. in a sheltered warm situation, or under shelter of a frame in bad weather; especially if sown in autumn; that the seeds may be protected from severe frost, and continued forward in their vegetative efforts: and thus they will sometimes come up in the spring; which, however, are frequently apt to remain in the ground till the second year; observing when the plants are come up, the pots should be placed in an east border to have only the morning sun, but open to the free air, giving frequent but very moderate waterings all the summer; and in winter remove the pots again to a sheltered place till spring; then may be pricked out in nursery-rows, or if they are very small and weakly, let them remain in the pots another year, placing them in a shady situation during the summer, and in a sheltered place in winter;

and in spring following plant them out in the nursery, in rows a foot or two asunder, to remain to acquire due size and strength, for final transplantation.

By Layers.—The young shoots only of one or two years growth are the proper parts for laying, which may be performed early in autumn, bending down the branches to the earth; and lay all the young wood on each, either by slit, or twist-laying, with their tops only appearing a little above ground; shortening any that have much longer tops than the others (see LAYING): thus they will most of them emit roots in the earth, and be proper plants by autumn following; when, or rather in spring after, they should be separated from the stools, and planted in nursery rows, to remain two or three years, or till of due size for the shrubbery, &c.

By Cuttings.—Autumn is the best season for planting the cuttings, which must be of the young shoots, principally all of the same year's growth; and should be planted in a shady border. Taking therefore opportunity of showery weather, if possible, and chusing the most robust young shoots, cut them off with a small part of the old wood, where practicable, and plant them in rows a foot asunder, closing the earth well about them: they will be properly rooted in one year, fit for planting out in wider nursery-rows.

THYMBRA.

Mountain Hyssop.

A genus furnishing for the green-house, two species of small under-shrubby exotics of diminutive growth, six or eight inches to a foot high, garnished with small, narrow, acute, and spear-shaped, opposite leaves; and the branches terminated by thick spikes and verticillate clusters of small purple flowers, of the ringent or lip kind; having stiff bilabiate cups; a monopetalous two-lipped corolla, with two long, and two short filaments; a four-parted germen, half-bifid style, and four naked seeds ripening in the calyx.

Class and order, *Didynamia Gymnospermia*.

The species are,

1. THYMBRA *spicata*.

Spike-flowered Macedonian Thymbra.]

With flowers growing in thick close spikes.

2. THYMBRA *verticillata*.

Verticillated Spanish Thymbra.] With flowers growing in verticilluses or whorls.

Both these species are of small bushy growth, closely set with small leaves; and produce flowers in June or July, sometimes succeeded by ripe seeds; the plants being exotics from warm countries, require the protection

tion of a green-house here in winter: and must therefore be planted in pots of light garden earth, and placed among the green-house exotics, and managed accordingly.

They are propagated by seeds sown in March or April, either in a warm border, and have occasional shelter from bad weather, with glasses or mats; or in pots placed under glasses, or in a hot-bed; and may also be raised by slips, or cuttings of the side shoots in the spring and summer; and by bottom offsets in the same seasons or autumn.

THYMUS.

Thyme.

This genus furnishes the common Thyme, and several other low aromatic plants, mostly perennials of somewhat suffrutescent or under-shrubby growth; some valued as noted pot-herbs, others as medical plants, and some for variety in the pleasure-ground; rising with slender stalks and branches, from about half a foot to a foot or eighteen inches high; adorned with very small leaves, and small ringent flowers in verticillate spikes and heads, terminating the branches.

Class and order, *Didynamia Gymnospermia*.

Characters.] CALYX is monophyllous, tubular, bilabiate, and permanent; having the chaps hairy and closed, with the upper lip broad, plane, erect, and tridentate, and with the lower one ending in two equal bristles. COROLLA, a small ringent petal, having the upper lip short, erect, obtuse, and emarginate, and the under one long, broad, and tridentate, with the middle segment the longest. STAMINA, two long and two short filaments, having small antheræ. PISTILLUM, a four-parted germen, filiform style, and a bifid, acute stigma. PERICARPium, none; four small roundish seeds lodged in the permanent calyx.

There are seven or eight different species of *Thymus*, and of which the following are the most material sorts for general culture; consisting of the common Thyme of our kitchen-gardens,—*Serpyllum*, or Wild Thyme,—Mastic Thyme, &c. each comprising some varieties, and are all low, frutescent perennials, mostly of very branchy bushy growth, and durable in root, stem, and branches, and all hardy enough to grow freely in the full ground, in any common soil of a garden.

1. THYMUS vulgaris.

Common Garden Thyme.] Hath very fibry roots; erect, slender ligneous stems, of very branchy and bushy growth, a foot high, closely garnished with small oval revolute leaves, and all the branches terminated by numerous small, whitish-purple flowers, in

verticillate spikes, appearing in summer, and succeeded by abundance of ripe seed early in autumn.

Varieties.] Broad-leaved—Narrow-leaved—Variegated or striped-leaved.

It is an inhabitant of rocky places in France and Spain, &c. but all the varieties have been long residents of our kitchen-gardens as eminent aromatic pot-herbs, and as medical plants; also occasionally in the pleasure-ground for variety, and sometimes as edgings to beds and borders, on account of its close bushy growth; but its principal estimation is for kitchen and medicinal uses.

2. THYMUS Serpyllum.

Creeping Wild Thyme, or Mother of Thyme.] Hath decumbent creeping stalks, six or eight inches long, or more, garnished with very small, obtuse, plane leaves, ciliated at the base, and the branches terminated by numerous small, purplish flowers, growing in heads, appearing in summer, succeeded by plenty of ripe seeds in autumn.

Varieties.] Broad-leaved.—Narrow-leaved—Broad hairy-leaved—Variegated-leaved—Silver-striped-leaved—Citron-scented, commonly called Lemon Thyme—Greater purple-flowered.

This species inhabits pastures, heaths, and commons, in most part of Britain, and other parts of Europe; and is admitted into many gardens for variety, more particularly the variegated sort. Silver striped and Lemon Thyme, which are sometimes disposed singly in tufts about the borders, &c. and occasionally planted in pots; and also sometimes employed to form edgings; but the Lemon Thyme in particular, is in high estimation for its agreeable odour.

3. THYMUS Mastichina.

Mastic Thyme.] Rises with slender ligneous stalks and branches, a foot long, or more, garnished with oval, obtuse, hoary leaves; and the branches terminated by the flowers in verticillate, downy heads, appearing in June, but rarely succeeded by seeds in England.

Varieties.] White-flowered—Red-flowered.

It is a native of rocky places in Spain, but is an old inhabitant of our gardens, chiefly as a finely-scented aromatic, and for variety.

4. THYMUS Zygis.

Shrubby narrow-leaved Spanish Thyme.] Rises with low, under-shrubby, erect stalks; long, very narrow leaves, ciliated at the base; and flowers terminating the branches in verticillate spikes.

5. THYMUS cephalotus.

Large-headed Portugal Thyme.] Rises with

low ligneous stalks, and stiff hoary branches, half a foot long; spear-shaped hoary leaves, placed opposite; and many whitish flowers, terminating the branches in large imbricated heads, having oval bracteal leaves.

Variety.] With small flowery heads.

All these five species of *Thymus*, and their varieties, are of an aromatic quality, and their chief virtue resides in the leaves, which impart a very agreeable aromatic fragrance. But the first three species are the most noted sorts in the English gardens; though the *Thymus Vulgaris*, or Common Thyme, is considerably the most generally known and cultivated, chiefly for its superior aromatic property, for culinary purposes.

They are wholly perennial, somewhat between a shrubby and an herbaceous nature, wholly abiding in root and top, generally of somewhat bushy growth; their leaves in general very small, but closely placed, and mostly ever-green: the flowers also are very small, monopetalous, and ringent, and collected numerously in whorls, either forming spikes or close heads, each flower succeeded by four seeds lodged in the calyx; and by seeds all the species may be raised, as also by slips and cuttings.

As to the use in gardens of these aromatics, the Common Thyme is in universal estimation as a pot-herb for various culinary purposes; and being easy of propagation and culture, merits a place in every kitchen-garden: which also, together with the other sorts, and their varieties, might be introduced in the pleasure-ground, in assemblage with other small frutescent plants, to embellish the front of flower-borders, shrubby clumps, small and sloping banks, &c. placing them detached or singly, to form little bushy tufts, and in which the variegated sorts, and the Silver Thyme, and Lemon Thyme, particularly form a very agreeable variety together, or in assemblage with the others; and the Lemon Thyme is also in much estimation for its peculiar odoriferous flavour; some of each of these sorts may also be potted, in order to move occasionally to any particular compartment, as may be required, and under occasional shelter in severe winters to preserve the plants more effectually in a lively state; likewise some of the Mastic Thyme: Spanish and Portugal Thymes are also sometimes potted for the above occasion, and to place under protection of a garden-frame or green-house in winter, to continue them more fresh and lively, as observed above of the others.

Sometimes, some of the smaller Thymes are

sown or planted for edgings to particular beds or borders for variety, such as the Lemon Thyme, Silver-leaved and variegated sorts; also, occasionally the Common Thyme; and all kept low, close, and regular, by clipping them at sides and top annually in summer.

But as to the *Common Thyme*, designed for kitchen use, it should be cultivated in beds, or borders, in rows half a foot asunder at least; either the seed sown where the plants are to remain, or young seedling plants previously raised for planting out; or slips of old plants detached with roots, which being planted the above distance, they will soon increase into bushy plants, proper to gather for use: or may be occasionally planted as an edging in the herbary, &c. and in either method the plants will prove abiding, and multiply exceedingly by off-sets; and by which the plants may be propagated at pleasure, by slipping them as above, when wanted for increase; though it is also advisable to raise a quantity of plants every year or two from seed, as the young seedlings possess a stronger aromatic quality than the older plants; and it being sown in spring in a bed of light earth, either broad cast and raked in, or in shallow drills, as directed below, they soon come up, and will be fit for use the following autumn and winter, &c.

In gathering Thyme for use, in private gardens it may be cut or slipped a little at a time, as it is wanted, not stumped too close; but when intended for market, the London gardeners generally pull it up root and all, especially the seedling plants, which remain in the bed where raised, and so raise a fresh crop from seed annually.

Method of propagating all the sorts.

All the species of *Thymus* may be easily raised from seed, and by slipping the roots and branches, and by cuttings thereof.

By Seed.—All the sorts may be raised plentifully from seed, though it is rarely practised to any but the first sort, Common Thyme; and March or early in April is the proper season for sowing it; choosing any light, rich, dry ground; which let be properly digged, and the surface moderately smoothed with the spade, because the seed is very small, and should not be sown too thick, nor covered too deep; this observed, let the seed be sown whilst the ground is fresh stirred, sowing it either broad-cast on the surface, and rake it in lightly, or sow it in flat shallow drills, and earth it over thinly in proportion; it will soon germinate, and the plants will appear in two or three weeks, being careful to keep them

well

well weeded, and give occasional light waterings in dry weather; and thus by June they will require thinning, especially if desirous to have the plants grow stocky, and with bushy full heads, in which they should be thinned, to six or eight inches distance; when, if required, those thinned out may be planted in another place, in rows, six or eight inches asunder, giving water till fresh rooted, observing to keep the whole clean from weeds by occasional hoeing between them in dry days, which will also stir the surface of the earth, and thereby much improve the growth of the plants; and they will arrive to good perfection for use in summer or early in autumn.

But sometimes the market kitchen gardeners about London, who raise large quantities in beds, for the daily supply of the markets, leave the whole thick, without thinning; so when of proper growth in summer and autumn, &c. they pull them clean up root and top together, from time to time, as wanted, and tie them in bunches for sale in the market aforesaid.

However, it is always proper to thin out, or transplant a quantity in single bunches, to grow stocky and bushy, as before observed, to remain for the occasional supply of a family.

Remark, in respect to the varieties, that there is no depending on raising them the same from seed; therefore, when intending to propagate any particular varieties, and continue them the same with certainty, it can only be effected by slips and cuttings as below.

By Off-sets and Slips.—All the sorts multiply both by off-sets of the root and slips of the branches; the rooted slips are the most expeditious method; for the old plants increase into many off-set stems, rising from the root, each furnished with fibres; and that by taking up the old plants in the spring, &c. and slip or divide them into separate slips not too small, with roots to each, and plant them in beds of good earth, in rows half a foot asunder, giving water directly, and repeat it occasionally in dry weather till they have taken root, and begin to shoot at top; and thus they will soon grow freely, and form good bushy plants in two or three months.

But slips also of the branches without roots, will likewise succeed, if planted, any time from March or April until about Midsummer; observing to slip off a quantity of the stoutest young outside shoots, of moderate length, and plant them in a shady border, in rows four or five inches distance, giving due waterings; they will soon emit roots, and become good plants by autumn, when they may be transplanted to where they are to remain.

By Cuttings.—Cuttings of the young branches grow readily the same as slips thereof, there being no other difference, than that the cuttings are the young shoots cut off with a knife, and the slips are slipped off from the side of the branches with the hand only; so that the propagating them by cuttings may be performed any time in spring, or early part in summer, planting them in a shady place, and duly watered, they will readily take root, and grow.

The propagation by slips or cuttings is also the only method by which the respective varieties of the different species are with certainty continued the same, as the plants thus raised will be in every respect similar to the parent.

THYRSUS.

A Thyse.

One of the modes of inflorescence, or manner of flowering, of the aggregate kind; being many flowers collected in a bunch, or sort of close panicle, of an oval or egg-shaped form, having the lower foot-stalks, which are longer, extend horizontally, whilst the upper ones are shorter, and mount vertically, as in lilac and horse chestnut, &c.

TILIA.

Lime, or Linden-tree.

Consist of two principal species commonly known and cultivated, comprising some varieties; all very noted hardy deciduous trees, of formal growth, proper for ornamental and timber plantations, &c. they rising with large upright trunks a considerable height, branching numerously all around, into large regular conical heads, adorned with broad heart-shaped leaves, and small pentapetalous flowers, in loose bunches.

Class and order, *Polyandria Monogynia*.

Characters.] CALYX is concave, five-parted, coloured, and deciduous. COROLLA, five oblong, obtuse petals, crenated at top. STAMINA, numerous awl-shaped filaments, and simple antheræ. PISTILLUM, a roundish germen, slender style, as long as the stamina, and a pentagonal obtuse stigma. PERICARPUM, a globular, coriaceous, quinquevalvular, quinquelocular capsule, opening at the base, containing roundish seeds singly in each locument or cell; though very commonly there is but one seed in the whole, and so situated that the capsule often appears unilocular, if incautiously examined.

Of the two species, one is a European tree, and the other is of America; each comprehending some varieties, and are all very hardy, and of the deciduous tribe.

1. *TILIA europæa*.

7 H 2

European

European or Common Lime Tree.] Rises with an upright straight trunk to a great height and magnitude, branching regularly all round into a large conical head; garnished with large, broad, heart-shaped, acute-pointed, serrated leaves, of a light-green colour; and small whitish-green flowers in bunches, at the ends of the branches, having all the flowers destitute of nectaria.

Varieties.] Common green-twigged Lime-tree, having all the young shoots of a light-green colour—Red twigged Lime-tree, having all the shoots of a beautiful red colour, appearing very singular in winter, when destitute of leaves—Large-leaved—Smaller-leaved—Rough or elm-leaved—Variegated-leaved, &c.

The green and red-twigged varieties are tolerably permanent, so that being raised from seed, the plants of each will be mostly similar to the parent tree.

This species grows naturally in England and most parts of Europe, and has been long cultivated as an ornamental tree in garden plantations, both to grow rural, and to form hedge-work regularly trained.

2. *TILIA americana.*

American Black Lime Tree.] Grows with an upright large lofty trunk, branching regularly into a large formal head, having the branches covered with a blackish-brown bark; large, broad, heart-shaped, acuminate, serrated leaves, of a deep-green above, and paler underneath; and small greenish flowers in bunches at the ends of the branches, having all the flowers furnished with nectaria.

Varieties.] Larger-leaved—Smaller-leaved—Carolinian long-pointed-leaved.

Both the species, and their respective varieties, flower in summer; the flowers small, and of inconsiderable appearance, and are succeeded by plenty of ripe seed in autumn, contained in small coriaceous or leathery capsules; and by the seed all the sorts are easily raised in beds of common earth.

These noble trees are quick handsome growers, and obtain a great stature and substance of trunk, particularly the Common Lime, which grows sixty or seventy feet high; and there are accounts of some that have measured ninety feet in height, and more than eight or ten feet circuit in the trunk, with branchy heads proportionably large; but the timber being of a soft light texture, is unfit for any strong purposes; is however excellent for numerous light uses, in the turnery and carving branches particularly.

But for purposes in gardening, the Lime-

tree has been long in great esteem for ornamental purposes, in various garden districts, being valued for its quick and fine picturesque growth and large elegant light-green foliage, that affect a very distinguishable diversity; was therefore in great repute formerly to plant for avenues, and arrange on the boundaries of extensive lawns, and other spacious open spaces, as well as to disperse in parks, &c. both as detached single objects, and in groups, also to plant in regular groves, and for shade; and in all of which, suffered to grow rural, and display their beautiful conic heads: they were likewise used for formal ornamental hedge-rows in large-gardens, and along near the fronts of houses by road sides, &c. and trained regularly by clipping them once or twice in summer; and were also often clipped into pyramids, hemispheres, arches, &c. though for the general part they are considerably better calculated for rural objects in natural standards than for any kind of hedge-work, or other regular training, especially as they generally begin to drop their leaves the earliest in autumn of any other tree, and, when clipped, soon appear naked: I should therefore advise all the sorts of Limes to be employed principally only as rural trees, and disposed at sufficient distances to allow them full scope to branch out all around, and exhibit their heads distinctly in their natural growth; and in which they will always appear considerably the most conspicuously ornamental.

Though from the circumstance of these trees shedding their leaves early in autumn, which is more peculiar to the large than smaller leaved kinds, they are not in such general repute to plant for ornament in gardens as formerly, because in very dry hot summers the leaves often begin falling in July or August, and cause a continual litter for a long time.

However, for the singularity of their handsome growth, and foliage, they highly demand culture both for variety, ornament, and shade; and the red-twigged sort has also an agreeable effect, even in winter, when entirely devoid of leaves.

These trees are likewise proper to plant as forest-trees, as they will soon arrive to timber; and the wood being soft and tough, is valued for making many sorts of household utensils, and for various light purposes in carved and turnery works, as before noticed.

For all of which purposes, these trees may be planted almost any where, as they will prosper in any common soil and exposure; are raised in abundance in all the nurseries, for sale, and may be transplanted any time in open weather, from October till March.

Method

Method of Propagation, &c.

The propagation of these trees is by seed, by layers, and by cuttings.

By Seed.—This ripens abundantly in October, which may be beaten down with a long pole, keeping the green-twigged and red-twigged sorts separate; and may either be sown soon after, or preserved dry and sown till spring; sowing them in a bed or border of common earth, previously digging the ground, and divide it into four feet wide beds; draw the earth off the surface evenly, about an inch deep, into the alleys; then sow the seeds thinly, touch them lightly down into the earth with the back of the spade; which done, directly earth them over, the depth just mentioned, which finishes the work of Sowing.

Being thus sown, they will all come up freely in the spring; at which time be careful to keep the beds clean from weeds, and give some moderate waterings in dry weather, to forward the plants in growth as much as possible, fit for planting out in nursery-rows by autumn or spring following; though, if they have shot rather weakly, let them stand another year: then planted out in rows two feet and a half asunder, by eighteen inches distance in the lines; here to remain three or four years or more to acquire due size to transplant for the purposes intended, trimming off large side-branches from the lower part of the stem occasionally, to encourage their aspiring more expeditiously at top, which must be always suffered to remain entire.

These trees, when raised from seed, generally in the end assume a more handsome and expeditious growth, than such as are raised from layers and cuttings.

When they are from about five or six to eight or ten feet high, they are of proper size for final transplantation: though if any are designed principally as forest-trees for timber, it is advisable to transplant them finally in their destined places, while they are young, and not more than from three or four to five or six feet high.

By Layers.—All the sorts grow freely by this method: and is also or by Cuttings, a very certain method to continue the varieties. For the purpose of furnishing layers, proper stools must be prepared (see STOOLS), and the young shoots of a year or two old, are the proper parts to lay; which should be performed in autumn or winter, by slit-laying, shortening the tops of each layer within a little of the ground: they will all be well rooted by autumn following, and mostly fit to plant out in the nursery in rows, and there managed as the seedling Limes just above directed.

By Cuttings.—Cuttings of all the sorts of Limes will grow, though not near so readily as layers: however, when cuttings are intended, chuse the strong young shoots of the year, in autumn or spring, and plant them in a moist good soil; or any scarce sorts may be planted several together in pots, and plunged in a hot-bed; they will more readily strike root.

TINUS.

Tree Volkameria.

Consist of one species, a tender exotic tree of America for variety in the stove; adorned with oblongish-ovate leaves, and branchy spikes of flowers: having a five-parted calyx and corolla, pitcher-shaped nectarium; nine stamina, single germen and style, and a trilocular berry, with a single seed in each cell.

Class and order, *Enneandria Monogynia*.

The species is,

TINUS occidentalis.

Occidental, or West-India Tinus.] Rises with an upright woody stem of branchy growth, garnished with oblong-ovate leaves; smooth above, sub-villous and nerved underneath: and terminal branchy flower spikes.

This exotic is retained in some of our principal stove collections, a plant or two, for variety; which being planted in pots of rich light earth, placed in the stove, the future culture is the same as other plants of that department, and may be propagated by seeds, layers, and cuttings, in pots plunged in the bark-bed.

TOLUIFERA.

Balsam of Tolu Tree.

It is a large tree of South America, retained here in stoves by the curious for variety; is adorned with large winged leaves, and bunches of pentapetalous flowers.

Class and order, *Decandria Monogynia*.

Characters.] CALYX is monophyllous, bell-shaped and quinque-dentate at top. COROLLA, five petals, four of them being linear and equal, but the fifth is twice as large as the others, and nearly heart-shaped. STAMINA, ten very short filaments, having antheræ longer than the calyx. PISTILLUM, an oblong germen, very short style, crowned with an acute stigma. PERICARPium and SEMEN, at present undescribed.

There is but one species, viz.

TOLUIFERA Balsamum.

Balsam of Tolu Tree.] Rises with a strong robust trunk, branching numerously and spreading, thirty or forty feet high, covered with a thick tough brown bark; large pinnated leaves, composed of several pair of ob-

long oval lobes, terminated by an odd one; and at the axillas small bunches of yellow flowers, having four smaller petals, and one large.

It grows naturally in the Spanish West-Indies, and in this country is retained in hot-house collections, a tree or two for variety; must be cultivated in pots, and placed always in the stove, and managed as other tree and shrub exotics of that department.

A balsam of great virtue is extracted from this tree, and is much used in medical compositions.

This tree is raised from seeds obtained from abroad by the seedsmen; which should be sown as soon as they arrive in pots of light earth, and plunged in the bark-bed; and when the plants are come three or four inches high, pot them off separately, giving water, and plunge them again in the bark-bed; and afterwards managed as directed for other woody exotics of the stove. See STOVE PLANTS.

TOMENTOSE Plants.

Such as are covered with *Tomentum*, being a sort of woolly or hoary, downy pubescence, which covers the surface of many plants, more particularly those that inhabit the neighbourhood of the sea; and many of which plants having their leaves and branches so closely covered with this substance as to give them a hoary white appearance.

TOURNEFORTIA.

Tournefortia.

Consists of several shrubby exotics from the West-Indies, and hot parts of America, and cultivated here in stoves for variety; one of which is a climber, the others erect growers, garnished mostly with oval and lanceolate simple leaves, and monopetalous infundibuliform flowers at the sides and ends of the branches.

Class and order, *Pentandria Monogynia.*

Characters.] CALYX is monophyllous, five parted, and permanent. COROLLA is monopetalous, funnel-shaped, with a cylindric tube; globular at the base, and with a spreading brim, cut into five acuminate horizontal segments. STAMINA, five awl-shaped filaments in the mouth of the corolla, having acuminate connivent antheræ. PISTILLUM, a globular germen, simple style, and single stigma. PERICARPium, a globose berry, having four roundish seeds.

This genus received the name *Tournefortia* in honour of M. Tournefort, the illustrious French Botanist.

There are many species in this genus, mostly of a shrubby nature, and perennial in root

and top; and the most noted sorts in the English gardens are the following; all of which being natives of the hot parts of America, require to be continued always in a hot-house in this country.

1. TOURNEFORTIA *volubilis.*

Volubilate-climbing-stalked Tournefortia.]

Rises with long, slender, woody volubilate stalks, twining round any adjacent support, fifteen or twenty feet high; oval, acuminate, smooth leaves, on reflexed foot-stalks; and small white flowers in loose spikes, at the sides and ends of the branches.

2. TOURNEFORTIA *suffruticosa.*

Under-shrubby Tournefortia.]

Rises with an under-shrubby stalk, branching moderately about three or four feet high; oblong, almost spear-shaped, hoary, whitish leaves; and small white flowers in bunches, at the sides and ends of the branches.

3. TOURNEFORTIA *serrata.*

Serrated-leaved Tournefortia.]

Rises with a shrubby, upright, thick stem, branching twelve or fourteen feet high, or more; having oval, serrated leaves on rough spinous foot-stalks; and white flowers in recurved spikes terminating the branches.

4. TOURNEFORTIA *fœtidissima.*

Most-stinking Tournefortia.]

Rises with woody stalks and branches, eight or ten feet high, or more, having oval-spear-shaped, hairy leaves; and white flowers, terminating the branches in ramose, pendulous spikes.

5. TOURNEFORTIA *cymosa.*

Cymose-spiked Tournefortia.]

Rises with woody branching stalks, six or eight feet high; large, oval-oblongish, naked, smooth, entire leaves; and white flowers terminating the branches in cymose spikes.

6. TOURNEFORTIA *hirsutissima.*

Most-hairy-stalked Tournefortia.]

Rises with woody very hairy stalks; ovate leaves, foot-stalked; and branching terminal spikes.

7. TOURNEFORTIA *humilis.*

Dwarf Tournefortia.]

Rises with shrubby, low, slender stalks, branching moderately two or three feet high, spear-shaped, close-fitting leaves, and white flowers in simple or unbranched recurved spikes, produced laterally, or along the sides of the branches.

8. TOURNEFORTIA *diffusa.* — Diffused-branching Tournefortia.

These plants remain in leaf, mostly the year round, and flower in spring or summer, &c. succeeded by small succulent berries, containing three or four seeds.

They being all very tender exotics, that require the continual shelter and heat of a stove,

stove, in this country must be cultivated in pots of good earth, and placed in the stove accordingly, and treated like other shrubby exotics of this collection, as directed under the article STOVE PLANTS.

All the sorts may be raised from seeds obtained from abroad, where the plants grow naturally; and it is advisable to sow them as soon after their arrival as possible, in pots of light mould, and plunged in a bark-bed; giving occasional sprinklings of water, and they will probably come up the first year; or if they should remain longer in the ground, continue to keep the mould in the pots all the while moderately moist; and when the plants are come up, and advanced three or four inches high, prick them out singly in small pots, and plunge them in the bark-bed, and continue them constantly in the stove.

Their propagation may also be tried by layers, &c. in pots plunged in the bark-bed.

TRACHELIUM.

Throatwort.

One hardy herbaceous perennial, of the flowery tribe, for the pleasure-ground, compose this genus; rising half a yard high, with oval leaves, and terminal umbellate bunches of monopetalous blue flowers.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is small, five-parted, and placed above the germen. COROLLA, one funnel-shaped petal, with a long, slender, cylindric tube; and divided at the brim into five small concave spreading segments. STAMINA, five capillary filaments, the length of the corolla, having single antheræ. PISTILLUM, a triquetrous, subrotundous germen, slender style, and globose stigma. PERICARPIUM, a roundish, obtuse, trilobate, trivalvovous capsule, of one cell, having numerous small seeds.

There is but one species, viz.

TRACHELIUM *caruleum*.

Blue Trachelium or Throat-wort.] Hath a thick, fleshy, fibrated, perennial root; upright stalks, about half a yard high; garnished with oval-spear-shaped, serrated leaves, and terminated by many small fine blue flowers, in a sort of umbellate clusters in June and July, ripening seeds in September.

It is a native of shady places in Italy and the East, and is cultivated in our gardens to increase the variety of ornamental-flowering perennials; planted in light dry soils, where it will abide several years: also, if sown in the crevices of old walls, ruins, and rock-work, they will flourish, and be of great duration; but when cultivated in rich moist soils,

they are not so durable, often proving biennial.

It is propagated by seeds sown in autumn, soon after they are ripe, or early in spring, in a bed or border of light earth: the autumn sowing will probably come up more freely than that of the spring. Observing when the plants are two or three inches, prick them in nursery-rows six inches asunder, to remain till autumn; then may be transplanted where they are to remain.

TRADESCANTIA.

Virginia Spiderwort, or Flower of a Day.

It is a hardy herbaceous perennial, of the flowery collection, for adorning the pleasure-garden; rising with erect annual stalks, a moderate height, ornamented with very long narrow leaves, and tripetalous flowers.

Class and order, *Hexandria Monogynia*.

Characters.] GALYX, three oval, concave, spreading, permanent leaves. COROLLA, three large, orbicular, plane, spreading petals. STAMINA, six slender, erect, hairy filaments, having kidney-shaped antheræ. PISTILLUM, an oval, obtusely-trigonous germen, filiformous style, crowned with a trigonal obtuse stigma. PERICARPIUM, an oval, trivalvovous, trilocular capsule, covered with the calyx, having numerous small seeds.

There are different species, but not more than one in the English gardens, viz. *Common Virginia Spiderwort*; comprehending several varieties, all hardy perennials.

TRADESCANTIA *virginiana*.

Virginia Spiderwort, or Flower of a Day.]

Hath a thick root, furnished with many fleshy fibres, crowned with many narrow leaves near two feet long; amidst them erect, thick, smooth stalks, two or three feet high; garnished with long, graminous leaves singly; and large tripetalous, blue, and other coloured flowers in the varieties, crowning the stalks in close clusters.

Varieties are,] Common pale blue-flowered—Deep blue-flowered—Purple-flowered—Red-flowered—White-flowered.

They all flower in June; each flower is generally but of one day's duration; hence the name *Flower of a Day*; but the same plant continues producing a plentiful succession of new flowers every morning, for a month or six weeks, succeeded by plenty of ripe seed in autumn.

This species, &c. is a native of Virginia, but have been many years in the European gardens as ornamental flowery plants, for the common borders; they may therefore be planted in any of the borders, or other compartments

partments of the pleasure-ground, in which they will abide by the roots many years, producing new stalks annually in spring, and flower very ornamentally every summer; and will multiply exceedingly both by their roots, and scattered or self-sown seeds; even so much as often to over-run the ground, and require trimming in to reduce them within proper bounds.

They are all easily propagated by parting the roots in autumn, or early in spring; also by seed sown in the spring, in any bed or border of common earth, and raked in; and the plants will rise plentifully, and be fit to prick out in summer, to gain strength till autumn, then transplanted finally.

TRAGOPOGON.

Goat's Beard.

Consists of hardy, herbaceous plants, mostly biennials, the principal of which in the gardens is an esculent called *Salsafy*, esteemed for its carrot-shaped, eatable root, and by some for the tender shoots of its young stalks in the spring, to eat like *asparagus*; are mostly tap-rooted plants, with the roots crowned with long narrow leaves, and with upright stalks in spring, of moderate height, surmounted by large compound flowers.

Class and order, *Syngenesia Polygamia Aequalis*.

Characters.] CALYX, a compound flower, having the general cup single, composed of eight spear-shaped leaves, alternately larger and joined at the base. COROLLA, the general flower is compound, imbricated, and uniform, composed of many monopetalous tongue-shaped hermaphrodite florets, five-parted at top. STAMINA, five very short filaments, having cylindric antheræ. PISTILLUM, an oblong germen filiforme style, crowned with two revolute stigmas. PERICARPIMUM, none; the seeds, one in each floret are angular, rough, crowned with down, and lodge in the swollen connivent calyx.

From the circumstance of the seed being covered with a pappus or down, as they remain in the cell, resembling a goat's beard, it obtained the name of *Tragopogon*, or Goat's Beard.

There are ten or twelve species, but many of which being plants of no estimation for use, are but little known; and the most noted sorts are, first the *salsafy*, an esculent, having an eatable root and stalks, &c. and two others sorts principally for variety: the first two sorts are biennials, and the third a perennial.

1. TRAGOPOGON perrifolius (Biennial).

Leek-leaved Tragopogon, commonly called Salsafy.] Hath a perpendicular, carrot-shaped, white, eatable root, a foot or more long, crowned with many long leek-shaped entire leaves, closely gathered; and when it runs to seed, rises with upright, hollow, smooth, whitish stalks two feet high, terminated with large compound blue flowers, having the peduncles thickest above, and the calyx longer than the radius.

It flowers in July, and the seeds ripen in autumn, then wholly decays.

This plant grows naturally in meadows in some parts of England, &c. but is cultivated in gardens in the manner of carrots, for its long carrot-shaped root, which attains a moderately large size by autumn and winter, when it is boiled for use, and served to table in different ways, and is very tender and palatable: also the young shoots of the flower-stalk in spring and summer, cut while young and tender, when only a few inches high, are dressed in the manner of asparagus, and served up to table with butter, &c.

It being a biennial, rises from seed in the spring, and attains perfection in the root in autumn following, remaining good all winter, and in spring after shoots up stalks for flower and seed, and the root then becomes sticky and useless, and totally perishes soon after the seeds are ripe.

2. TRAGOPOGON pratensis (Biennial).

Meadow Tragopogon, or Greater Yellow Goat's Beard.] Hath a taper fibrated root, crowned with very long, narrow, acute, entire leaves gathered together; upright stalks near a yard high, garnished with long narrow leaves singly at each joint; and terminated each stalk with one large compound yellow flower, having the calyx and radius of equal length.

Variety.] Smaller Meadow Tragopogon, having much narrower leaves, and stalks only a foot high.

Both the varieties flower in June and July, and the seeds ripen in September.

They grow naturally in meadows in England and most parts of Europe; and are sometimes cultivated in gardens for variety, and the young shoots in spring are often gathered and dressed, as observed of the *Salsafy*, being frequently brought to the London markets by the simplers who gather them in the meadows in April and May; or may be raised in gardens by sowing their seed in spring, in rows six or eight inches asunder, and the plants will shoot up for use in the spring following.

3. TRA-

3. *TRAGOPOGON Dalechampii* (Perennial.) *Dalechamp's Greater Hawkweed, or French Tragopogon.* Hath the root crowned with many large, oblong, runcinated, deeply indented leaves; low stalks only about five or six inches high, surmounted by one large yellow flower, having a monophyllous calyx shorter than the corolla, appearing in June or July, and the seeds ripen in autumn.

All these plants are hardy: the first two being biennials, rising one year from seed and the next shoot up into stalk, producing flowers and seed, then wholly decay; and the third is a perennial, durable in root, sending up stalks annually in spring, which decay in autumn.

The first species (*Tragopogon porrifolius*) is the principal sort for general culture, as an esculent, and as such merits culture in every kitchen-garden principally for its roots, as before observed, chiefly for autumn and winter use; they being easily raised from seed in the open quarters, and will arrive to perfection early in autumn, and continue good till they begin to shoot in spring following.

It is much cultivated in the London kitchen-gardens for market, where it is commonly brought in bunches, in autumn and winter.

The other two species are retained in some gardens for variety, and the second sort particularly: is also sometimes cultivated for its tender shoots in spring, as already hinted.

Method of Propagation, &c.

The *Salsify* is raised only from seed sown in spring, in March and April, in an open situation to remain; sowing it either broadcast and raked in, or in shallow drills, eight or nine inches asunder, scattering the seeds thinly, and cover them half an inch deep; and when the plants are come up two or three inches high, thin and weed them by hand or hoe, leaving them eight or ten inches asunder, repeating the weeding as may be required during the summer, which is all the culture they require; and they will have large roots by September or October; when you may begin taking them up for use; and in November, when the leaves begin to decay, a quantity may be taken up and preserved in sand for use in time of severe frost, when those in the ground cannot be dug up.

In spring, when those remaining in the ground begin to shoot, the shoots, when a few inches high, may be cut for use as before mentioned; which, when quite young and tender, being boiled, are excellent eating. Suffer, however, always a few plants to run up to stalk every spring, to produce seed for sowing.

The other two sorts may be raised also from seed like the *Salsify*, and the plants, when a little advanced in growth, may be

planted out if they are required for variety in any particular compartments. If the *Tragopogon pratensis* is required for its shoots, it should remain where sown, and thinned to proper distances.

But the third sort may also be propagated by parting the roots in autumn or spring.

TRAINED TREES.

For walls and espaliers.

The appellation of Trained Trees is to be understood principally of young fruit-trees designed for walls and espaliers, being trained in the nursery to the intended form, by planting them against any kind of walls, pales, reed-hedge, or other close fence, when a year old from the grafting or budding, training them in the manner of wall or espalier trees, for two, three, or more years, till they obtain a good spread of branches, arrived to a fruitful state, in order that any persons, being in haste to have their walls or espaliers covered at once with bearing trees, it may be effected in one season; as the trees thus trained in the nursery, &c. being transplanted in autumn or spring to the places intended, they will both cover the wall or espalier considerably at once, and bear a great deal of fruit the ensuing summer, if a favourable fruit season.

So that, whosoever may incline to have his walls thus at once furnished with bearing trees, without waiting three or four years longer for younger trees attaining a bearing state, may be supplied with such at all the public nurseries, where large quantities are always ready trained for sale, more particularly peaches, nectarines, and apricots for walls; likewise in many places, cherries and plums, &c. also apples, pears, and other fruit-trees for espaliers; and are very eligible both to furnish the walls and espaliers of any new garden, and occasionally those of old ones, either wholly or in part, to bear some fruit, till younger trees, planted untrained, come forward and become fruitful, or may be used occasionally to supply the place of very old trees that may happen to fail or bear bad fruit; in all of which, the planting of Trained fruitful trees may prove so far preferable to quite young untrained and unfruitful ones planted at the same time, in that there will be three or four years difference in the time of their bearing, which is a very material object of consideration; and that, if the Trained Trees are purchased in the public nursery gardens, you are freed from the trouble of the first training them to the requisite form, which requires particular attention the two first years, the effecting of which, often ruins many young wall and espalier trees at first setting off, when under the hands of ignorant practitioners,

tioners; and as to the expense of the purchase, between Trained bearing trees of five to ten shillings, and that of one or two years old untrained ones, of a shilling or eighteen pence, cannot be any great object to persons of fortune, or of any tolerable circumstances in life, at least to furnish some part of the best walls.

Therefore, in both public and private nurseries, it is of much importance to have some of the best sorts of wall and espalier trees always in training for walls, &c. against any kind of fence, either walling, paling, or reed-hedges, both dwarf and half-standard wall-trees; also against ranges of stakes in the open quarters, that there may always be some well trained spreading trees arrived to a fruitful state, to furnish any place as above occasionally with immediately bearing trees of some considerable spreading growth.

When, therefore, it is intended to raise trained fruit-trees for walls and espaliers, a quantity of the best young plants of the respective sorts, both dwarf and half-standards aforesaid, of one year old, with the first shoots from the budding and grafting entire, should be transplanted in autumn against any kind of fence of any aspect in a free situation, not less than four or five feet high; either a wall, paling, reed-fence, &c. before hinted, placing them five or six to eight or ten feet distance, and here to remain for training as below.

The trees being thus planted, then in spring following, just as they begin to make an effort for shooting, they should be headed down, that is the first main shoots produced last summer immediately from the budding, &c. to be cut down low, with a clean sloping cut upward, to within four, five or six eyes or buds of their origin, or place of insertion in the stock, especially those intended for dwarfs, also the half-standards, if worked on tall stocks; and this heading down both prevents their running up too high with a single naked stem, branchless below, and causes them to throw out lateral shoots from the lower part to fill the wall or espalier regularly with branches quite from the bottom upward; for being thus cut over low, they will soon after push forth strong shoots from all the remaining lower buds, sufficient to give the tree its first proper formation as a wall tree, &c. which shoots, when advanced in length in summer, should be trained along to the fence equally to the right and left, in a somewhat inclined position at full length till next spring, when these shoots may also be cut down to six or eight inches length, to force out a further supply of more branches near the bottom, for there is nothing like being well furnished with branches below, at first setting off, to form a good foundation,

whereby you will be able to keep every part of the wall from the very bottom to top covered with bearing wood; for no part of a good wall should be lost.

So that, agreeable to these hints, continue shortening more or less the two or three first springs on the last summer's shoots, as you shall see necessary, in order to obtain a proper spread of lower branches to give the tree its intended form; though this work of pruning short to obtain laterals may also be performed occasionally in summer, in May or early in June, on the strong young shoots of the year, cutting or pinching them down to a few eyes, and they will thereby throw out lower laterals the same season, and by that means a year's growth is gained.

According as the supply of branches thus gained by the above methods arrive to proper length in summer for training in, they should be accordingly all trained along close to the wall, and if any fore-right or back shoots come out, rub them all off close; leaving, however, all the well-placed side and terminal shoots in every part, and let the whole, or as many as possible, be trained in during this season, to have a plenty to chuse from in the general pruning season of winter or spring, training them close to the wall, &c. equally to the right and left as aforesaid, on each side of the tree, in a spreading somewhat horizontal manner, no where crossing one another but at parallel distances, and mostly all at full length during the summer's growth; thus to remain till the general winter or spring pruning.

In the winter pruning we are to observe, that if more wood was trained up in summer than now appears necessary; or that can be trained in with due regularity, should retrench such superfluities; likewise any remaining fore-right or back shoots and other irregular growths omitted in summer, not eligibly situated for training in, should also be now all pruned out, cutting every thing of the above nature, both superabundancies and irregularities, quite close to their origin; being careful, however, to leave all the regular, well-placed, useful shoots that can readily be trained with proper regularity, without crowding or crossing one another, all of which should also be cleared from all lateral or side shoots, if any; and with respect to their being shortened more or less, or left entire, you will order according to your discretion, agreeable to the above-mentioned hints, and also as noticed below, as the different sorts may require; though if any Rambler extend considerably beyond all the others, it must be reduced, or cut down to some lower shoot, consistent with the general form and extent of the rest of the branches; then,

then, after performing these regulations, proceed to the training and nailing in the whole close to the wall, &c. in exact order, by ranging them equally each way, in a spreading fanned manner, all as straight as possible, somewhat horizontally, no where crossing the branches, but all ranged parallel as aforesaid, one above another, four, five, or six inches distance, according to the sorts, making the opposite branches of each side range as equally as possible in the same position.

Thus, after having obtained a regular spread of branches, proceeding immediately near the head of the stem, sufficient to effect the proper expansion requisite to form a trained wall or espalier tree, they must then be pruned according to the method peculiar to each respective sort of fruit, as directed in their culture, each under its proper genus.—Some requiring the branches shortened annually, others to be trained mostly always at full length.

For in the general course of training and pruning wall trees and espaliers, it must be observed, that some sort of wall trees require almost a general shortening every year of the annual supply of branches, such as peaches, nectarines, and apricots, which always bear their fruit principally on the young year old wood, have that of each year shortened in the winter pruning, to force out a sufficient supply of succession shoots in proper places all over the tree for the future year's bearing: on the other hand, as apples, pears, plums, and cherries do not want an annual renewal of bearing wood, the same branches continue bearing from two or three to many years old; so that, after undergoing the operation of shortening the first two or three years wood, to obtain a spread of lower branches to effect the intended form as a wall or espalier tree, they are not afterwards, in the general course of pruning, to be shortened, but generally always trained at full length, except occasionally shortening some particular young shoot to fill a vacancy. See each kind under its respective head; also DWARF TREES, ESPALIERS, and the article of PRUNING, &c.

The training of espalier trees is effected exactly in the manner as above, only these may also be trained as they stand in the nursery lines, in the open quarters or borders, &c. by ranging some stout stakes in the ground along one side of each tree, not in a continued straight range immediately the way of the row, but those of each tree ranged separate and obliquely, somewhat cross-ways the row as it were, that the branches of the different trees may range beside one another, and thereby have

more room to extend the branches both ways, than the common distance in the nursery lines would admit, if ranged directly the way of the row.

Observe, that as it may sometimes happen some of the trained trees, both of the wall and espalier kinds, in the course of training, may assume a state of vigorous luxuriant growth, either in general, or in some particular parts, producing strong, rampant, rude shoots of a very unfruitful-like nature; they in such cases, should be ordered accordingly in a peculiar manner, till they have exhausted their redundancy of sap, or excessive luxuriance, and effect a more moderate state of growth.

Therefore, where a general luxuriance prevails, while under the course of training or after, it is advisable in the work of pruning to use the knife with moderation, in regard to thinning and shortening, and rather humour the trees somewhat, according to their natural tendency, by leaving the shoots and branches thicker or closer together than the common rule, and all at their full length, especially during the summer's growth; and to such as are usually shortened in winter pruning, as in peaches, nectarines, &c. they should be shortened much less in proportion; continuing those of apples, pears, plums, and cherries, always at their whole length; that in the whole, by dividing the sap amongst a greater number, as well as larger extent of branches, it checks the luxuriance which would take place in a smaller number and less extent of growth. For the more wood we cut out of a generally vigorous shooting tree, and the more the shoots are shortened, as often erroneously practised, the more vigorous will it continue to shoot without ever becoming properly fruitful; and if severe cutting is repeatedly continued, the tree often exhausts itself so greatly by luxuriant shooting, that it suddenly assumes a weak consumptive state.

But that the natural inclination of very vigorous young trees being somewhat indulged at first by training as many branches as can be conveniently laid in, and those that require shortening, cut but moderately, or some very luxuriant ones hardly at all, which being practised two or three years with discretion, it will gradually reduce the trees to a moderate growth, and good state of bearing; when they may be ordered in the common way peculiar to the different sorts.

On the other hand, such trees as are vigorous only in particular shoots, may, in some cases, have such shoots radically retrenched, and in others reserved; that if a very vigorous shoot runs considerably stronger than all the

rest, and seems to support its vigour at the expense of the others in its neighbourhood, it should be retrenched to the very origin, as early in the summer as discoverable; in other cases, if a luxuriant shoot arise in any vacant space, towards the bottom especially, where a supply of more wood is wanted, it may be retained, and pinched or topped down to a few eyes in May or June, it will send out several laterals below, the same season, and instead of one rude luxurious shoot, there will be four or five probably of more moderate growth to fill the vacancy more effectually, and that will much sooner attain to fruitfulness.

Thus far is chiefly all we have to observe relative to the ordering of Trained wall and espalier trees in the nursery, which being in training from three to four or five years, they obtain a handsome spread of fruitful branches, fanned in the requisite regular form for the purposes intended; so as when planted in the garden, they at once cover a large space of walling, &c. bearing good fruit the following summer.

Other particulars respecting their culture, after being planted in their destined places, in the garden, are exhibited under the heads separately of the respective sorts. See also DWARF TREES, ESPALIERS, and PRUNING.

Notwithstanding what we have here advanced respecting the planting of Trained Trees for walls, &c. we would also observe, that for any general plantation, unless good Trained Trees can be readily obtained, from three or four to five or six years old, of a clean free growth, it will be better to plant entire young trees of one or two years old, immediately from the nursery rows untrained, planting them at once where they are to remain, and they will probably root more effectually, and assume a freer growth than stunted Trained Trees, managing them as directed for the Trained Trees, to give them the proper formation, and afterwards agreeable to the rules of pruning directed for the different sorts in their proper places.

But some, to have as great a chance as possible, plant both young untrained trees to remain, and Trained Trees of a bearing state, dwarfs and half-standards between, so as to cover the wall more effectually at once, and furnish a supply of fruit directly, as it were, and until the young ones are trained and arrive to bearing; then according as the trees of both sorts advance in that state of growth, those which appear the most prosperous are retained, and the others are gradually cut away,

leaving the more thriving trees to occupy the wall wholly at last.

In most of the public nurseries, they raise many Trained Trees for sale, which occupy all their close fences of walls, pales, or reed-hedges, planted near together, and after being in training two, three, four, or more years, till of a good spread and become fruitful, they are ready for sale, and fetch a very good price, generally from three to five or ten shillings per tree, according to the sorts, age, and goodness of growth; which pays well for the trouble of training, as any sort of fence of any aspect, openly exposed, serves for training them to the proper form.

TREILLAGE, Or TREILLIS.

A *Treillage* is ranges of stakes and railing on which to train espalier trees; also occasionally for wall trees, where the wall does not admit of nailing the branches immediately against it; likewise for training wall-trees in forcing frames, &c. and may be of different degrees of taste for use and ornament, as well as of different dimensions, from four or five to six or seven feet high, as noticed below.

For common espalier fruit-trees in the open ground, a Treillage is absolutely necessary, and may either be formed of common stakes or poles, or of regular joinery work.

The cheapest, the easiest, and soonest made Treillage for common espalier trees, is, that formed with any kind of straight poles or stakes of underwood, as cut in the coppices or woods, being cut into proper lengths, and driving them in the ground in a range a foot distance, all of an equal height, and then railed along the top with the same kind of poles or rods, to preserve the whole straight and firm in a regular position. See ESPALIER.

Therefore, to form a Treillage of this kind, we must provide some bundles of straight poles or rods, either of ash, beech, or of any other firm durable wood; which, if in the country, may be readily obtained in the adjacent woods or coppices, at a moderate expense, and are sold at many of the timber yards in the vicinity of great towns; choosing such as are perfectly straight and of sufficient substance, i. e. full an inch and half thick, cutting them into six or seven feet lengths, and having pointed them at one end, drive them with a mallet into the ground in a straight range close along behind the row of trees, a foot deep at least, and the same distance in the line; after which saw them even at top, all of an equal level four or five feet high; then let slips of deal or straight poles be ranged horizontally along the top the whole length, and nailed down to each stake,

stake, which finishes the whole firmly in a straight range, as well as gives an air of greater uniformity; and when thus finished, the branches of the espalier trees are to be trained and extended along horizontally from stake to stake, as directed for the different sorts under their proper heads, and in the article *ESPALIER*.

To render the above sort of Treillage still stronger, may run two or three horizontal ranges of rods along the back part of the uprights, a foot or eighteen inches asunder, fastening them to the upright stakes either with pieces of strong wire twisted two or three times round, or by nailing them.

But where a more elegant and ornamental Treillage, of joinery work, is required in any particular district, it is formed with regularly squared posts and rails of hard timber, neatly planed and framed together; having for this purpose deal or oak posts, uniformly worked two or three inches square; but if the main posts are of oak, it will be of particular advantage in respect to strength and durability, fixing the main posts in the ground ten or twelve feet asunder, with smaller ones between, ranging the horizontal railing from post to post in three or more ranges; the first being ranged about a foot from the bottom, a second at top, and one or two along the middle space, and, if thought convenient, may range one between each of the intermediate spaces; then fix thin slips of lath, or the like, upright to the horizontal railing as far as the branches of the trees extend, ten inches or a foot asunder; and paint the whole white in oil colour, to render it more ornamental and durable; and in training the trees, tie their branches both to the railing of the Treillage, and to the upright laths, according as they extend in length on each side.

In either of the above Treillages for an espalier, five feet is generally of sufficient height, as if much higher, the winds, having greater power, will loosen and displace them.

Treillages for wall trees are in some places necessary, where the walls are built with large stones with the joints irregular and far asunder, not affording opportunities like brick walls, for nailing properly in the regularity required; in which case a neat Treillage is eligible, erected all along close to the wall, on which to train and nail or tie the branches in regular order.

This kind of Treillage may also be formed with rods or strong laths, arranged horizontally and upright, chequer fashion, fastened and framed together closely to the wall with iron hooks and pieces of wire, as below.

That being provided with a due quantity of clean straight rods or poles, or squared laths an inch and half thick, and a quantity of hooked iron holdfasts, which are previously driven into the joints of the wall in rows at regular distances, projecting about an inch or inch and half to receive the rods or laths, both horizontally and perpendicularly, nine or ten inches asunder; fixing the first row of holdfasts towards the top, the second near the bottom, and the third along the middle space; this done, and the rods or laths ready, the latter, if thought proper, may be squared and planed, then proceed to frame the Treillage by first fixing the rods horizontally in three rows, in the three ranges of hooks, as above; observing, these horizontal rods should be previously chopped off to nothing at each end, so as they may be readily spliced to one another to extend them in length as far as required; thus, having fixed up the three first rows of horizontal poles, fasten up some uprights or standard rods in front of the horizontal ones, five or six feet distance, then range the remainder of the horizontal laths behind the standards, nine or ten inches asunder, fastening them with wire to the uprights, and being all thus placed and fixed, the rest of the standards are fastened up in front at the same distance, and the whole is made fast with wire twisted round the hooks and the crossings or intersection of the rods of the Treillage.

Or a Treillage of the above kind may be formed of squared laths, about an inch and half thick, planed even and smooth, and neatly framed together by mortise and nailing, &c.

When the Treillage in either of these methods is finished, it is advisable to paint the whole all over with white lead, to render it both more beautiful and durable.

In forcing frames and stoves, where wall trees are intended for forcing, as they are planted both against the back wall, and occasionally in a detached low range forward towards the middle or front space, a Treillage is indispensably necessary upon which to arrange the branches of the trees in a regular expansion, not to train them immediately close to the wall of the flues of that department, but the Treillage erected detached several inches therefrom; formed with light neat squared upright battens, and small horizontal rails, uniformly framed together in a light open erection.

TRIBUS.

Tribes of Plants.

As the whole vegetable creation is distributed systematically into classes, orders, genera,

nera, and species, &c. according to the sexual system, there are numbers of plants in these different artificial arrangements, that, although they differ essentially in the fructification or sexual distinction, yet are nearly allied in some essentials in their general growth, habit, and appearance; and may, therefore, agreeable to nature's system, be divided into Tribes according to the affinity they bear to one another in their nature of growth, either in general, or particular parts, &c.

For example, they may be considered as forming different Tribes according to the following natural orders.

Herbaceous Tribe.] All plants of the herbaceous or herb kind, rising mostly with leaves immediately from the root, and with soft herbaceous stalks not becoming woody, but mostly die at the end of the same year they were produced.

Ligneous or Woody Tribe.] All trees and shrubs having woody durable stems and branches.

Arboreous Tribe.] All plants of the tree kind, rising with an upright main stem to a lofty stature. See ARBOR.

Fruticose or Shrubby Tribe.] Plants of the shrub kind, rising but a moderate height, and divide low into several stems, &c. branching in a somewhat bushy manner.

Deciduous Tribe.] All kind of trees, shrubs, and other plants that cast their leaves in winter.

Sempervirent or Evergreen Tribe.] The various trees, shrubs, and other plants that retain their green leaves the year round.

Annual Tribe.] Annual plants, called annuals, being such as are only of one year's duration. See ANNUAL PLANTS.

Biennial Tribe.] Plants of two years' duration. See BIENNIAL PLANTS.

Perennial Tribe.] Plants that are perennial or of many years' duration, and is applicable both to herbs and trees, though more generally applied to herbaceous perennials. See PERENNIAL PLANTS.

Fibrous-rooted Tribe.] All kind of plants with fibrous roots. See RADIX.

Bulbous-rooted Tribe.] Plants with bulbous roots, such as the onion, tulip, lily, &c.

Tuberous-rooted Tribe.] Plants with thick, knobbed, fleshy roots, such as the anemone, potatoe, and Jerusalem artichoke.

Succulent Tribe.] Plants with fleshy, juicy leaves, as in *sedum*, *cactus*, *mesembryanthemum*, *aloe*, *agave*, &c. See SUCCULENTÆ.

Pinnated Tribe.] All sorts of trees and other plants that have pinnated or winged leaves.

Ensataceous or Sword-leaved Tribe.] Plants with sword-shaped leaves, as in *iris*, *gladiolus*, &c.

Spathaceous Tribe.] Plants producing their flowers out of a spathe or sheath, as in *narcissus*, *galanthus*, and *amaryllis*, &c. See SPATHACEÆ.

Liliaceous Tribe.] Plants producing flowers with six petals, or distinct segments, resembling a lily in form, such as the tulip, &c. See LILIACEÆ.

Papilionaceous Tribe.] Plants that have papilionaceous or butterfly-shaped flowers, such as all the pea and bean kind, and all the other leguminous plants. See PAPILIONACEÆ.

Leguminous Tribe.] Plants having that kind of seed-vessel called a legumen, legum, or pod, as in all the pea, bean, kidney-bean, and other papilionaceous-flowered plants.

Campanaceous Tribe.] Plants with campanulated or bell-shaped flowers, as the *campanula* and *convolvulus*, &c.

Rotaceous Tribe.] Plants with rotated or wheel-shaped flower, as in *lysimachia*, *anagallis*, &c.

Umbelliferous Tribe.] Plants producing their flowers in an umbel, as in *angelica*, *anethum*, *pastinaca*, &c. See UMBELLA.

Verticillate Tribe.] Plants producing their flowers in a verticillus or whorl, as in *thymus*, *hyssopus*, *melissa*, *origanum*, *sclaria*, *mentha*, &c. See VERTICILLATÆ.

Aggregate Tribe.] Plants producing their flowers in an aggregate, consisting of numerous small flowers or florets, each having its proper calyx, and all collected into a close aggregate head, as in *scabiosa*, *statice*, *globularia*, &c. See AGGREGATE.

Composite or Compound Tribe.] Plants with compound flowers, consisting of numerous florets contained in one common calyx, as in sun-flower, marigold, aster, &c. See COMPOSITUS FLOS.

Amentaceous Tribe.] Plants producing their flowers in amentums or catkins, as in *populus*, *corylus*, *fagus*, *betula*, &c. See AMENTACEOUS FLOWERS.

Coniferous Tribe.] All trees and plants bearing that kind of fruit called a cone. See CONIFERÆ and CONUS.

Baccaceous Tribe.] All berry-bearing plants.

Pomaceous Tribe.] Plants bearing fruit of the apple kind (*pomum*) as in the *pyrus malus*, *pyrus communis*, *pyrus cydonia*, *amygdalus*, *prunus*, *mespilus*, *punica*, &c.

Nuciferous Tribe.] All nut-bearing plants.

Oleraceous Tribe.] Esculent or eatable plants for the table, and other domestic uses.

Lurid Tribe.] Plants of an ominous appearance, hurtful or noxious; as in *atropa*, *datura*, *nicotiana*, *solanum*, *capsicum*, *digitalis*.

Fungous Tribe.] Mushrooms, and all plants similar.

Graminous Tribe.] Grassy plants: all plants of the grass and corn kind.

TRICHOMANES.

Maiden-Hair Fern.

A genus composed of herbaceous plants of the fern tribe; of which two perennials are retained in our garden collections for variety, one for the green-house and one for the pleasure-ground; rising with compound leafy stalks or fronds, formed of the main foot-stalk of united compound leaves of the pinnated kind; producing minute, imperfectly-visible flowers and seeds on the back of the leaves.

Class and order, *Cryptogamia Filices*.

The species are,

1. TRICHOMANES canariense.

Canary Maiden-Hair Fern.] With frondose stalks; supra-decompound leaves, having the folioles alternate, and these pinnatifid alternately.

2. TRICHOMANES tunbrigense.—Tunbridge Maiden Hair.

Both the species are herbaceous perennials, curious in their peculiar frondose growth; they form a distinguishable curious variety in assemblage with other different plants; the first sort to be stationed among the green-house exotics, and the second in the pleasure-ground compartments; planting the former in pots of light earth, for moving to the green-house in winter; and the latter may be disposed in any dry border, &c. or some also in pots, in order for placing in any particular situation occasionally.

They are propagated by slipping or dividing the roots in autumn or spring; planting the slips as above.

TRIFOLIUM.

Trefoil, or Clover, &c.

The plants are herbaceous annuals, biennials, and perennials, rarely cultivated in gardens, but of great estimation for pasture lands as fodder for cattle; have all fibrous roots, crowned mostly with tufts of small trifoliate, or three-lobed leaves, and send up stalks in summer a foot or two high, and some trailing; adorned also with trifoliate leaves, and terminated by small papilionaceous flowers in heads or spikes.

Class and order, *Diadelphia Decandria*.

Characters.] CALYX is monophyllous, tubular, five-parted at top, and permanent. COROLLA is papilionaceous, having the vexillum reflexed and with short wings and carina. STAMINA, ten diadelphous filaments, having

simple antheræ. PISTILLUM, a nearly oval germen, awl-shaped style, crowned by a simple stigma. PERICARPIUM, a short univalvular pod, containing a few roundish seeds.

There are near fifty different species of *Trifolium*, but many of them being plants of but little value or estimation, either for garden or field culture, are rarely cultivated; so that the most material sorts are the following first two species.

1. TRIFOLIUM pratense.

Meadow Trefoil or Red Dutch Clover.]

Rises with many slender branchy stalks near two feet high; having trifoliate leaves of three large folioles; membranous stipulæ placed opposite round the foot-stalks; and monopetalous reddish-purple flowers in hairy spikes or tufts, at the ends of the branches, in May and June.

Varieties.] Purple-leaved—White flowered.

2. TRIFOLIUM repens.

Creeping White Dutch Clover.]

Hath trailing, creeping stalks, spreading and rooting at the joints; trifoliate leaves; and white flowers growing in umbellate heads at the sides and ends of the branches, succeeded by pods having four seeds.

3. TRIFOLIUM fragiferum.—Strawberry Trefoil.

Both the first species of Trefoil or Clover are found in abundance in our meadow and pasture grounds, and are the only sorts of this genus for general culture in laying down grass-land, and are raised from seed sown in May or autumn as directed below.

They are perennials, though the first often proves only biennial, by sometimes dying away after it has ripened seeds, but the second sort is always perennial, growing very close and thick, is more valuable than the other for continued pasture.

However, the first sort, or red Dutch Clover, grows abundantly, producing wonderful great crops, and is most excellent for laying down land to cut for fodder for all kinds of cattle for two years; for, on account of its biennial nature above-mentioned, it does not always succeed well much longer; though if it is close eaten in summer, or mowed down when coming into flower, it shoots out below from the root again, and often proves somewhat perennial; but considered as a biennial, the farmers commonly sow it with barley in the spring, and when the barley comes off in July or August, the Clover spreads and covers the ground, and shoots up strong early next summer, either to feed off, or mow for hay; and after standing two years, they generally plough the ground again for corn.

But the second sort, creeping white Dutch Clover,

Clover, is more valuable than the other for laying down ground, designed to be continued long in pasture, its seeds being mixed and sown with grass; and as it grows low and close, with trailing abiding shoots, spreading every way, and rooting at the joints, it soon overpreads the ground, and forms a close thick sward, of many years duration; and affords the most excellent feed for all sorts of cattle.

Both the sorts are propagated by seed, which is sold by all the seedsmen, generally at so much per pound; and from six to eight or ten pounds is the allowance for an acre.

The season for sowing it is principally in the spring, in March and April, or may be sown in autumn, any time in August, or early part of September; is generally mixed with grass seeds, and sown broad cast and lightly harrowed in with a short-toothed harrow, and in a day or two after, when the surface is dry, roll the ground with a horse wooden roller, to break the clods and smooth the surface; but the farmers commonly sow these seeds with corn, such as barley, &c. for the sake of making the most of the land, and when the corn comes off, the Clover and grass take their growth, though it will prove much more prosperous and forward if sown alone, as the corn, when very thick and high, is apt to retard its growth, and sometimes spoil the crop.

TRILLIUM.

Herb True-Love of Canada.

A genus furnishing, for the pleasure-ground, some low tuberous-rooted flowery perennials, of but five or six inches growth, garnished with smaller and larger-ovate leaves, and tri-petalous, purple flowers, nodding and erect, in different species.

Class and order, *Hexandria Trigynia*.

Characters.] CALYX, a spreading three-leaved cup. COROLLA, three oval petals, a little larger than the cup. STAMINA, six erect, awl-shaped filaments, topped with oblong terminal antheræ. PISTILLUM, a roundish germen, slender, recurved style, and simple stigma. PERICARPium, a roundish three-celled berry, containing many roundish seeds.

The species are,

1. TRILLIUM *cernuum*.

Nodding-flowered Trillium.] Hath a tuberous root with many fibres, the stalk rises single naked, about five or six inches high; with three oval, smooth leaves, spreading out at the top, from between the three leaves; the flower arises upon a short foot-stalk, nodding downward; it is of a whitish-green with-

outside, and purple within; making its appearance in April.

2. TRILLIUM *seffile*.

Scffile-flowered Trillium.] Hath a tuberous root, sending forth many fibres; the stalk rising about the height of the other sort, with three larger oval, pointed, maculated leaves; and a dark-purple flower without foot-stalk; and long, narrow, and erect petals, appearing in April and May.

3. TRILLIUM *erectum*.—Erect-flowered True-love.

These plants require a light soil and shady situation; they are propagated by seeds sown on a shady border, soon after they are ripe; and in the following spring they will make their appearance in summer, must be kept from weeds, and in autumn may be transplanted where they are intended to remain to blossom.

TRIOPTERIS.

(*Triopteris*).

This genus furnishes for the green-house or stove, a climbing woody exotic from the West Indies, garnished with oblong leaves, and yellow flowers with five petals, ten stamina, and three styles, succeeded by trilocular capsules, containing three seeds, furnished each with a membranous wing.

The species is,

TRIOPTERIS *Jamaicensis*.

Jamaica Triopteris.] This being a tender exotic, it must always be kept in pots, and placed among the green-house or stove plants, in which it will effect a desirable variety; and is propagated by cuttings, assisted by a hot-bed; also by layers; likewise by seed.

TRITICUM.

Wheat.

This universally noted genus consists of hardy herbaceous plants, mostly annuals or biennials, valuable for producing that most excellently useful grain called Wheat; are fibrous-rooted plants, rising with grassy leaves, and upright, tall, slender stalks, terminated by close spikes of chaffy flowers, succeeding to spikes or ears of corn.

Class and order, *Triandria Digynia*.

Characters.] CALYX is a bivalvous chaff, having the valves oval, obtuse, and concave, containing sometimes four, several, or but two florets. COROLLA, small bivalvous florets, as large as the calyx, having the outer valve bellied and pointed, and the inner one plane. STAMINA, three hair-like filaments, with oblong forked antheræ. PISTILLUM, a turbinate germen, two capillary reflexed styles, and plumose stigmas. PERICARPium, none;

one oval-oblong seed for each floret, obtuse at both ends, and wrapped up in the corolla.

There are many different species of Wheat, the principal sorts of which are,

1. *TRITICUM hybernium*.

Winter or Common Brown Wheat.] Hath long spikes or ears, having four florets in each calyx; and the grains of corn ranged in four rows, in an imbricated manner, with smooth, ventricose, or bellied chaff, almost without beards or awns.

This is commonly sown in autumn to stand the winter; hence called Winter Wheat.

2. *TRITICUM aestivum*.

Summer or Spring Wheat.] Hath spikes with bellied smooth calyxes, ranged imbricatum, containing four flowers each, and are furnished with awns.

This sort is sometimes sown in spring, as it ripens much earlier in summer than the other.

3. *TRITICUM turgidum*.

Turgid or Duck-bill Wheat.] Hath large thick turgid spikes with bellied hairy calyxes, placed imbricatum, having four florets each, and mostly furnished with awns.

4. *TRITICUM polonicum*.

Polonium or Poland Wheat.] Hath long spikes with naked calyxes, having two flowers in each, which are long, and furnished with awns or beards.

5. *TRITICUM quadratum*.

Four-rowed Conical Wheat.] Having oblong conical spikes, armed with long awns or beards.

These are the principal species of Wheat generally cultivated, and which comprehend several varieties, differing somewhat in the form of their spikes and chaff, &c.

But the sort proper to cultivate for general use, is principally the Winter or common brown Wheat without awns; though all the sorts are also occasionally cultivated in different parts of the country.

All the sorts of Wheat may be considered both as annuals and biennials; for considered as annuals, that being sown in the spring, they shoot up to stalk, and produce ripe corn the same year in autumn, and wholly perish soon after; and as biennial, that being sown in autumn, as practised for the Winter, and Turgid Wheat, &c. the plants rise the same year, stand all the winter, and shoot to stalk and corn in spring and summer following, and totally die in autumn, as soon as the corn is ripe.

These plants having spreading fibrous roots, they generally rise with several stalks, especi-

ally if they have room to spread, in which case they often produce from five or six to eight or ten stalks, each stalk terminated by a spike of corn.

They shoot up into stalk in May, and flower in June, consisting of numerous chaffy florets, collected into long close spikes at top of the stalks, each chaff or calyx containing two, three, four, or more chaffy florets, and mostly placed imbricatum or over one another like scales of fish, all along the spike, some entirely without awns, and some with, either less or more, as in their description, and succeed to ripe heads of corn in July or August, fit to reap and stack up for use.

As to the propagation of Wheat, it is effected by seed sown every year, principally in autumn, from August or September until November, and occasionally in the spring; the ground being previously well ploughed for the reception of the seed, allowing generally two or three bushels to an acre; which for the general part is sown broad-cast and harrowed in, and in some places in drills drawn by the drill plough, &c. a foot distance or more, which method of sowing requires a considerably less quantity of seed than the broad-cast sowing, and affords opportunity of horse-hoeing between the rows to kill weeds, and stir the surface of the earth about the plants; which, as having more room, generally grow stronger and produce a greater number of stalks on each root, than such as grow close in the broad-cast; though as the broad-cast sowing is the most ready and expeditious method, it is the most generally practised for sowing Wheat, and almost all sorts of corn.

TRIUMFETTA.

Triumfetta.

Comprises two tender exotics, a shrubby, and an herbaceous plant, natives of the Indies, and retained here in stoves for variety; rise with erect stalks several feet high, adorned with roundish leaves, and pentapetalous flowers in spikes at the ends and sides of the branches, succeeded by round bur-like capsules.

Class and order, *Dodecandria Monogynia*.

Characters.] CALYX, five spear-shaped deciduous leaves. COROLLA, five linear, concave, retroflexed petals. STAMINA, twelve or fifteen awl-shaped rising filaments, having single antheræ. PISTILLUM, a roundish germen, a single style the length of the stamina, having a bitid acute stigma. PERICARPIUM, a globular prickly capsule, having four cells, each containing two seeds.

There are two species, one a woody perennial,

nial, the other an annual, but the former of which is the sort commonly kept in the English gardens.

TRIUMFETTA Lappula.

Jamaica Triumfetta.] Rises with an upright woody stem, dividing upward into a few branches, and grows five or six feet high; roundish trilobed leaves, emarginated at the base; and numerous small yellow flowers, collected in spikes at the ends of the branches.

It must be always kept in pots, and placed in the hot-house or stove, and managed as other ligneous plants in the stove collection.

It is propagated by seed obtained from abroad, sowing it in a hot-bed, or in pots, and plunged in the bark-bed, where the plants will soon come up; which, when advanced one, two, or three inches high, should be planted in pots separately, and placed in the bark-bed of the stove, &c. to remain till well fresh-rooted.

TROLLIUS, Globe Ranunculus.

Globe Flower or Locker Gowls.

They are hardy, herbaceous, flowery perennials for adorning the flower garden; have fibrous roots, crowned with divided leaves and upright annual stalks, two feet high, terminated at top with large polypetalous globular flowers.

Class and order, *Polyandria Polygynia.*

Characters.] *CALYX*, none. *COROLLA*, about fourteen nearly oval connivent petals, and nine narrow, incurved, umbilicated nectariums. *STAMINA*, numerous bristly filaments, having erect antheræ. *PISTILLUM*, numerous germina, sitting close in a columnar form; no style, but the germen crowned by pointed stigmas. *PERICARPIUM*, numerous capsules collected in a head, each having one seed.

There are only two species, both perennials, one an European plant, the other an Asiatic exotic, but both hardy enough to grow in the open ground all the year.

1. *TROLLIUS europæus.*

European Globe Flower, or Locker Gowls.]

Hath a black, fibrous, perennial root; sending up many roundish leaves, deeply cut into five segments, which are also divided and notched; upright stalks, about two feet high, dividing into branches upwards; each terminated by one large globular yellow flower, having the petals connivent or converging together, and the nectaria the length of the stamina.

2. *TROLLIUS asiaticus.*

Asiatic Globe Flower.] Hath a fibrous perennial root, crowned with large divided leaves, upright stalks, near two feet high,

dividing into branches, terminated each with one large saffron-coloured flower with spreading petals, and the nectaria the length of the corolla.

Both these plants flower in May very ornamentally, each flower being large and elegant, composed of many large concave petals; which in the first sort particularly, converge or turn inward in a revolute manner, so as to give the flower a perfect globular form; hence is called Globe Flower, and is succeeded by plenty of ripe seed in autumn; but the flower of the second species *Trollius asiaticus*, is not connivent but spreads out, and exhibits the nectariums and stamina, also of a fine saffron-colour, effecting an elegant singularity, and is sometimes succeeded by ripe seeds in our gardens; and by seed both the sorts may be raised, and they also multiply exceedingly by the root, which will be of many years duration, and produce flowers annually.

As therefore those plants, when in flower, effect a singular variety, they merit a place in every curious collection in the compartments of the pleasure-ground; and the season for planting them is in autumn when the leaves decay, or early in spring.

Remarking, however, that as they are natives of moist, shady places, they are generally the most prosperous planted in such situations in gardens, though they will also succeed in any of the general compartments, in common with other hardy perennials.

Their propagation is accomplished by parting the roots, and occasionally by seed.

By parting the Roots.—Autumn, when the leaves decay, is the best season to perform it, or early in the spring, taking up the roots, and divide them into several parts, not, however, into two small slips; and plant them either where they are to remain, or in nursery rows for a year; they will grow freely, and mostly flower the summer following.

By Seed.—Sow it in a somewhat shady border in autumn or spring in shallow drills, and cover it almost half an inch deep, they will readily grow and produce plants fit to plant out in summer, or towards autumn, in rows half a foot asunder, to remain six or eight weeks to acquire strength, then planted out finally.

TROPÆOLUM.

Indian Cress, commonly called *Nasturtium*.

Consists of herbaceous annuals or perennials, of trailing and climbing growth, in estimation for effecting variety in the pleasure-ground in summer, and in the kitchen garden for domestic occasions, in the same season, and one sort for the green house in winter; grow with long trailing stalks; some of slender

slender moderate growth, others strong and rampant, extending many feet along the ground, or upon support, adorned with large roundish peltated or shield-shaped leaves, and numerous pentapetalous flowers all along the branches, of singular structure.

Class and order, *Ostendria Monogynia*.

Characters.] CALYX is monophyllous, horned, coloured, divided into five, acute, erect, spreading segments, and is deciduous. COROLLA, five roundish petals, inserted into the divisions of the calyx; the two upper ones sit close, and the three lower ones have oblong ciliated tails or claws. STAMINA, eight short, declinated, unequal filaments, having erect, oblong, rising, quadrilocular antheræ. PISTILLUM, a roundish, trilobate, streaked germen, single erect style, and a trifid, acute stigma. PERICARPIUM, three roundish, convex, furrowed berries, having three roundish, furrowed seeds, with one side gibbous, the other angular.

There are only two species common in the English gardens; considered principally as annuals, but if sheltered in winter in a greenhouse, will prove of a perennial nature, as exemplified in the double *Nasturtium*.

The species are,

1. *TROPÆOLUM minus*.

Minor or least Nasturtium.] Hath dwarfish slender trailing stalks, branching and extending moderately along the ground, or upon any support; large, roundish, or orbicular peltated, slightly-scalloped entire leaves, of a grey colour, having the footstalk inserted into the centre; and numerous yellow flowers at the axillas, all along the side of the stalk and branches; all the flowers having acuminate petals.

Varieties.] Pale yellow-flowered—Orange-coloured.

2. *TROPÆOLUM majus*.

Major or greater Nasturtium.] Hath large, very long, trailing stalks, branching and extending ten or fifteen feet or more along the ground, or on support, garnished with large, orbicular, peltated leaves, somewhat slightly five-lobed; having the foot-stalks inserted into the centre; and numerous large yellow flowers at the axillas, all along the sides of the branches; with all the flowers having obtuse petals.

Varieties.] Pale yellow-flowered.—Orange-coloured flowers.—Double-flowered, commonly called Double *Nasturtium*, retained generally as a green-house plant.

Both these species of *Tropæolum*, and respective varieties, flower in great profusion from June until autumn, or till killed by the frost; and the flowers are of singular form, being, in their single or characteristic state,

composed of five unequal petals, the two upper ones large, and the three lower ones narrow, with long tails joining together, and extended considerably behind; but in the Double *Nasturtium* the petals are multiplied exceedingly, even to the exclusion of the generative organs, and consequently no seed is produced; but in all the common single varieties the flowers are succeeded by great plenty of seed, contained in roundish, berry-like, green fruit. See the *Characters*.

These plants are all hardy enough to grow any where in the full ground all summer, until October or November, but are unable to endure the cold in winter.

They are generally deemed annuals, as they rise from seed in the spring, attain full perfection, flower, and produce seed the same year, and totally perish the ensuing winter, if in the full ground; but if any are raised in pots, and removed under shelter of a greenhouse, or good garden-frame, under glasses, at the approach of cold weather, they will stand over the winter, and may thus be preserved several years, as practised for the double *Nasturtium*; and, like that sort, be propagated also by cuttings, planted in the spring; though as they are easily raised in great abundance from seed sown in spring or summer in the full ground, the preserving them over the winter is rarely attended to, except to a plant or two, by way of variety: and always for the double sort in particular, as not producing seed, nor, if it did, would there be any certainty of continuing its doubleness by that method, is therefore propagated always by cuttings, and kept in pots to have shelter in winter.

All the sorts are cultivated in gardens, both as flowery plants, and for economical uses in their flowers and seed for sallads and pickles; considered, however, as ornamental flowery plants, the common single sorts are dispersed in patches about the borders, and other compartments, and generally trained up to some support, especially the *Nasturtium majus*, or to run on any kind of treillage, railing, hedge, or the sides of arbours, or to be trained against fences, &c. sowing the seeds at once where they are to remain; some in patches, as aforesaid, three or four seeds together, near an inch deep; placing tall branchy sticks, when they come up, for the plants of the large sort particularly to run upon; others may be sown in shallow drills, the same depth, along any kind of fences, as above, on which also to train the plants: and in some particular open compartments may sow some to remain as trailers, and extend along the ground, agreeable to their natural growth: but the *Nasturtium minus* being

of slender, moderate growth, may be sown in patches, &c. and either have support of low branchy sticks, or permitted to run upon the ground. In all of which methods, the seeds being sown any time in spring or summer, they will grow freely, and the plants will soon shoot out stalks and branches numerously, when they should be trained in the order intended, as hinted above.

But as to the double *Nasturtium majus*, this is always considered as a green-house plant; for although it will live in the open air all summer, like the other varieties, it cannot bear the winter's cold, so must be kept always in pots of light earth, and placed among the green-house exotics, placing sticks for their support: thus they will remain ever-green, and effect variety very agreeably, and produce abundance of flowers all summer and autumn; also often moderately in winter; observing during the winter to allow them but very little water, as too much moisture would rot them at this season of the year.

Considered as economical plants, or esculents, before noticed, the common single varieties of both the species are often cultivated for their young leaves, flowers and fruit, the two former for sallads, and the latter to pickle; for the leaves and flowers being of a warm, agreeable relish, are by many greatly esteemed to mix in sallads, the flowers also as garnish to sallads, when sent to table in form: and are likewise in great estimation for garnishing dishes of meat, &c. and as to the fruit, this, when young and green, is an excellent pickle, and for which purpose particularly the plants are cultivated in many gardens.

When, therefore, it is intended to cultivate these plants as esculents, for the flowers and fruit, they may be sown in the kitchen-garden in April or May, either in patches or in shallow drills, an inch deep; and when the plants come up, place branchy sticks for their support, and they will thus supply you with abundance of young leaves, flowers, and fruit, from June or July until October.

Method of Propagation, &c.

The method of propagation is by seed annually, for all the common single varieties, sowing it in spring, the end of March, or in April or May, in patches or drills, in the places where the plants are to remain, as above observed.

But the double *Nasturtium* not producing seed, and being only a variety, is propagated by cuttings of its branches, and by which it will always retain its double property: planting the cuttings any time from April until July, in pots of light earth, and placed in the shade, giving moderate waterings occasionally; or those planted early may be plunged in

any moderate hot-bed, to facilitate their rooting more effectually.

TROWEL. A Garden Trowel.

A Garden Trowel, made of iron, in a hollow or scooped form, is a handy useful implement in taking up and transplanting numerous sorts of small plants and bulbous roots, planting in pots, sowing in patches, &c. and various other similar light works in gardens.

This kind of Trowel being of iron, from twelve to six inches long in the plate, and half as broad, hollowed like a scoop, and fixed on a short handle, to hold with one hand, proves a most convenient, handy tool in a variety of garden operations; for being hollowed semi-circularly, it is remarkably handy in removing many sorts of small plants with a ball or lump of earth whole about their roots, so as not to feel their removal; lifting several sorts of bulbous flower roots, after the flowering is past in summer; planting bulbs in patches or little clumps about the borders; as also for digging small patches in the borders for sowing hardy annual flower-seeds; likewise for filling mould into small pots in planting any sort of plants therein; stirring the surface of the mould in pots, and fresh earthing them when necessary. It is also most useful for filling in earth about plants in hot beds, and under frames, and any small compartments where a spade cannot be readily introduced. And such a Trowel is likewise very convenient for pointing over or stirring the ground between rows of small close-placed plants in beds or borders, &c. and for many other purposes occasionally.

But to suit the several purposes more effectually, it would be proper to be accommodated with two different sizes of scooped Garden Trowels, viz.

A common larger one for general use, being about twelve inches long in the plate, and six broad, narrowing gradually to about four inches at the lower end, not pointed, but somewhat rounding.

A smaller one for particular purposes, about eight inches in the plate, and five broad, narrowing towards the lower end proportionably, as above, to introduce between small plants.

They may be had of different sizes at most of the ironmongers where they sell spades.

TRUNCUS, Trunk, the main Stem of trees and plants.

The Trunk rises immediately from the root, and may be deemed the stock or main body of the vegetable, as it multiplies into branches, buds, leaves, flowers, and fruit. See CAULIS.

The Trunk or Stem is of seven sorts, viz.

Caulis.—The most common species of Stem, both of trees and herbs, or such as produces.

stems and supports the leaves, flowers, and fruit. See CAULIS.

Scapus.—Is an herbaceous, naked Stem, that elevates the fructification only, and not the leaves, as in *Narcissus*, *hyacinthus*, &c.

Culmus.—A straw or haulm, being the Trunk or Stalk peculiar to the grasses and corn, bearing both leaves and flowers; and sometimes flowers and no leaves.

Frons.—The Trunk of the palm and fern tribe, being a compound Stem, formed of a branch and leaf blended together, and frequently also the flower and fruit.

Stipes.—The Trunk or Stem of the mushroom, and other *fungi*.

Pedunculus.—A peduncle, or flowering-stalk, rising sometimes from the root, but mostly from the branches, elevating the flowers and fruit, but not the leaves. See PEDUNCULUS.

Petiolus.—A leaf-stalk bears the leaves only, and not the flowers. See PETIOLUS.

TUBEROUS ROOTS, such as consist of one or more swelled or knobbed tubers, of a solid fleshy substance.

Of the Tuberous-rooted tribe are comprised many plants of the ornamental flowery kind, and some esculents of the kitchen garden; such as (in the former) anemone, ranunculus, filipendula, many sorts of iris, aconitum, pæony, orchis, cyclamen, winter-aconite, day lily, &c. some also with bulbo-Tuberous roots, as in gladiolus, polyanthes or tuberose, ophrys, &c. and of the esculent Tuberous roots, are the potatoe and Jerusalem artichoke; all of which Tuberous-rooted plants are principally perennial in their said roots, or perpetuating and propagating their respective species by off-sets annually.

TUBS, for the containment of large greenhouse exotics, and other potted plants and trees, when grown too large for pots.

In greenhouse plants particularly, some of the larger-growing sorts, in the process of many years growth, become too large to be contained longer in pots, even in pots of the largest size, which being sometimes both too small for the increased roots of the respective plants, and of insufficient strength to admit of moving them with the plants therein, as may be required, either out or into the greenhouse, &c. such as large orange and lemon-trees, myrtles, oleanders, and some other tree kinds; and large plants of the great American aloe, &c. so that when any of these, or other similar large-growing trees and plants are advanced considerably in size in their general growth, as above, some proper strong Tubs, of larger dimensions than the above-mentioned largest

pots containing the plants, should be prepared ready in proper time, in which to shift them accordingly.

These Tubs are made, according to directions, by the coopers, proper for this purpose, of proportionable size, according to that of the different sorts of plants for which they are intended; made somewhat in the garden-pot form, a little wider at top than bottom, a foot and half to two and a half deep; the width in proportion; constructed of the strongest thick staves and bottoms, and well hooped with iron, and with two iron handles at top, one on each side opposite, by which to move them, containing the plants, on different requisite occasions; the handles being strong and generally hooked, especially very large Tubs, in order to receive a pole in each occasionally, that the Tub and plant together may thereby be more readily moved as required; the bottom of the Tubs having auger-holes bored in different parts, at regular distances, by which to discharge the superfluous moisture after watering, &c.

Having the Tubs ready for this occasion of shifting therein large-grown plants of the above description, the plants should be removed from their present pots, with the ball of earth about the roots entire; and having earthed the bottom part of the Tub, set the plant, with its whole ball of earth therein, filling up properly around, and an inch or two over the top of the ball with more fresh mould, and then watered.—See *Shifting Plants in Pots*, &c.

Probably, after some years considerably advanced growth, the same sorts of large plants will require shifting into larger Tubs, which should be provided accordingly of proportionable dimensions.

But when plants in Tubs are occasionally shifted into others of some considerable large size, according to the nature of growth of the said plants, the said Tubs may probably serve as their final or last, in which they are mostly always to remain; except occasionally shifting them once in two or three years, into a little fresh earth in the same Tubs, as intimated under the article *Shifting Plants*.

Though, as in the course of time the Tubs will decay, either in part or wholly, when they should either be repaired, where practicable; or, if not, replaced with entire new ones of the same, or advanced sizes, as may be judged expedient.

Sometimes plants of considerably large growth require Tubs of very capacious dimensions, as casually occur in large old plants of the American aloe; and sometimes the said

Tubs

Tubs and plants together are so exceedingly large and heavy, that they cannot be readily lifted or moved as required by the common method, the Tubs are obliged to be fixed on low four-wheeled trucks, for moving them thereby out and into the green-house; though this is not very common. I, however, have had such under my care, particularly some superbly large plants of the common and striped-leaved agave.

Any large, curious, hardy flowering-shrubs, or ornamental evergreens, of the full ground, being occasionally potted, for moving therein to adorn particular compartments, and have been shifted by degrees, as required, into pots of the largest size, and that, by their increased growth, are become too large for the said pots, they, if intended to be continued for the occasion as above, should be shifted into Tubs of the before-mentioned kind.

TUBUS, a Tube or Pipe, being the lower, narrow, hollow part, of a monopetalous flower.

TULBAGIA. (*Tulbagia*). This genus furnishes for the stove two species of tender herbaceous exotics, garnished with filiform and lance-linear leaves, and funnel-shaped, liliaceous flowers, having a six-parted corolla, a three-leaved Nectarium, six stamina and one style; succeeded by a capsular seed-vessel.

Class and order, *Hexandria Monogynia*.

The species are,

1. TULBAGIA *alliacea*.

Alliaceous, or Garlick Tulbagia.] With small, narrow, somewhat thread-form leaves.

2. TULBAGIA *cepeacea*.

Cepaceous, or Onion Tulbagia.] With leaves lance-shape-linear.

Both these species are tender exotics, requiring a constant residence in the stove, in which they will effect an agreeable diversity; and may be propagated by seed, slips, and offsets.

TULIPA. Tulip.

This most noted genus furnishes a grand collection of bulbous-rooted flowery perennials of admirable beauty and elegance, consisting of about two or three species, one of which in particular produces most beautiful and superb flowers, and comprehends a prodigious family of varieties, even to the amount of thousands, having all large bulbous roots, crowned with long, broad, spear-shaped leaves, and each an erect flower-stalk, from half a foot to a yard high, terminated with one large, liliaceous, bell-shaped flower.

Class and order, *Hexandria Monogynia*.

Characters.] CALYX, none. COROLLA is bell-shaped, and composed of six large, ob-

long, oval, concave, erect petals. STAMINA, six shortish, awl-shaped filaments, having oblong, quadrangular, erect antheræ. PISTILLUM, a large, oblong, trigonal germen, without a style, and crowned by a triangular, three-lobed stigma. PERICARPium, a trigonous, trivalved, trilocular capsule, containing many plane or flat semicircular seeds, resting upon one another in a double order.

There are three species, two of which only are known in the English gardens, and one of these in particular (the *first sort*) is famous for the extraordinary beauty of its large noble flowers, most elegantly striped and stained with a vast diversity of rich colours, in a thousand various forms; constituting so many different varieties, all very great ornaments to our gardens in April and May.

1. TULIPA *gesneriana*.

Gesner's Turkey Tulip of Cappadocia, or common Garden Tulip.] Hath a large, oblong, solid, bulbous root, covered with a brown skin, sending up long, oval-spear-shaped leaves; an upright, round stalk, from half a foot to a yard high, garnished with a few leaves, and its top crowned with a large bell-shaped, erect, hexapetalous flower, of almost all colours and variegations in the different varieties.

Varieties.] Early Dwarf Tulip (*Præcocca*), rising with short stalks, from five or six inches, to ten or twelve high, with smallish flowers.—Tali, late-flowering, or common Tulip (*Scrotina*) rising from about half a yard to two or three feet high, with large well-formed flowers.—Double Tulip, rising a foot or two high, or more, having large double-flowers.—Whole-blowing, or one coloured Tulip, being all of one original colour, either purples, reds, violets, greys, copper-colours, yellows, &c. which gradually break into numerous variegations.—Variegated Tulip, comprising innumerable varieties, in respect to the different colourings, variegations, and stripes.

Each of the above principal varieties of this species comprehends numerous intermediate ones, in respect to the colours and variegations of the flower; each, however, having been originally all of one colour, especially seedling-raised bulbs, which, when arrived to a flowering state, each separate flower being either wholly red, purple, violet, grey, brown, black, or yellow, &c. without any variegations or stripes, consisting of one-coloured flowers, with white bottoms; with yellow bottoms; and some also with blue, purple, and blackish bottoms; all of which, whilst they retain this original same colour, are in the florists'

florists' language, called *Whole Blowers* or *Breeders*, because each flower is wholly of one colour; and the roots being planted a year or two in prepared soils, to breed, or dispose them gradually to produce flowers that break from the original single colour into variegations and stripes, in various different forms; and are then called *Breakers*, or *Variegated Tulips*, each different variegation constituting a distinct variety; consisting of flowers with white bottoms, broken with brown stripes, with blue stripes, violent stripes, rose stripes, red stripes, &c. separated by streaks of white and other colours, variously disposed.—Yellow bottoms, broken with different reds, crimsons; and golden-yellow flakes, and various other colours.—Some also with blackish purple bottoms, &c. broken with stripes of dark colour, yellow, and tints of red; so that in these sorts of *Breakers*, or *variegated Tulips*, with white and yellow bottoms particularly, there are also, white and red-striped flowers—white and purple-striped—white and violet-striped—white and rose-striped—white and brown-striped—violent and white-flaked—red and white-flaked—red and yellow-flaked—brown, yellow, and red-flaked,—and numerous other intermediate variegations and stripes, variously disposed in an endless diversity.

Thus the *Breakers* or *variegated Tulips* are diversified with an infinity of colours in innumerable different ways, forming so many different varieties, the principal of which are by the florists distinguished by various names, either of some great personages, eminent florists, places of their original growth, &c. but as vast numbers of new varieties are annually obtained from seedlings, in so many different places, distinguished by various new names, and old ones rejected; and often the same flower, with a different name, that the varieties being thus multiplied innumerable, without end, it would be impossible to give any correct list here of the names of such a numerous tribe so often changing every where.

2. *TULIPA sylvestris*.

Wild European Tulip.] Hath an oblong bulbous root, sending up long, narrow, spear-shaped leaves; and a slender stalk, supporting at top a small yellow flower, nodding on one side, having acute petals.

Both these species of *Tulipa* are hardy perennials, durable in root, or at least, although the old bulb decays annually, it perpetuates its species by off-sets, and is annual in leaf and stalk; which rising from the bulb early in the spring, arrives to a flowering state in

April and May, each plant having only one flower, supported on the top of the naked stalk, without any calyx or cup, and consists of six large petals, three within and three without, mostly in an erect position; the whole together forming a sort of large cup, either bell or egg-shaped; though the *Double Tulip* have the petals multiplied in an indeterminate number. All the varieties are succeeded by plenty of ripe seed in July and August, contained in an oblong capsule of three cells, having the seeds placed on each other in double rows, (see the *Characters*); and by the seeds numerous new varieties may be raised; which, however, will not attain a flowering state till they are from six to seven or eight years old, and after that will require two or three years to break into variegations, when the approved varieties may be marked, and increased by off-sets of the root, as directed in their *Propagation*.

It is remarkable, that although the Tulip may be said to be a perennial plant, yet, after the bulb arrives to a flowering state, the same individual old root or bulb does not always remain to flower again, but gradually wastes away, as may be observed by its relics at the lifting season, when the flower and stalk decays in summer; but, previous to its dissolution, it affords from its sides a supply of suckers or off-set young bulbs, to perpetuate the species; and one of which being large, and similar to the parent bulb, is capable of flowering equally strong next year; so that at the end of many years, what is often still supposed to be the same individual bulb, is in reality another in every respect.

Remark, that of the two species of Tulip, the first sort, *Tulipa gesneriana*, or common Garden Tulip, and its vast train of varieties, is the sort so generally cultivated for the ornament of our gardens, and so much admired for its great variety and beautiful appearance, grows freely in the open ground in any common soil of a garden, and proves a very great decoration to the beds and borders of the pleasure-ground, for six weeks or two months in spring, by different plantings of early and late sorts; planting the principal part in autumn, and the rest towards Christmas, and in January or early in February; the autumn plantings will come earliest into bloom, and flower the strongest; and the others will succeed them in flowering; observing that in summer, when the flowering is past, and the leaves and stalks assume a state of decay, the bulbs of the choicest varieties are generally taken up, the off-sets separated, and the whole cleaned from the stalk, earth, and any loose

skins

skins of the bulbs; then put up in the dry till October or November, and then planted again for the future year's bloom.

As to the second species, *Tulipa sylvestris*, it having but inferior beauty, in comparison with the others, is not near so generally known or cultivated; though it was formerly in estimation, before the Turkey Tulip was so general, and is still to be seen remaining in many old gardens; and it also deserves culture in modern ones, both for its early flowering, and to increase the variety, in concert with the common Tulip, and other spring flowers in the open borders.

However, all the sorts of Tulips being very hardy perennials, they will prosper in any common soil of a garden, and are admirable fine ornaments for adorning the borders and flower-beds; the roots being planted in autumn, the common sorts in rows or patches, towards the front of borders, and the fine varieties in beds by themselves, as hinted in the articles *General Observation* and *their General Culture*.

Arrangement and Merit of the different Varieties.

As we formerly observed, the first species, Common Tulip, &c. is the florist's delight, and merits universal estimation for its vast profusion of beautiful varieties, which may be divided into two principal classes, viz.

1. Early or Dwarf Spring Tulips (*Præcocæ*).

2. Late flowering tall Tulips (*Serotina*).

Remark however, of these two classes, that although the first class (early Tulips) is in great estimation for its early bloom and lively colours, yet the second class is in still higher repute for its stately growth and great diversity of rich colours, and profusion of varieties; and is the most universally cultivated. See each class as below.

Early Tulips.—The early Tulips are among florists distinguished by the appellation of *Præcocæ* (early), because they flower early in the spring, a month or more before the others; are much shorter stalked, and the flowers smaller; but are in great reputation for their early bloom, and their gay lively colours, both of single colours, and broken into flaked variegations; such as reds, crimson, scarlet, carnation, violets, purples, yellow, &c. with flowers of each, edged and flaked with red, yellow and white, in many diversities.

The bulbs of these early sorts being planted in any good, light, rich earth, in a warm situation, in the end of September, or any time in October or November, in yard-wide beds, in rows, six or eight inches asunder, and about

three inches deep, they will rise early in the spring, and arrive to flower in March, continuing till the late Tulips come into flower.

Though as the early dwarf sorts are also well adapted for forcing, they may still be blowed earlier, by either planting the roots in pots or boxes in autumn or winter, and place them in a stove, or a hot-bed, whereby they may be forwarded into bloom in January and February, or earlier; and a succession continued till the natural ground-bloom arrives; or may place a quantity of bulbs upon phial-glasses of water, in autumn or winter, one bulb in each glass, and place them either in any warm, light room of a house, near the windows, or in a green-house or stove, by which they will also flower very agreeably in winter, and early in spring; they being the best adapted sorts of Tulips for all these methods of blowing.

They are sold by the seedsmen and nurserymen in great collections of different sorts, by names, chiefly Dutch or French, as may be seen in most of the flower catalogues.

Late-flowering Common Tulips.—This class is denominated late-flowering, and by the florists called *Serotines*, because they blow later in the spring, a month or more, than the *Præcocæ*, i. e. not coming into flower before the end of April, and in May and June; are all of tall growth, supporting large flowers, and furnish an almost endless variety in the vast diversity of colours, after they break from whole-blowers into variegations and stripes, exceeding all others of the Tulip kind in beauty and elegance of flower.

Tulips are also subdivided into other classes, such as Whole Blowers, and broken or variegated Tulips.

Whole Blowers or One-coloured.—These are seedling Tulips, having flowers wholly of one colour; they being raised from seed to a state of flowering, the flowers often remain two, three, or more years of one colour, before they break into variegations; which are also divided into classes, according to the Dutch florists called,—1. *Bizarres*; being generally almost of a brown copper colour, having at the bottom a small round spot, either yellowish, or black mixed with a little yellow, which when broken into different colours, becomes *Bizarres* with yellow bottoms.—2. *Violetes*, being either all of a purple-violet, pale-violet, grideline, cherry-crimson, or red; having the spot at bottom, either a clear white, or blackish-grey mixed with a little white; and their production when broken into different colours become Tulips with white bottoms, called by the Dutch, *Bybloemens*.

Broken or Variegated Tulips.—Such that are broken

broken from the original single colour of the whole-blower or breeding Tulips, into variegations and stripes of different colours; observing, they generally break into different variegations according to that of the former single colour; generally however, either wholly expelling the original colour of the breeder, or leave but very little remains thereof, which is a desirable requisite in these kind of flowers among professed florists; and when thus broken or variegated with different colours, they exhibit themselves variously mixed, striped, flaked, feathered, marbled, spotted, edged, &c. a thousand different ways in an admirable manner; and are by the florists divided into the following classes, called by the Dutch—

Baguettes.—Tulips with white bottoms, striped with brown—Tulips with a white bottom, broken with dark brown stripes, &c.—numerous varieties, variously striped.

Bybloemens.—Tulips with a white bottom, striped with violet and blackish brown, &c.—White bottom Tulips striped with rose-colour, vermilion, and ruby.—Many varieties.

Bizarres.—Yellow bottom Tulips, striped with various colours—numerous varieties.

Of each of the above classes of the Tulip, there are numerous varieties in the different variegations of the flowers, both of the common tall and smaller dwarf kinds; variously striped, flaked, and tinged with different colours of reds, yellows, whites, purples, &c. in innumerable diversifications, curious and beautiful.

Double Tulips.—Many different varieties in the colouring of the flowers, such as Yellow-flowered—Yellow and Red—White and Red striped—White and Blush coloured—with many intermediate variegations.

And Parrot Tulips.—Having long hooked petals of the flower, consisting of Yellow-flowered—Red-flowered—Yellow and Red striped, &c.

Among florists the principal properties requisite in the capital varieties of the common large Tulips of the Serotine kinds, particularly to constitute a fine flower, are—The stem must be tall, from half a yard, to two or three feet high, or more, being proportionably thick and strong; the flower large, composed of six petals, as in the characteristic state, these being broad, thick, rounded at top, and stand firmly erect without turning much inward or outward, but so as to cup well, and give the flower a regular form. The colours and stripes of the flower must be bright, arising unmixed, regularly and distinct from

the bottom, with but little or none of the original single colour remaining.

The colours in greatest estimation in the variegated or striped tulips, are the blacks, golden yellows, purple violets, rose, and vermilion, each of which being variegated various ways; and such as are striped with three different colours distinct and unmixed, with strong regular streaks, with but little or no tinge of the breeder, may be called the most perfect Tulips.

Though it is rare to meet with a Tulip possessing all the properties, yet have sufficient perfection to render them of high estimation as fine flowers.

As to the manner of obtaining this wonderful variety of colours in Tulips, it is often accomplished principally by nature alone, which however is sometimes assisted and forwarded by some operations of culture, such as, that in the first place, when the seedling bulbs of the whole-blower or breeder are arrived to full size, and have flowered once, to transplant them into beds of any poor dry barren soil, in order that by a defect of nutriment in the earth, the natural luxuriance of the plant may be checked, and cause a weakness in their general growth, whereby they generally in this state, gradually change and break out into variegations, some the first year, others not till the second or third; and according as they are thus broke, they should be planted in beds of good earth, as hereafter hinted.

Another method to assist nature in effecting the work of breaking the breeding Tulips into diversified colours, is to make as great a change as possible in the soil; if they were this year in a light poor soil, plant them the next in a richer garden mould, and another year in a compost of different earths; or transplant them from one part of the garden to another, or into different gardens, &c. all of which contributes in assisting nature in producing this desirable diversity of colours and variegations.

The double Tulip is also a variety of the common Tulip, is very beautiful, though not in such estimation among the florists as the common single variegated sorts; not possessing such a profusion of variegations in the colours and regularity of stripes; they however exhibit an elegantly ornamental appearance, as they rise with an upright, tallish, firm stem, crowned with a very large double flower composed of numerous petals, multiplied in several series one within another like a double peony, but far more beautiful in their diver-

ity of colours, variegations, and stripes of white and red, or yellow and red, &c. so that they highly deserve culture both in beds alone, near the other sorts, to increase their variety; also to plant in patches about the borders, in assemblage with the common large variegated Tulips, as they blow nearly about the same time, i. e. April and May.

General Observations.

As we before hinted, all the varieties of Tulips succeed in the open ground, in beds or borders of any common garden-earth planted as hereafter directed.

The roots are sold in full collection, consisting of numerous varieties, at most of the nurseries and seedsmen's, who both propagate them themselves by off-sets and seed, and import vast quantities annually from Holland; the Dutch being famous for raising the grandest collections of the finest Tulips, and other bulbous flowers, in the greatest perfection, for the supply of almost all the other European gardens; distinguishing every variety in their vast collections by some pompous name or other, as before observed, arranged in regular catalogues; charging prices in proportion to their estimation, which formerly was so great among the Hollanders themselves in particular, that there are accounts of a single root being sold for from two thousand to five thousand five hundred guilders; however, they are now more plentiful, and are sold at from five or ten shillings to so many pounds, per hundred, and sometimes considerably more for very scarce capital sorts; and the most eligible season to buy in a collection, is early in autumn, i. e. any time from August or September till November.

And as to the season for planting them is in autumn; about October and November is the most proper period for putting in the main collection, to blow in April and May following; but, in order to have a later bloom by way of succession, some may be planted in December, January, or February; though they will not flower near so strong as those planted in autumn or the early part of winter.

But the early dwarf Tulips should generally be allowed a warm, sheltered, sunny situation, on account of their early rising and flowering in the spring, whilst the weather remains cold and pinching; generally also always kept separate and planted in beds by themselves, not promiscuously with the late tall Tulips; for as their stature and time of flowering are different, they would not distinguish themselves to proper advantage: may also distribute

some in the fronts of warm borders in patches, in concert with anemones, ranunculuses, &c.

However, as to the late Tulips or *Scrotime*s, they may be planted in any of the common beds or borders, as they will be in no danger from any inclemency of weather.

But the fine or more valuable sorts in general, both early and late kinds, are commonly deposited mostly together in beds by themselves; the early and late kinds in separate beds, in rows, eight or nine inches asunder, that they may exhibit a grand blow together, and in which they can also be readily defended, if necessary, especially when in bloom, from heavy rains, and the scorching sun, occasionally.

Though as to the inferior or common sorts, or even any of the capital varieties, they may be distributed about the common borders in assemblage with other spring flowers, both of the bulbous and other kinds: planting them in patches, three or four roots in each, in which they will have a fine effect when in bloom.

Their General Culture.

First, with regard to soil and situation, it has already been suggested, that all the varieties of Tulips will grow very freely in any common light mould that lies dry in winter, generally preferring an open sunny exposure; though nothing can hurt a Tulip but too wet soils, so that if the situation of the ground in any place proves naturally low and wet, the beds must be raised a few inches above the common level; though the florists often prepare studied composts to form beds for their finest Tulips (see COMPOSTS). However, to save trouble and expense, they will be found to succeed in any good garden earth; only observing it is not advisable to plant the fine sorts particularly, more than one or two years together in the same bed or earth, without making some alteration in the soil, either wholly or in part, by removing some of the old, and adding an equal portion of fresh light earth, either from any of the kitchen-garden quarters, or any compost heap, or elsewhere, that is good, and wheel away the old earth to supply the place of the new; and thus, by renewing the soil, less or more, the Tulips may be expected always to blow stronger and fairer in proportion; though this is only advised for the finest sorts that are planted together in beds; those intended to decorate the open borders, may be planted any where as the soil happens, and they will also flower very well.

But to proceed in preparing the beds for the choicest

choicer sorts, as formerly observed; let the ground be well digged one or two spades deep, and form the beds three or four feet wide, with alleys one or two feet wide between bed and bed; and rake the surface of the bed even, ready for the reception of the bulbs.

Then, when the beds are thus prepared, proceed in a dry day to plant the bulbs or Tulip roots, in rows, either by bedding-in, drilling, or dibble-planting (see PLANTING); having for the latter method, a thick, blunt-ended dibble to make the holes sufficiently wide below as above, to admit the bulbs clean to the bottom; marking out lines lengthways the bed, eight or nine inches asunder, in which plant the roots singly, three or four inches deep, and six distant in the lines; and when they are all thus planted, rake the surface of each bed smooth.

Those you intend for the open borders may either be planted in a line, a foot or eighteen inches from the edge, or disposed in patches or little clumps, three or four roots together, in a patch of six or eight inches diameter, some patches forward, others more backward, to effect a greater diversity.

After the Tulips are planted, they require no care till the following spring and summer; as being in no danger from the rigours of winter, they do not want covering; and in spring, no more is required than keeping them clean from weeds; except you choose to protect the buds of the choicer kinds in the beds, by covering them in cold nights and severe weather, with mats, supported on hoop arches, though it is not absolutely necessary; or when the bedded Tulips are come into flower, if you would protect them to preserve their beauty as long as possible, it may be effected by shading them from the noon-day sun, heavy rains, and tempestuous winds, with a shade or awning of canvas or mats erected across the beds, which by some is made high like a tent, to walk under and view the flowers at pleasure; though we would also observe that these flowers will blow in great perfection without all this care of covering; only that by protecting some of the finest sorts growing in beds, the blow may be prolonged a week or fortnight longer in full beauty, than those that are fully exposed; being careful to remove all covering as soon as ever the flowers begin to fade, to admit the free air, rains, &c. for the benefit of the roots.

When, however, the flowering is past, or as soon as ever the flowers are faded, it is proper to cut off the head or seed vessel of the fine varieties particularly, that it may not rob the root of any nourishment, which will

thereby increase more considerably in size and strength.

Though when intended to save seed for sowing, some heads of the stoutest plants must be left to ripen.

The next care is in June, when the leaves and flower-stem are decayed and withered, determining that the roots have ceased growing, and draw no nourishment from the earth; at which period of rest is the time for lifting or taking them up out of the earth, in order both to separate the increased off-sets, and to reserve them out of ground till autumn, that they may have some respite from growth, as well as to be planted in fresh-prepared beds to promote the merit of the future year's bloom; and which work of lifting these bulbs should be practised annually, at the above period, to all the choicer kinds, in the beds, and also to the more inferior sorts in the borders, &c. at least every other year, if they appear to have increased by off-sets considerably. See BULBUS.

Therefore, at the above period of the decay of the stem and leaves, taking the opportunity of dry weather, proceed with a garden trowel to dig them up carefully one and one, with all the off-sets to each; spreading them in a dry, airy, shady place, here remaining two or three weeks out of the sun and wet; but exposed to the free air, they will gradually dry and harden; then detach the off-sets and all adhering earth, and the outer decayed skins or hulks that are the relics of the old bulb; after which expose them again in the same place to dry, and harden effectually; then put them up safe in the dry, in boxes, the large bulbs and the off-sets separately, to remain till the time of planting them again arrives.

Observing, the flowering bulbs are to be planted as has been already advised, and the off-sets in separate beds, by way of a nursery, to remain to acquire due size and strength for full flowering, then managed as the other flowering bulbs. See BULBUS.

Thus far concludes the principal general culture of the great family of Tulips: we shall now next exhibit the general method of propagation.

Method of Propagation.

All the sorts of Tulips are propagated abundantly by off-sets of the root annually; and are also raised from seed to gain new varieties.

By Off-sets.—The old bulbs increase fast by off-set bulbs from their sides, and which should generally be separated annually, especially those of the fine Tulips; and the season for this is in June, when the flower is past,

and the leaves and flower stems begin to wither; then take up the roots wholly, and separate the small increased off-sets from the larger bulbs, planting the off-sets in nursery beds, in drills six inches asunder, and three deep, to remain a year or two to grow to a flowering state; managing the flowering bulbs as already directed.

Thus by off-sets may all the sorts of Tulips be propagated in great abundance, and by off-sets every approved sort continued always the same, so that being in possession of any new or approved varieties, may, with a few bulbs, soon increase the stock by off-sets annually, and will generally produce flowers similar to their respective parent bulb. See BULBUS.

By Seed.—This is a most tedious undertaking, as the Tulip, from the time of sowing the seed, is seven or eight years before it produces flowers; and after all, they at first appear only single-coloured, before explained, often requiring two, three, or more years longer before they break into different colours or variegations, so that the tediousness of raising seedling Tulips to a flowering state often deters many from the undertaking. It is, however, the method by which all the fine varieties of Tulips were first obtained, and new varieties are still annually gained, as many persons sow some every year, in expectation that after the first six or seven years a new show of flowers will be produced, and out of which many new varieties will annually discover themselves in each parcel; and it is by this process the Dutch are famous for furnishing such an infinity of fine varieties, supplying almost all other countries in Europe.

Therefore, for the satisfaction of those who may incline to embark in this tedious undertaking, we will explain the method of sowing and rearing the seedlings to a flowering state.

The seed for this purpose should be saved from some strong-blowing plants, that are always fully exposed to the free air, suffering them to stand till the heads or seed-pods and seed are duly ripened; then gathered in a dry day, and laid upon a shelf, &c. till September, the season for sowing them; which may be performed either in a bed of any good light mould, in the full ground, exposed only to the morning sun; or in boxes or large pots of light earth, and placed in a similar situation: observing, if in beds, to sow the seed in shallow drills, and cover it near an inch deep; and if in boxes or pots, sow it on the surface, and cover it the same depth; they will come up the following spring with fine grass like leaves; at which time be careful to keep the young plants very clean from weeds; likewise

give frequent moderate waterings in dry weather, continuing it occasionally as long as they retain their green leaves in a growing state, and not after; and when the leaves decay, clear the surface carefully from weeds and moss, if any, and directly sift a little fresh mould over the surface half an inch deep, which is all that is required till next year; when the plants will rise with much stronger leaves, in proportion to the increased growth and strength of the bulbs; which, when their leaves again decay in summer, should be taken up and planted in nursery beds, in drills two inches deep, and the same distance in the lines, with the rows four or five inches asunder; here to remain and take their growth for two years, keeping the beds clean from weeds, and sift some fresh earth over the surface every autumn, half an inch deep; then, in the summer, when their leaves decay, the roots being by that time considerably improved in growth, should be again taken up, and planted in a fresh prepared bed, in drills three or four inches asunder, in which to remain two years longer; then at the decay of the leaf, should be again transplanted into fresh beds, in rows as before; where let them remain to blow; afterwards ordered as the other flowering bulbs of Tulips, in the manner already shown.

Observe, however, when they are in full flower, to examine them with attention, in order to mark such of them as discover the best properties, that they may be separated from the others at the proper lifting season, and replanted in beds by themselves for breeders; removing them annually at the proper season into different beds of opposite or contrary soils, as before suggested; such as one year in poor hungry earth, the next in a much richer mould; and so continue till they break into variegations and stripes of different colours.

Thus each year as the flowers break into colours, mark them in order to be taken up, and ranked with the other improved varieties.

TURF.

Grass Turf cut from a pasture, &c. for laying in gardens, to form immediate grass-compartments for lawns, plats, bowling-greens, &c.

When designed to form immediate grass lawns, walks, bowling-greens, and other grass compartments in pleasure-grounds, it is effected by procuring Turf, cut or slayed with a Turling-iron, in some close fine grass sward, in regular lengths of two or three feet, and a foot wide, and being properly laid down close and regular in the places intended, it immediately forms an even grass sward, which quick-

ly

ly strikes root in the ground, in proper growth and verdure; and may be performed any time in autumn, winter, and spring, in open weather, or occasionally in summer, in a moist season.

The best Turf for gardens is that of some fine close fed pasture, common, or downs, &c. where the sward is close and even; or that of any grass field of similar close firm sward, where the grass is not rank and coarse, nor abounding in weeds, or much over-run with the common wild daisy.

In proceeding to cut Turf, being furnished with a proper Turfing-iron, (see TURFING-IRON) and a racer or sward-cutter to race out the requisite width and length of the Turf, by dividing the surface of the sward; (see RACER) and having a line, strain this tight lengthways the grass ground, and with the cutting racer, striking it into the surface of the sward, close to the line, pushing it along before you, cut or score the sward in a straight cut the length of the line, accordingly, about an inch and half deep; and having thus raced out one length, move the line a foot width farther, race out another length as before; proceeding the same to a third, and in as many lengths of the line, in foot widths, as may be required; then by the same means race the sward cross-ways in yard distances, and thus is formed the proper widths and lengths of the Turf; that is, a foot wide and yard long, being the general common size for marking them out, ready for proceeding with the Turfing-iron.

Then the sward being thus raced out, proceed with the Turfing-iron to flay or cut up the Turf; beginning at one side, cut them evenly longways the whole length of each raced line, about an inch or inch and half thick; a person following immediately after, rolls them up one and one in yard lengths, according to the order in which they were raced out, as above, rolling them up regularly, grass side inward, as close and tight as possible; and having cut up one range, proceed with another in the same manner, and so continue with the whole, rolling them up directly as cut, to make room to proceed in the cutting; and according as rolled up, pile them close and regular together, ready for carrying to the destined place.

But when Turf is cut by the hundred, as often done where large quantities are required, they are commonly piled up in tens; four below, three next, then two, and one at top, for the more ready reckoning of the number wanted.

In preparing the ground for laying Turf, it should, where loose, be well trodden or oc-

casionaly rammed; then properly levelled with the spade, and afterward raked smooth, and is then ready for laying.

When proceeding in laying the Turf, unroll them regularly on the ground, one and one in its place, making them join close edge to edge, forming at once a close even sward; beating the whole down close and even, with heavy wooden beaters both to settle the roots of the grass close to the earth, and to form the surface equally close and firm, even and smooth; the Turf will thus soon strike root below, and grow above, without any farther care in this part of the business, except occasionally beating down any swelling inequalities, and sometimes rolled with a heavy roller.

Though sometimes Turf laid in summer and early part of autumn, and dry, hot weather succeeding, will shrink and open considerably at the joinings, and assume a decayed-like appearance, when, if convenient, some good waterings would be serviceable; or, however, if this should be omitted, the first heavy rain will recover the whole effectually, swell the sward, close all the chasms, and revive the verdure of the grass; giving at this time a heavy rolling to settle the whole firm and even.

The after culture of grass compartments, formed with Turf as above, is to give occasional mowing in spring and summer, from March, April, or May, according to the growth of the grass, till October, and occasionally poled and rolled. See GRASS.

TURFING-IRON.

An implement for flaying or cutting up grass turf from pastures, for laying in gardens to form grass lawns, plats, and walks, &c.

This instrument is formed with an iron plate for the cutter, six to seven or eight inches wide, a little rounding forward at the edge, which is thin and sharp for cutting, but thickening gradually behind to the upper part, where it is forged to a long bent iron handle, the bending so formed as to admit of the plate or cutter resting flat with its back on the ground, in the proper position for readily cutting or flaying the turf evenly, all a regular depth accordingly, the iron handle at top being either formed with an open handle like the top of a spade, or have a socket in which to fix a short wooden handle like the top handle of a spade aforesaid.

With this instrument, in proceeding to cutting the turf, the workman taking hold one hand in the top handle, the other below, the latter guiding the tool in the proper position, whilst the upper hand is placed against his knee, &c. which assists him in thrusting it

it forward into the ground evenly under the sward; and thus he proceeds along in a regular manner, moving the Turling-iron gradually along at each stroke, level and even, at an equal depth of about an inch and half, and a foot wide, to as many yard lengths as required; thereby separating the surface sward or turf clean from the ground, ready to roll up in separate turfs of a foot wide and yard long, as explained under the immediately preceding article TURF.

According as one range of turf is thus flayed a foot width, or in as many yard lengths as convenient, in one range, a person should roll them up immediately after the cutter, separately turf and turf, grass side inward, and placed out of the way of the workman, ready for him to proceed in another row. See TURF.

TURNERA. (Turnera.)

Comprehends for the stove, an ornamental flowering exotic, of somewhat ligneous growth, native of the hot parts of America, and retained here in stoves for variety; rising with erect stalks, dividing into branches; adorned with oval-spear-shaped leaves, and pentapetalous flowers at the sides of the branches.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX is monophyllous, bell-shaped, tubulous, divided into five segments, and is permanent. COROLLA, five heart shaped, pointed, plane-spreading petals, with narrow claws, inserted into the tube of the calyx. STAMINA, five awl-shaped short filaments, having acuminate erect antheræ. PISTILLUM, a conical germen, three slender styles, and multifid capillary stigmas. PERICARPIUM, an oval, trivalvular, unilocular capsule, containing many oblong obtuse seeds.

1. TURNERA *ulmifolia*.

Elm-leaved Shrubby Turnera.] Rises with ligneous, shrubby-like, branchy stalks, six or eight feet high; garnished with oval-spear-shaped, rough leaves, having two glands at the base; and large yellow flowers sitting close to the foot-stalks of the leaves towards the upper part of the branches.

Variety.] TURNERA *angustifolia*—Narrow Elm-leaved Turnera.

This species and variety are somewhat of a biennial nature, as that after being raised from seed, &c. they are frequently apt to go off the second or third year; though they also often prove of longer duration. Observing, that as they are tender exotics from South America, they must be kept always in pots, and placed constantly in the stove.

They begin flowering in June, continuing

in succession very ornamentally all summer and autumn, succeeded by ripe seeds in September.

Both the varieties are easily raised from seed, sown in the spring in pots, and plunged in the bark-bed, or any other hot-bed, under glasses; and when the plants are come up two or three inches high, plant them separately in small pots, which plunge also in the stove bark-bed, to forward them a little in growth; afterwards may be placed in any part of the stove, and order them as other exotics of similar temperature.

They may also be propagated by cuttings planted in pots, and forwarded as above.

TUSSILAGO. Colt's-Foot.

It consists of low, hardy, herbaceous, creeping-rooted perennials, for variety and medical uses, remarkable for producing their flowers before their leaves, rising with low erect stalks only a few inches high; roundish, heart-shaped, and oval leaves close to the ground, and the stalks terminated by small compound flowers, some radiated, and some without a radius.

Class and order, *Syngenesia Polygamia Superflua*.

Characters.] CALYX, a compound flower, having a cylindrical cup composed of fifteen or twenty linear, spear-shaped, equal squama or scales. COROLLA, a variously compound flower; being either mostly all hermaphrodite florets, or hermaphrodites only in the disk; funnel-shaped, and four or five-parted at the brim; and female florets in the radius, narrow, tongue-shaped, and entire. STAMINA, in the hermaphrodites, five very short hair-like filaments, having cylindric antheræ. PISTILLUM, a short germen, thread-shaped style, longer than the stamina, which in the females is bifid. PERICARPIUM, none; a single seed in each floret, which is oblong, compressed, and crowned with a hairy down.

There are many species of *Tussilago*, the most material of which are the following, consisting of the common *Tussilago*, and five other species.

1. TUSSILAGO *Farfara*.

Common Tussilago, or Colt's-foot.] Hath fibrated, creeping, white, perennial roots; sending up single, thickish, imbricated stalks, five or six inches high, that are uniflorous, or each crowned with only one largish, pale-yellow, radiated flower, appearing in March and April before the leaves; and when the flower is past, the leaves arise, being large, roundish, nearly heart-shaped, angulated, indented, and hoary.

This species, in its natural growth, inhabits moist situations every where in Britain, and most

most parts of Europe in great plenty, creeping and multiplying exceedingly by the roots; and is not much cultivated in gardens.

It, however, is worth culture in the herbaceous collection, both to effect variety among the spring flowers, in patches in the borders, where it will exhibit an agreeable singularity; and may also be cultivated as a medicinal plant, its leaves being often used in decoctions, and as a principal ingredient in the British Herb Tobacco.

It is one of the *filius ante patrem* tribe, i. e. son before the father; because the flowers always arise before the leaves.

2. TUSSILAGO *alpina*.

Mountain Colt's-Foot.] Hath a creeping perennial root, sending up an almost naked stalk, only three or four inches high, which is uniflorous or crowned with only one purple flower, in March and April, and almost round, or orbicular heart-shaped, crenated leaves, downy underneath.

Variety.] Round hoary-leaved.

3. TUSSILAGO *Anandria*.

Siberian Colt's-Foot.] Hath a creeping perennial root, sending up erect somewhat scaly stalks, three or four inches high, crowned each with one purplish flower early in the spring; and oval lyre-shaped leaves close to the ground.

4. TUSSILAGO *Petasites*.

(*Petasites*) — *Tussilago Major*, or *Common Butter Bur.*] Hath a thick, fleshy, creeping perennial root, sending up thick hollow stalks, six inches high, crowned with several purplish flowers, collected in an oval thyrse or spike, having all the florets floscular hermaphrodites, and large roundish heart-shaped leaves, from one to two feet broad; grows wild in moist meadows, &c. in England and other parts of Europe, and is a medicinal plant.

5. TUSSILAGO *hybrida*.

Hybridan German Tussilago, Greater Colt's Foot, or Long-stalked Butter Bur.] Hath a creeping perennial root; sending up stalks six or eight inches high, crowned with an oblong thyrse or spike of flowers, having many naked, floscular, female florets; and large leaves arising after the flower is past.

6. TUSSILAGO *alba*.

White Alpine Tussilago, or smaller Butter Bur.] Hath creeping perennial roots; slender stalks, three inches high, crowned with a flat thyrse or spike of white flowers; and largish leaves, arising after the flowers are past.

All these species of *Tussilago* are very hardy perennials, of great duration in root, but annual in stalk and leaves, and mostly all possess the singularity of producing their flowers before the leaves; the flowers rising immediately from the root on low slender foot-stalks, having in some sorts only one flower at top; in others, several collected in a thyrse or close bunch, generally all appearing early in spring; and when the flowers fade, the leaves arise directly from the root, on short foot-stalks near the ground, continuing till autumn, then decay: and the roots remaining, send up flowers and leaves again every spring; producing also abundance of downy seeds early in summer.

These plants may be employed in gardens for variety, and although they naturally affect moist situations, they will succeed almost any where, and will increase abundantly by the root, be of many years duration, and exhibit their flowers annually in spring.

But the *Common Tussilago*, &c. may also be cultivated in beds as medicinal plants.

They are all very easily propagated by parting the roots in autumn or spring, the smallest slip will readily grow, and soon multiply.

U.

U L E

U L E

U L E X.

Furze, Gorse, or Whins.

They are shrubby, thorny plants, consisting of two species only; one sort, *Common Furze*,

is a noted, hardy, European shrub of heaths and commons, sometimes cultivated for variety in shrubberies, and occasionally to form field hedges; and the other is a tender exotic shrub

shrub of Africa, requiring shelter of a greenhouse here in winter; are both of very branchy, bushy growth, five or six feet high, remarkable for their evergreen shoots and branches, armed with strong evergreen spines; small, thinly placed, deciduous leaves, and numerous papilionaceous flowers all along the sides of the young branches.

Class and order, *Diadelphia Decandria*.

Characters.] CALYX, two oval, oblong, concave, permanent leaves. COROLLA is papilionaceous, with five petals, having a large, oval, heart-shaped, emarginated vexillum; two short, oblong, obtuse wings, and a bipetalous carina or keel. STAMINA, ten diadelphous filaments, having simple antheræ. PISTILLUM, an oblong, cylindric germen, a rising style, crowned with a small obtuse stigma. PERICARPIUM, an oblong, turgid, bivalvular, unilocular pod, containing roundish seeds.

There are only two species, both of shrubby growth, as before suggested; one of which is hardy and grows wild in all European countries; the other tender. See each below, under its proper head.

Hardy Kind and Varieties.

Consists of one species, *Common Gorse* or *Whins*, having several varieties, all shrubby, very thorny plants, natives of England, &c.

1. *ULEX europæus*.

Common European Ulex, commonly called Furze, Gorse, or Whins.] Rises with upright, hard, woody, whitish-brown stalks, branching numerous and bushy, five or six feet high or more, having green shoots and branches, all very closely armed with strong green spines sparsedly; small, acute, hairy leaves; and numerous large yellow flowers along the sides of the young branches.

Varieties are,] Common yellow Furze of our wastes and heaths — White-flowered Furze — Long-spined Furze — Short-spined Furze — Large French Furze — Dwarf Furze — Round-podded Furze.

They all flower in March, April, and May, very profusely, succeeded by turgid pods, containing the seeds; ripening in autumn.

This species and varieties are remarkable for having all their young branches, shoots and spines of a lasting green colour, but are deciduous in leaf, which come out in the spring and soon fall off, though from the nature of their numerous branches and spines remaining always green, they appear like evergreens, and we have ranked them accordingly in that tribe. See EVERGREENS.

It grows wild on wastes, heaths, and commons in England and all other countries in Europe, often overspreading large tracts of

ground, so is not generally cultivated in gardens, except sometimes a few in extensive thrubberies for variety and observation, and for which purpose a few plants of the different sorts merit admittance in large grounds, both as flowering shrubs and evergreens, as they will effect a singular diversity at all seasons.

The Common Furze is likewise sometimes cultivated for outward hedges to fields, generally sowing the seed on the top of dry banks, in a single or double row in drills an inch deep, where the plants are always to stand, suffering them to grow up thick quite from the bottom; and will form a close fencible hedge, and may either be trained regular, by clipping with garden-shears every summer, in moist weather, or permitted to run up in a natural growth, rough and bushy; though as this kind of hedge, when old, is apt to die off in gaps, become straggling, and naked and hollow at the bottom, it is but in small estimation; however, those who incline it may easily raise a hedge, by sowing the seed in autumn or spring in any light soil, in drills as above in the place where the hedge is intended.

Tender Kind.

2. *ULEX capensis*.

Cape, or African Berry-bearing Furze.] Rises with a hard ligneous stem, branching four or five feet high, having flexible green branches, terminated each with a single spine; small, obtuse leaves singly, and numerous flowers along the sides of the branches.

The flowers of both these species of *Ulex*, and respective varieties, are all of the papilionaceous or butterfly-flowered kind, composed each of five petals (see the *Characters*); and in the Common Furze particularly, the flowers rise very numerous all over the plants, appearing very conspicuous; succeeded by great abundance of seed, which is discharged from the pods widely around, and fill the ground with many young plants.

If intended to cultivate the Common European Furze and varieties, it may be introduced sparingly in any of the large shrubbery quarters, as before hinted; either raising them from seed, or procure young plants.

And the second sort must be potted, and placed among the greenhouse plants to have shelter in winter.

They are all propagated by seed.

Sow that of the first sort either in autumn or spring in any light ground, either in patches in the thrubbery, where it is designed the plants are to remain, or in drills in nursery beds, and transplant the plants while they are quite young, for as they have hard, woody, naked

naked roots, they do not succeed well by transplantation when grown large.

But when intended to raise a Furze hedge, always sow the seed at once in the place where you design the hedge to be, in drills an inch deep, suffering the plants to remain in the same place, being careful to keep them clear from weeds the first two or three years, till they are a little advanced in growth.

The second species may also be raised from seed, which must be obtained from Africa, its native soil; sowing it in pots and plunge them in a hot-bed, and when the plants are come up, two or three inches high, prick them in separate small pots, and manage them as other green-house shrubs.

The propagation of this sort is also sometimes effected by layers and cuttings, assisted by plunging the pots of cuttings in a hot-bed or bark-bed.

ULMUS.

Elm Tree.

The Elm is a most valuable deciduous timber-tree, of lofty and magnificent growth, and of great estimation and importance, as a most capital forest-tree, and for various garden plantations, hereafter hinted; arises to a very considerable stature and magnitude, with a large, regular, branchy head, closely adorned with oblong, oval, rough, dark-green leaves, and bunches of small apetalous flowers of no beauty, succeeded by small roundish seeds.

Class and order, *Pentandria Digynia*.

Characters.] CALYX is monophyllous, five-parted at the rim, coloured within, and permanent. COROLLA, no petals. STAMINA, five awl-shaped filaments, twice the length of the calyx, having short, erect, four-furrowed antheræ. PISTILLUM, an orbicular erect germen, two reflexed styles, terminated by downy stigmas. PERICARPIUM, a large, oval, compressed, membranous, drupaceous fruit, including one roundish compressed seed.

There are four species of *Ulmus* that merit observation in this genus, eligible for general and occasional culture; all of the tree kind and deciduous tribe, and all proper for any hardy plantation; though there is only one principal species in general cultivation, which, however, comprehends many excellent varieties, consisting of the various sorts of Elms that exhibit themselves in field hedge-rows, woods, parks, and garden plantations in almost all parts of the kingdom.

1. ULMUS campestris.

Champaign or Common Elm Tree.] Rises with an upright, straight stem, and regular branchy head, sixty or seventy feet high or

more, covered with a rough bark; largish oblong-oval, double-ferrated, rough, dark-green leaves, unequal at the base; and reddish or green flowers in bunches towards the ends of the branches; succeeded by oval fruit, furnishing ripe seeds the end of May or beginning or middle of June.

Varieties.] Common small-leaved English Elm — Larger rough-leaved English Elm — Small-leaved Cornish Elm — Smooth-barked or Wych Elm — Narrow-leaved Wych or Scotch Elm — Broad-leaved Wych Elm — Smooth-leaved Wych Elm — Rough-barked Dutch Elm, with large leaves — Yellow or gold striped-leaved Elm — Silver striped Elm — Silver-dusted Elm. All of which are varieties of the same species, having all doubly-ferrated leaves, unequal at the base.

Their principal variation and difference of growth is as below.

Small-leaved English Elm.] Is of fine, straight, lofty growth, branching very numerous, regular, and erectly in a beautiful picturesque manner, very closely garnished with smallish rough oval leaves, and attains a great magnitude.

It is found growing abundantly in the hedge-rows of fields in the south of England, and the counties round London, &c. and on account of its lofty stature, and close, regular, branchy head, is an approved sort for all garden ornamental plantations, as being the most estimable for beauty and elegance of growth, of all the varieties of Elm; also as a forest or timber-tree next in size and value to the oak for strength and durability.

The large-leaved English Elm is distinguished from the former by its leaves being broader and rougher.

Narrow-leaved Cornish Elm.] Is also of straight handsome growth, almost next in stature to the Common English Elm, branching erect, very close and regular, and very closely garnished with small, oval, lively green leaves.

Is highly valued both for ornamental plantations, and as a forest tree.

Wych or Scotch Elm.] Rises to a great height and magnitude of trunk, with a large, spreading, branchy head, having very large, oblongish, rough leaves.

All the varieties of this *Wych Elm*, consisting of the Narrow, Broad, and Smooth-leaved, are alike in their general growth, having much more spreading branches than the two former sorts; are remarkably swift growers, and will prosper in almost any soil, and soon attain a stately growth, so are proper to plant as forest trees, and for ornament in parks and other capacious places, and in avenues, &c.

Dutch or Rough-barked Elm.] Grows very large, branching irregularly, and widely around, covered with a rough fungous bark; produces large, vigorous shoots distantly placed; and large, oval, acute-pointed, very rough leaves. Was first introduced from Holland many years since, and was formerly in much esteem for forming ornamental hedges in gardens, and other trained devices; but by its strong, irregular, open growth, is improper for such purposes, and is much better calculated for planting in parks, fields, avenues, &c. and suffered to grow rural; also to plant as a timber-tree.

2. *ULMUS americana.*

American Elm-tree.] Rises with an upright stem and branchy head many feet high, garnished with oblong-ovate, rough, equally sawed leaves, unequal at the base.

Varieties.] Red-twigged American Elm—White twigged—Pendulous branched.

3. *ULMUS nemoralis.*

Wood, or Hornbeam-leaved Elm.] With oblong smooth leaves, equally serrated; and sessile flower.

4. *ULMUS pumila.*

Dwarf Siberian Elm.] With small oval, equally serrated leaves.

Of the above four species of *Ulmus*, the first sort and its several varieties are the more noted and generally known in our principal plantations; and of which the first two and their varieties are superiorly estimable; but all the others are also eligible.

All the four species of Elm, and their respective varieties, are deciduous, and of hardy growth; will grow in any common soil and situation; and are proper to assemble in any general tree plantations, or in groups, and ranges, &c. separately, wholly of the Elm kind, both decoratively; and the larger kinds also as first-rate forest or timber trees, either in assemblage with other forest-tree kinds, or some in ulmarium plantations.

The different varieties of the Common Elm arrive to very large timber-trees, as may be observed by old trees growing in parks, hedge-rows, and avenues, and the timber is exceedingly valuable for many strong purposes, such as most kinds of wheel-wrights' work, water-pipes for conducting water under ground, for water-pumps, and various other uses in different trades, where strength and durability is required; and, therefore, as they are also of a free, expeditious growth, and will thrive in any common soil and exposure, they demand universal culture as forest-trees, both in assemblage with other trees of the forest kind, and to form woods, thickets, and ranges by themselves, and to plant in hedge-row & along the

borders of fields, and in clumps in the corners thereof; observing the English Elm, Cornish, and Wych Elms, are the most eligible sorts for general culture as timber trees; though it is advisable to plant some of all the varieties to effect the greater diversity in the plantations; and they are also all eligible to arrange in any large ornamental plantations, in extensive pleasure-grounds, parks, and out-grounds of estates, as hereafter noticed: and for these different occasions, all the sorts may be plentifully raised, some from seeds, and all of them also, both by layers, suckers, and by grafting, as directed in their propagation, or may be purchased at all the public nursery-grounds.

Remarking, they should generally be planted out finally while they are young, i. e. from four or five to six, eight, or ten feet high, as at that size they will generally take root, establish themselves, and grow more freely and expeditiously than older trees. See PLANTATION.

Though it is observable of the Elm, in particular, that they will bear removal when large, better than almost any other tree, on account of the root being furnished with numerous smaller roots and fibres, spreading horizontally near the surface, so as trees of fifteen or twenty feet high, may, on particular occasions, be safely removed, as they will often readily rise with a large spread of roots, and frequently with balls of earth thereto; and being planted in a capacious pit, will readily strike, and grow freely.

However, this removal, or transplantation of large Elms, is not an eligible practice for those intended for any general plantation, but only occasionally in garden plantations in places where an immediate shade or shelter is wanted, or to form a blind where necessary, or to hide any disagreeable object; for all of which purposes large Elms may be more readily removed with success than any other trees of the deciduous tribe.

But Elms, considered for purposes in garden plantations, are employed occasionally for ornament, and for shade and shelter; both as rural objects, and for training uniformly. Considered, however, as rural trees, they are excellently adapted for forming avenues, either alone, or in concert with other deciduous trees of lofty stature, and to assist in forming boundary plantations of capacious lawns in parks, &c. likewise to form shade, by being disposed either in thickets or clumps, or ranged along near the verge of shady walks, &c. and are likewise excellent to plant for shelter, where necessary, being planted in groves, thickets, clumps, or single ranges, at a little distance, they will break the violence

of tempestuous winds and violent blasts, both from the main habitation, and from particular districts of the garden; and have a fine ornamental effect, disposed in extensive open places, some in straight ranges, others in clumps, and some as single detached standards; in all of which modes of planting them, they should generally be suffered to assume their own natural growth, except trimming off strong lateral shoots and low straggling branches from the stem, and reducing very irregular straggling branches of the head.

For training uniformly, no deciduous tree is better adapted; they form beautiful lofty hedges, very close from bottom to top, from ten to forty or fifty feet high, the English and Cornish elms particularly, and which two varieties were formerly in great repute in forming lofty, towering hedge-work in gardens, both internally, and on the outer boundary, along road sides, serving both for ornament and shelter. And Elm hedge-work was also often trained into arches, porticoes, pilasters, galleries, &c. so as to produce a very noble effect in the ancient style of ornamental gardening: and for all which purposes of uniform training, the small-leaved English and Cornish Elms, above noticed, are considerably the best calculated, on account of their thick and regularly-branching growth, and close placed foliage. See HEDGES.

All the sorts of Elm will grow well enough in any common soil, but succeed best in a rich, deep earth, or that of a loamy nature; though we may often see large and prosperous Elms on all sorts of land, both rich and poor, moist and dry; generally, however, allowing the English Elms the best situations; and the Wych and Dutch Elms may be planted occasionally on the coarsest soils.

The season for removing or transplanting Elms, may be almost any time in open weather, from the first fall of the leaf in October or November, till March. See PLANTING.

Method of Propagation, &c.

The propagation of Elms is effected different ways; as by seed, suckers, layers, and occasionally by grafting.

By Seed.—The raising of Elms from seed is more particularly practised for the Wych Elm, which ripens seeds abundantly every summer, in May or June; the others do not always perfect seed sufficiently; but where attainable, it may also be raised successfully in their propagation: therefore, when the Wych Elm-seed, and any of the other sorts, is perfectly ripe, let a due quantity be procured for sowing. Then may proceed to sow some of it almost directly, in four-feet-wide beds,

half an inch deep (see SOWING SEED); and the rest may be kept till spring, to insure the greater chance of success; previously drying it well, out of the sun, then put it up close, till towards autumn, when it will be proper to mix it with sand, to preserve it more effectually through the winter, till the middle of February; then sow it in beds as above; remarking of that which was sown in summer, or as soon as gathered, it will be of advantage to hoop the beds over with rods, in order to be covered with mats occasionally, to afford shade from the hot mid day sun, giving also occasionally waterings in dry weather; and thus in a month many of the plants will come up, being careful to keep them well weeded, as they may require, and a repetition of moderate waterings, continued in dry weather: though the whole will not probably come up before the following spring; but those of the spring sowing generally all come up regularly together the same season, in April, and often assume a freer growth than those which came up in autumn; however, in both cases, suffer the seedling plants to have one or two years growth in the seed-bed; then plant them out in nursery lines, the rows two or three feet asunder, and the plants fifteen or eighteen inches distant in each row; here give them the common nursery care, and train them for the purposes intended. If for standards, either for timber, or ornamental plantations, train each to a single stem, and as they advance in height, clear the stem from all lateral shoots, leaving only the very small twigs, just to draw and detain the sap, for the better augmentation of the stem; suffering the leading top-shoot to remain entire, as also the principal branches of the head.—And those designed for hedge-work, &c. let them branch out all the way, and become feathered or branchy to the bottom, or as low as may be required for the trained purposes intended, only trimming them occasionally, either with the knife or garden shears, as you shall see proper, to give them the intended form.

And thus all the sorts being trained in the nursery for the purposes intended, till they have four or five years growth, of four or five to six, eight, or ten feet high, as before intimated, they will be fit for transplantation where they are to remain.

By Suckers.—Most of the sorts of Elms send up many suckers from the roots, but most plentifully in the English and Dutch sorts; and which, if taken up carefully with root fibres, they will form good plants; therefore in autumn, winter, or spring, having recourse to any large trees that send up plenty of suckers,

let these be dug up, with as many root fibres as possible; and of which chusing only such that are well rooted, trim them for planting, by cutting them down at top to six or eight inches; place them in small trenches or drills, five or six inches deep, one row in each, half a foot apart, and the drills about half a yard asunder; giving waterings in spring and summer; and here let them remain two years, to form good roots, then transplanted in wide nursery rows, and managed as directed for the seedlings.

By Layers.—All the sorts of Elms may be easily raised by layers, previously preparing a quantity of stools, to produce shoots, situated near the ground, for laying (see STOOLS). And the proper season for laying them is autumn, winter, or early in spring; performing it by slit-laying (see LAYERS); and as soon as all are layed, and moulded in, top every layer with a knife down to one eye above ground, and the work is finished.

Thus, those layers will readily take root in spring and summer following, and shoot at top probably two or three feet long by the next autumn, when they should be detached from the stools, and planted in nursery rows, two feet or a yard asunder, and half a yard distant in the rows; and when they begin to shoot, train them with one leading shoot only, as observed for the seedling Elms, managing them in the same manner.

By Grafting.—All the varieties of elms may be propagated, and continued distinct, by grafting upon stocks of the Wych Elm, raised from seed, suckers, or layers, though the seedling stocks are preferable; and this method of propagation upon the Wych Elm stocks particularly, as being the fastest and largest growers, will be found a good improvement of the other more moderate growers; such as the English Elm in particular, which being grafted on the Wych Elm, generally attains a larger growth, and sooner grows to maturity. So that having raised a quantity of seedling Wych Elms, as before directed, some rows of them may be allotted for stocks, which, after having two years growth in the nursery lines, they will be fit to graft; and the beginning of February, is the proper season: at which time having procured a quantity of cuttings of young moderate shoots of the best English Elm, or any other variety you intend to propagate, and cut into four or five-inch lengths, proceed to insert them in the stocks by the method of whip-grafting. (See GRAFTING.) Observing, however, as it is most advisable, to graft them as low as possible, the earth should be removed away a little down to each root, then cutting

off the head of the stock, within two or three inches of the bottom, insert the grafts, one in each stock, as above, binding them close, and clay them well; then draw the earth up about and over the clay, the more effectually to secure it from falling off by the effects of frost, &c.

Being thus grafted, the grafts will unite timeously the same spring, and shoot forth strongly in summer, half a yard, or two or three feet in length; observing to encourage only one leading shoot; so that if they fork at top into two or more shoots, take off the weakest, and leave the best shoot for the leader; displacing also all large side-shoots from the stem; and let the top or leading shoot remain always entire, as also the general upper branches of the head grow in height as fast as they can, agreeable to the nature of their growth, especially all those intended for standards.

UMBELLA. An Umbel of flowers.

It is a mode of cluster-flowering; many flowers being produced close together on so many slender foot-stalks, proceeding all from one point, or common centre, and rise all to an equal height; so as the flowers they support forms generally an even round surface at top, such as in the flowers of *angelica*, carrot, parsnep, &c.

The umbellate mode of flowering differs from the *corymbus*, in which the foot-stalks also elevate the flowers to an equal height at top, resembling an Umbel. The foot-stalks of the umbellate flowers issue all from one centre or point of the common receptacle, attaining all nearly an equal length and height; whereas those of the *corymbus* rise from different points, lower and higher, and each lower foot-stalk attains a greater length than that immediately above it; so as they altogether, with the flowers at top, form also an even surface, like the umbellate flowers. See CORYMBUS.

In the umbellate flowers, when none of the foot-stalks of the Umbel are subdivided, it is termed a simple Umbel; when on the other hand each flower-stalk is subdivided at its extremity into a number of smaller foot-stalks, that immediately support the flowers, so as each such foot-stalk bears at top a little Umbel, is commonly called a partial Umbel, and that the main or general Umbel, or aggregate, being made up of several such smaller ones, it is termed a compound Umbel.

Umbellate flowers are generally produced at the top of the stalks, and extremity of the branches of the plants of the umbelliferous tribe.

The flowers that compose an Umbel are generally

generally numerous, and separately small, consisting each commonly of five petals, five stamina, and two styles, and each flower is succeeded by two naked seeds.

UMBELLIFEROUS plants are such as produce their flowers in an Umbel, and consist both of herbaceous vegetables and trees, but mostly of herbaceous plants.

The principal of which are, angelica, carrot, parsnep, parsley, celery, fennel, dill, chervil, fennel-giant, lovage, Alexanders, coriander, carraway, black master-wort, Macedonian parsley, samphire, eryngo, hare's ear, &c. all of which being of the Umbelliferous tribe, mostly rise with erect, hollow stalks, generally branching in the alternate way; the leaves also are placed alternate; which in some are simple, in others fingered, and some pinnated or winged; and all the stalks and branches generally terminate in an Umbel of flowers, either simple or compound, in the different plants. See each in its proper genus.

Of this tribe of plants, several of them are valuable esculents of the kitchen-garden, and some are wholesome medicinal plants. See KITCHEN-GARDEN and MEDICINAL PLANTS.

UMBILICATUM. Navel-shaped leaf, or fruit, &c.

An Umbilicated leaf, of the peltate or target-form kind, shaped like a navel at the insertion of the petiole or foot-stalk, which is commonly inserted into the middle or disk, on the under, and sometimes above.

This term is also applicable to some sorts of flowers and fruit: such in the latter as the apple, &c. which have one or both ends hollowed like a navel.

URENA. Indian Mallow.

In this genus are comprised, for the Stove, three species of ligneous malvaceous perennials of India and America, two of which being of upright growth, two or three feet high, the other a procumbent plant, adorned with angular-lobated, palmated, and halbert-cordate leaves, and mallow-shaped, reddish flowers, sitting close to the axillas of the stalks singly; having double calyxes, the outer quinque-dent, and the inner deeply five-parted; five oblong, obtuse petals, many monadelphous columnar stamina; a roundish-pentangular germen, with a single style; succeeded in the germen by a pentagonal, quinquelocular capsule, having five angular seeds.

Class and order, *Monadelphia Polyandria*.

The species are,

1. URENA lobata.

Lobated China Urena.] Rises with upright stalks, and angular-lobated leaves.

2. URENA sinuata.

Sinuuated Indian Urena.] Rises with upright stalks, garnished with sinuated-palmated leaves; the sinuses obtuse.

3. URENA procumbens.

Procumbent China Urena.] Grows with procumbent stalks, garnished with halbert-heart-shaped, undivided, serrated leaves.

These plants, natives originally of distant warm countries, are retained here in curious stove collections, for variety and as flowering plants, producing flowers, in successional order, two or three months in summer and autumn, often succeeded by ripe seeds, by which the plants may be raised in the spring, &c. by the assistance of a hot-bed, and by off-sets and slips.

URTICA. Nettle.

This genus consists of hardy, herbaceous plants, some of which are well known as common and troublesome weeds in gardens; and three or four species of foreign growth are retained in some gardens, to effect variety; rises with upright stalks, adorned with oblong and oval leaves, and monœcious flowers, without petals, growing in catkins at the sides and top of the stalks.

Class and order, *Monœcia Tetrandria*.

Characters.] CALYX, male and female; flowers separated on the same plant, having in the males a four roundish-leaved cup; and in the females an oval cup, composed of two valves, and is permanent. COROLLA, no petals, but in the males is a pitcher-shaped nectarium in the centre of the flower. STAMINA, four awl-shaped spreading filaments, having bilocular antheræ. PISTILLUM, an oval germen, no style, and a hairy stigma. PERICARPIUM, none; a single, oval, compressed seed lodges in the permanent female calyx.

There are many species of *Urtica*, but of which only three or four are common in the gardens, retained as plants of variety; the others being plants of but little use or estimation, and some of them are common weeds; such as the common Stinging-Nettle, which grows too fast every where, and never cultivated: the common Nettle, however, has great virtues as a medical plant, and is also in estimation as an excellent pot-herb among poor country people, in the spring, while it is young; and is of a very wholesome, cleansing property.

The most material sorts in our gardens are the following four species, all of foreign growth; but the first three sorts are hardy enough to succeed here in the full ground, and the fourth requires shelter in winter.

1. URTICA cannabina.

Hemp.

Hemp Urtica, commonly called *Tartarian Nettle*.] Hath a perennial fibrous root, sending up many square stalks, five or six feet high; having oblong, three-parted, deeply-cut leaves, placed opposite; and flowers produced in long catkins at the axillas, towards the upper part of the stalks.

It grows naturally in Tartary and Siberia.

2. *URTICA canadensis*.

Canadian Nettle.] Hath a fibrous, perennial root, sending up erect stalks, two feet high, adorned with heart-shaped-oval leaves, placed alternately, and flowers produced in branching amentums, growing erect.

3. *URTICA cylindrica*.

Cylindrical-flowered American Nettle.] Hath a fibrated, perennial root; upright stalks, three feet high; oblong, spear-shaped, opposite leaves; and flowers produced in cylindric, undivided, solitary amentums.

4. *URTICA nivea*.

Snowy, or White-leaved Chinese Nettle.] Rises with upright stalks, three or four feet

high, garnished with sub-orbicular, alternate leaves, acute-pointed at both ends, and hoary and very white underneath.

All these plants are perennial in root, sending up new stalks annually in spring, flowering in July and August, and the seeds ripen in Autumn.

The first three sorts are hardy plants, and succeed in any common soil.

They are retained in our gardens, to diversify the herbaceous collection, and effect variety in the pleasure-ground; and may be planted in any of the open borders, and other compartments, and in which they will endure many years, and flower annually; though their flowering is more singular than beautiful.

Propagate them by parting the roots in autumn, winter, or early in spring.

But the fourth sort being more tender, must have a warm, dry situation, and some always kept in pots to move under shelter of a garden frame or green-house in winter; and is propagated by slipping the roots in spring.

V.

V A C

V A C

VACCINIUM. Whortle-berry, Bil-berry, or Cran-berry.

This genus comprehends many species of hardy dwarf, under-shrubby, and ligneous plants, deciduous and evergreen kinds, all of humble growth; some erect, others procumbent, or trailing; producing eatable fruit of the berry kind, and are introduced in shrubberies, &c. for variety; grow mostly with slender stalks, six inches to two or three feet high, garnished with small ovate and oblong leaves, and monopetalous, campanulate flowers, singly and in clusters, at the sides and termination of the branches, succeeded by globular berries, in much estimation for tarts.

Class and order, *Ostendria Monogynia*.

Characters.] **CALYX**, a very small perianthium, situated on the germen. **COROLLA**, monopetalous, campanulate, divided into four revolute segments. **STAMINA**, eight simple filaments, with two-horned antheræ, having spreading aristæ outwardly. **PISTILLUM**, a germen situated under the cup; single style,

longer than the stamina, and an obtuse stigma. **PERICARPIUM**, a globular, umbilicated, quadrilocular berry, containing many small seeds.

The principal species are,

1. *VACCINIUM Myrtillis*.

(*Myrtillis*)—*Black Whortle-berry, or Bil-berry*.] Rises with slender, shrubby stalks, branching about two feet high; small ovate-oblong, serrated, deciduous leaves; and peduncles one flowered greenish-white, succeeded by large, blackish-red, eatable berries.

Grows wild on wastes and heaths in England, &c.

2. *VACCINIUM album*.

White Pennsylvanian Whorts, or Bil-berry.] Rises with a slender ligneous stalk and branches, about half a yard high; ovate entire leaves, downy underneath; and single peduncles, having two, three, or several flowers in a cluster, at the sides and ends of the branches; succeeded by small berries, ripening of a whitish colour.

3. *VACCINIUM*

3. *VACCINIUM Vitis idæa*.

(*Vitis idæa*)—or *Red Whortle-berry*.] Rises with very slender stalks and branches, six or eight inches high; small ovate, revolute, entire leaves, of a firm consistence, dotted underneath, and evergreen; and terminal, nodding clusters of reddish flowers, succeeded by red, juicy berries of peculiar estimation for tarts.

4. *VACCINIUM Oxycoccus*.

(*Oxycoccus*)—*Cran-berry*, *Moss-berry*, or *Moor-berry*.] Rises with slender, procumbent, creeping stalks; small oval entire leaves, revolute at the edges, and evergreen; and red flowers on long slender peduncles, at the termination of the branches, succeeded by eatable berries, well known for tarts.—A resident of boggy situations in England, &c.

5. *VACCINIUM uliginosum*.

Marsh Whortle-berry, or *Great Bil-berry bush*.] Rises with a woody, shrubby stalk, branching two or three feet high; ob-ovate, entire, obtuse, smooth leaves, whitish underneath, and ciliated at the base; and peduncles, sustaining each one whitish-purple flower, succeeded by large berries.

6. *VACCINIUM hispidulum*.

Hispid-stalked American Whortle-berry.] Grows with filiform, slender trailing, hispid-rough stalks; oval, revolute, entire leaves; and terminal, slender peduncles, sustaining the flowers, succeeded by large red berries.

7. *VACCINIUM mucronatum*.

Sharp-pointed leaved Whortle-berry.] The leaves ovate, dagger-pointed, smooth, entire; and simple peduncles, each sustaining one flower.

8. *VACCINIUM frondosum*.

Frondose Whortle-berry.] The leaves oblong entire, and frondose-leafy spikes.

9. *VACCINIUM corymbosum*.

Corymbous-flowering American Whortle-berry.] Ligneous stalks; oblong, pointed, entire leaves; and oval corymbouses of flowers.

10. *VACCINIUM ligustrinum*.

Privet-leaved Pennsylvanian Whortle-berry.] Shrubby stem and branches; leaves oblong, fine-notched; and naked racemes of flowers.

11. *VACCINIUM stamineum*.

Stamineous American Whortle-berry.] Leaves oblong, entire; and solitary peduncles one flowered, with stamina and antheræ longer than the corolla.

All these species of *Vaccinium* are hardy plants, mostly of low, slender growth, six inches to one, two, or three feet at most; the stems and branches ligneous, under-shrubby, and perennial; natives of wild moors, mosses, heaths, hills, and boggy and marshy situations,

in England, Scotland, and other northern parts of Europe and North America; flowering in April, May, and June, and produce abundance of ripe berries in autumn, of an agreeable acid relish, chiefly valued for tarts in the autumn and winter seasons.

They are admitted in gardens occasionally, a few plants of each, principally for variety, as they are not always very prosperous out of their native soils; and therefore, when intended to cultivate them, should generally be allotted some similar soil and situation as near as possible, in small shrubby compartments, borders, &c.

The first six species are the most commonly known, and of which the first four being natural residents of cold, light, sandy heaths, moors, and woods, &c. and the fifth and sixth natives of boggy, marshy places, they may be planted in somewhat similar situations, in which they will generally thrive and increase the most prosperously; and where convenient to procure some plants in the places where they abound spontaneously in their natural growth, it would be advisable to take that opportunity, removing them with some mould about the roots, and planted accordingly as above; or, however, the above-mentioned sorts, and all the others, may be planted in such situations as the garden affords, as nearly applicable as possible to that of their natural residences.

The season for transplanting them is either in the spring, or early in the autumn, about the middle or latter end of September, or in October, or soon in November.

They are propagated by off-set root suckers, creeping roots, and some by trailing rooting-stalks; and some growing with several rooted stalks and branches may be divided, root and top together, into separate plants; also by seed sown in autumn when ripe, or as soon as obtained, in a shady border, or in the places where the plants are to remain.

VALVULA. A Valve, or opening of a seed-vessel.

A Valve is the external division or opening of a dry seed-vessel, such as a capsule or pod, which, when ripe, splits into two or more openings, to disseminate the seeds, and each opening or division is called a Valve.

The Valves, or openings, as to number, are from one or two to five or many, in the plants of different genera; so that when a capsule, &c. is composed of one Valve, it is termed *univalve*; of two, *bivalve*; when of three, *trivalve*; four *quadrivalve*; and of five, *quinquivalve*, &c. See **CAPSULA**.

VALERIANA. Valerian.

The plants are hardy, herbaceous perennials

nials and annuals; some for variety in the pleasure-garden, and others for medical and esculent uses; all of the fibrous-rooted kind, sending up annual stalks, two or three feet in the perennials, the other but a few inches; ornamented with simple and pinnated leaves in the different species; and terminated by spikes, or umbellate clusters of monopetalous, five-parted flowers.

Class and order, *Triandria Monogynia*.

Characters.] CALYX, a kind of small border placed on the germen. COROLLA is monopetalous and tubulous, with the tube gibbous, and divided above into five obtuse segments. STAMINA, three awl-shaped, erect filaments, having roundish antheræ. PISTILLUM, a germen under the corolla, filiform style, and thick stigma. PERICARPIMUM, a coronated or crowned deciduous capsule, falling off before it opens, containing a single oblong seed.

There are many species; and the most material of which commonly cultivated are the following five; the first four being flowery and medical perennial plants, and the last is an esculent annual, used as a salad herb, commonly called Corn-Sallad, or Lamb's Lettuce.

1. VALERIANA *rubra*.

Red Garden Valerian.] Hath a thick, ligneous, spreading, perennial root; upright, round, smooth stalks, branching two or three feet high, adorned with spear-shaped, entire leaves; and the stalk and all the branches terminated by clusters of red flowers, having tails.

Varieties.] Deep red-flowered—Pale red-flowered—White-flowered—Narrow-leaved with bright-red flowers.

They all flower in May or June; continuing in succession most part of summer, appearing tolerably ornamental; and ripen abundance of seed in autumn, which is often scattered by winds all around, and in crevices of old buildings, &c. and from which many young plants naturally rise, and attain maturity.

2. VALERIANA *Phu*.

Alsatian White Garden Valerian.] Hath thick, fleshy, jointed, fibrous, creeping perennial roots, crowned with numerous leaves, mostly entire, and some divided; amidst them upright, round stalks, branching two or three feet high, garnished with pinnated leaves, and with all the stalks and branches terminated by umbel-like clusters of white flowers, having only three stamina; appearing in May and June.

3. VALERIANA *officinalis*.

Officinal Valerian.] Hath long, fleshy, fi-

brous roots, collected into heads, crowned with many winged leaves; upright stalks, two feet high, garnished also with pinnated leaves, and all the stalks and branches terminated by umbel-like clusters of flowers, tinged with purple, having only three stamina; flowering in May or June.

4. VALERIANA *pyrenaica*.

Pyrenean Mountain Valerian.] Hath fibrous perennial roots, crowned with large heart-shaped, serrated leaves, on long foot-stalks; amidst them upright, channeled stalks, a yard high, garnished with smaller heart-shaped leaves, sometimes by three together, near the top, and the main stalk and branches crowned with umbel-like bunches of pale-red flowers, having three stamina; flowering in June.

5. VALERIANA *Locusta* (annual).

(*Locusta*)—*Lamb's Lettuce*, commonly called *Corn-Sallad*.] Hath fibrous, annual roots, crowned with small, oblong, narrow leaves, broadest and rounded at the top; and when it shoots for seed, rises with a forking, slender stalk, only a few inches high, garnished with small leaves, and terminated by clusters of small white flowers, having only three stamina.

This grows naturally in corn-fields in England, &c. hence is commonly called Corn-Sallad, as being used as a salad herb; and as such it is also cultivated in gardens for winter and spring use.

Varieties.] There are many varieties of this, differing in the form and size of the leaves; some being very narrow, others broader and obtuse, or oblong and spear-shaped; some being entire, and some are serrated or indented, &c. but possess all the same virtues, and may be indifferently used as salad herbs, to use while young, before they grow large and rank tasted; and they prove substitutes in winter and spring sallads, when the garden-lettuce is scarce.

All these five species of *Valeriana* are very hardy plants, and prosper in any common soil of a garden, in all seasons of the year.

The first four are perennials, durable in root, and annual in stalk, which rise from the root every spring, flower in May or June, ripen seed abundantly in August, then decay down to the ground.

All these four perennial sorts may be employed in the pleasure-ground for ornament and variety; and the second and third sort also as medical plants, and as such are highly valued: may be all had at the public nurseries in the proper planting season, autumn, winter, or spring; and may all be planted in any of the open compartments, in assemblage with other large herbaceous perennials, where they will

will endure for years by the root, and flower annually in their proper season, and multiply abundantly by the root; and may also be raised from seed. See their *Propagation*.

However, the second and third sorts, *Valeriana Phu* and *Valeriana officinalis*, being also very valuable medical plants, if intended to cultivate them as such, they should be disposed in beds among other medicinal herbs.

But as to the fifth sort, *Valeriana Locusta*, an annual, it is calculated only as an esculent herb in fallads, principally in winter and early spring; being sown in autumn towards the latter end of August, and in September, in any open situation, and raked in, they will come up in the same year, thinning the plants to three or four inches, and they will be fit for use in winter and spring following: some may also be sown early in the spring, to continue a longer succession.

VARIETAS.

A Variety.

Varieties are the off-spring of certain species, varying in some accidental habit of growth from the natural species or parent plant; yet their variation being generally confined to some particular parts, they still retain the specific mark of distinction of the parent, to distinguish them from plants of a different species.

So that a species often comprise from one or two, to some hundreds of Varieties, varying in some particular, either in their habit of growth, foliage, flowers, fruit, æconomical qualities, &c. and both trees and herbs, annuals, biennials, and perennials, are subject to variation.

For example, species are subject to numerous accidental modes of variation, effected either by the difference of culture, climate, soil, age, &c. and consist often in the difference of magnitude; luxuriant, and dwarf growths; erect, and trailing plants; smooth and prickly Varieties; broad and narrow-leaved kinds; entire-leaved, divided-leaved, and curled-leaved; spotted, and variegated-leaved; smooth-leaved, hairy-leaved, and down-leaved plants; single-flowered, double-flowered, and poliferous flowered; white, red, blue, yellow, and variegated-flowered; sweet-scented, rank-scented, &c. Likewise the fruit in some species are liable to great variations; as round fruit, oval fruit, oblong fruit; also smooth fruit, furrowed fruit, warted fruit, hairy and downy fruit; likewise fruit varying greatly in size, in the same species; likewise in colour, taste, and quality: in some species also, the root is found to vary, as in the carrot, radish, turnep, and potatoe, which often assume different

forms and colours; and some species furnish both male and female Varieties in different plants, as in the dioecious class, comprising the hop, spinach, hemp, &c.; thus the above, and numerous other circumstances occur in the various forms of sporting nature, in exhibiting so many different Varieties in certain species.

But notwithstanding all the above different modes of variation in the particular parts of the varying plants of a species, if those of each species still all retain the same specific botanic mark of distinction, as that which distinguishes the respective natural species from all others, it proves them all Varieties or off-spring of the same parent species.

For as every different species in a genus is distinguished by some particular uniformly constant mark in some part of its growth, all plants in the same genus bearing exactly the same specific mark of distinction unchangeably, are, notwithstanding their accidental variation in other parts of their growth, all Varieties of one species.

Therefore, all the plants that are produced from the seed of the same species, although they may assume different forms and appearances, are to be regarded as the genuine Varieties.

The difference betwixt a species and a Variety is, that a true species raised from seed, will, notwithstanding it may sport into different variations, it still retains its true and constant specific mark through all its Varieties; and suppose there are Varieties of that species with broad leaves, and narrow leaves, white flowers, red flowers, and blue flowers, &c. and that if you sow the seed of any one, it will probably produce seedling plants of all these sorts, each having the parent specific mark of distinction.

It is principally from seedling plants that the different Varieties of particular species first obtain, exemplified in the *auricula* and *polyanthus*, &c. each being a distinct species of the same genus; and each consists of innumerable Varieties, in the colours and variegations of the flowers, all first obtained from seed; which from that of the same plant, often sport into many different colours and variegations in the flower; each variation forming a genuine variety; and probably not one of them with a flower exactly like that of the original parent plant: yet each Variety retains the specific difference of its respective species, the *auricula* never changing to the *polyanthus*, nor that to the *auricula*, but the Varieties of each keep their proper distinction; for the *auricula*, in all its Varieties, continues its *smooth, fleshy, serrated*

leaves; and the polyanthus, its *rough dentated leaves*. The same is also observable of the carnation, ranunculus, anemone, tulip, and numerous other plants, which sport wonderfully in Varieties.

Likewise numerous sorts of trees, of the fruit kind particularly, are remarkably sportive in Varieties; both in their modes of growth, foliage, and fruit: for example, the botanists admit of only one species of apple-tree, which however furnishes an almost endless Variety of its fruit, in regard to shape, size, colour, taste, and quality; as also in the growth of the trees, differing both in magnitude and size, as well as in the size and colour of the foliage; and its specific distinction is, *serrated leaves, and close-fitting flowers growing in an umbel*, which distinction runs through all the numerous Varieties, however different the trees may be in magnitude of growth, leaves, and fruit: the same is also observable of the pear, plum, common-cherry, peach, &c. there being only one principal species of each of these, but the Varieties of the fruit are very numerous; all of which different variations of the above sorts of trees were first obtained from seedlings; i. e. trees raised from the kernels or stones of the fruit; and almost all the fruit-tree kind sport exceedingly in their seedling plants; insomuch, that out of hundreds of trees raised from the seeds of the best fruits, very few, if any, will produce fruit exactly like the parent, or that possess any good perfection; so that on account of the uncertainty for continuing the approved sorts of fruits from seedling plants, recourse is always had to grafting and budding, and some by layers and cuttings, to propagate the sorts intended, or to continue and increase any new acquired good Variety.

The greater number of Varieties, both of herbaceous plants and most kind of fruit-trees, and some others, are of a variable or sporting nature; so as when raised from seed there is no dependence on having the seedlings come the same sort again, but vary into different sorts of one another; in which case, the propagation of those that are perennial, to continue them with certainty, is effected either by suckers, off-sets, or slips of the root; some by layers and cuttings; or, in the woody kinds, by layers, cuttings, grafting, and budding: but as to annuals, there is no other resource for propagating them than by seed, except in some few sorts by cuttings, such as the *Chrysanthemum* and *Nasturtium*, &c. but in many sorts where particular attention is observed in saving the seeds, always only from the most perfect kinds, they will continue tolerably permanent,

and often come the same again, or but with very little variation.

Many of the kitchen-garden plants and annual flowers consist of many Varieties in the same species; yet by good care in always saving seed from the most perfect plants that discover no signs of a degeneracy, they remain permanent from seed year after year.

However, most of the perennial tribe, both herbaceous and woody kinds, as they being generally more variable from seed, they afford abundant opportunities to continue the permanency of any particular Variety, by off-sets from the root, suckers, layers, cuttings, grafting, and budding, as before noticed.

Sometimes, however, plants, though not raised immediately from seed, will from some accidental cause vary considerably from their usual natural growth, and assume a very different appearance; originating either through culture, climate, exposure, soil, age, diseases, luxuriancy or poverty of nourishment, contusions, or other circumstances; and hereby produce accidental Varieties in some particular parts of growth.

As to the determining the reality of the Varieties, it is in many sorts most easily accomplished by comparing the variable plant with the specific description of the natural species, and the variations of growth of the variety with the same parts in the natural plant; though there are many varieties that require both the knowledge and experience of the most expert botanist to distinguish them with certainty.

From not observing the true specific distinction, Varieties have been ranged as distinct species, and thereby exceedingly increased the number of species erroneously, and caused great confusion in the botanic arrangement; for on account of the slightest difference new species were introduced, which modern improvers of botany discovered to be only Varieties of certain species, and have corrected the errors accordingly.

Therefore, in botanic arrangements, the botanists are careful not to substitute a Variety in the room of a species, which being sometimes a difficult point, requires the greatest care; and the cause of our running into so many errors in this particular, is owing to nature's working and appearing in so many different forms, either through the nature of different countries, climates, soils, exposures, and culture, &c. as before observed.

We have, however, in the course of the arrangement of the numerous articles in this book, been careful to collect the different principal Varieties under their respective species, exhibit-

exhibiting at once each species and its Varieties, when any, arranged distinctly together under their proper genera.

VERATRUM. White Hellebore.

This genus is composed of hardy herbaceous perennials for ornament and variety in the pleasure-ground, and for medicinal use; are of the fibrous and tuberous-rooted tribe, rising with upright annual stalks, some a yard or more high, others hardly a foot, garnished with large, oblong, and spear-shaped, nervous leaves; and all the stalks and branches terminated by spikes of closely-placed hexapetalous flowers.

Class and order, *Polygamia Monœcia*.

Characters.] CALYX, hermaphrodite and male flowers separate on the same plant, all without any calyx. COROLLA, six oblong, spear-shaped, serrated, permanent petals. STAMINA, six awl-shaped filaments, having quadrangular antheræ. PISTILLUM, three oblong, erect germens, terminating in a very short style, which in the males is scarce visible, and simple stigmas. PERICARPUM, three oblong, erect, compressed, univalvular, unilocular capsules, opening on the inside; containing many oblong, compressed, membranaceous seeds.

There are three species, all very hardy perennials; the two first of which are tall growing plants, with large broad leaves; and the third is of much lower growth and narrower leaves, as in their descriptions below.

1. VERATRUM album.

White-spiked Russian Veratrum; or Common White Hellebore.] Hath a thick, fibrated, perennial root, crowned with large, oblong, oval, nervous leaves, near a foot long, and half as broad; upright, round, thick, very branchy stalks, three or four feet high, garnished with leaves diminishing gradually upward; and all the stems and branches terminated by decomposed or subdivided spikes of whitish-green, closely-placed flowers, having erect petals; appearing in May and June.

It inhabits the mountains of Russia, Siberia, and Austria, &c. but hath been long introduced into the English gardens, both as an ornamental and medical plant.

2. VERATRUM nigrum.

Black-spiked Hungarian Veratrum.] Hath a thick, fibrous, perennial root, crowned with large, long, nervous, yellowish-green leaves; upright, thick stalks, branching four or five feet high, garnished with a few leaves; and with all the branches terminated by compound, less divided spikes of dark-red flowers, having spreading petals; appearing in June and July.

It grows naturally in Hungary and Siberia.

3. VERATRUM luteum.

Yellow-spiked Virginia Veratrum.] Hath a bulb-like tuberous root, sending up oblong, spear-shaped, nervous leaves, spreading close to the ground; an upright single stalk, about ten inches or a foot high, garnished with a few close-fitting leaves, and terminated by a close, single spike of yellow flowers, in June and July.

All these three species are hardy herbaceous plants, durable in root, but annual in leaf and stalk, which rise in spring; the leaves rising large, broad, and folded, assume a singular appearance; and between them the flower-stalks of thick, robust growth, rising to a flowering state in May, June, and July; having all the branches terminated by the spikes of flowers, which singly are rather small; but are collected numerous and close in each spike, succeeded by ripe seeds in autumn, in the first and second sort particularly; and soon after the seeds are ripe, the stalks decay.

These plants have been long inhabitants of the British gardens, for variety and medical purposes; particularly the first and second sorts.

They all succeed in any common soil and exposure.

As to their general merit as ornamental plants, or for variety, &c. they having great singularity in their large furrowed leaves, as well as in their different modes of flowering, they demand culture in every herbaceous collection, disposed in the open borders and other compartments of the pleasure-ground; in which they will effect a most agreeable diversity, in spring and summer.

Likewise, as medical plants, the first sort in particular (*Veratrum album*), is in great repute: the root of which forms a powerful sternutatory powder; and for which purpose, the plants may be planted in any bed or border of common earth.

The propagation of all the three species is by seed, and by parting the roots.

By Seed.—This may be sown either in autumn, soon after it is ripe, or in spring, in a bed of light earth, and raked in; and they will come up in April or May, giving occasional watering and weeding; and in July or August, prick them out in nursery-rows, to remain a year or two to grow strong; then transplanted where they are to remain.

By parting the Roots.—Autumn, when the leaves decay, or early in spring, before new ones shoot forth, is the proper period; when the roots may be divided into several slips, not too small, and planted at once where they are always to stand.

VERBASCUM.

Mullein.

The plants are hardy, herbaceous, perennials, biennials, and annuals, proper to diversify the borders and other compartments of the pleasure-ground as flowery plants; also for medicinal preparations; all of the fibrous-rooted tribe, sending up erect stalks, mostly tall, from two or three, to four or five feet stature; and some of much lower growth, garnished in the different sorts with oblong and oval leaves, and monopetalous, rotaceous flowers, in spikes, and singly at the sides and ends of the branches.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is small, monopetalous, acutely five-parted, and permanent. COROLLA is monopetalous, wheel-shaped, with a very short cylindric tube, and spreading brim cut into five oval segments. STAMINA, five awl-shaped, declinated, shortish filaments, having roundish, compressed, erect antheræ. PISTILLUM, a roundish germen, filiform inclining style, and a thickish, obtuse stigma. PERICARPIUM, a roundish, bilocular capsule opening at top, and numerous angular seeds.

There are many species of *Verbascum*, some perennial, others biennial and annual, as before noticed; and the most material sorts thereof are the following nine; though the first three or four sorts are the most common in the English gardens.

1. VERBASCUM *ferrugineum*. (*Perennial*.)

Iron-coloured Moth Mullein.] Hath a perennial root; oval-oblong, slightly-crenated leaves; upright stalks, three or four feet high, terminating above in long loose spikes of yellowish iron-coloured flowers.

2. VERBASCUM *nigrum*. (*Perennial*.)

Black Mullein with a yellowish-purple flower.] Hath a perennial root; oblong, heart-shaped, foot-stalked leaves, eight or ten inches long, hoary underneath; upright, angular stalks, four or five feet high, garnished with a few narrow leaves, and terminated by long spikes of yellow flowers with purple antheræ.

It grows by way sides, &c. in England, and most parts of Europe.

3. VERBASCUM *Phæniceum*. (*Perennial*.)

Purple Moth Mullein.] Hath a perennial, and sometimes a biennial root, sending up oval, crenated, rough-spreading leaves; an upright stalk about three feet high, almost naked of leaves; and purplish flowers along the side of the stalk and branches.

4. VERBASCUM *myconi*. (*Perennial*.)

Myconic Borage-leaved Mullein.] Hath a perennial root, crowned with oval, thick, crenated, woolly leaves, spreading flat on the

ground; slender, naked foot-stalks four or five inches high, divided upward into smaller, each terminated by one large blue flower. Is a native of the Pyrenees.

5. VERBASCUM *Thapsus*. (*Biennial*.)

(Thapsus)—*Great White Mullein, or High Taper.*] Hath a biennial root; long, broad, whitish leaves, woolly on both sides; an upright, thick, firm, single stalk, five or six feet high, garnished with decurrent, woolly leaves, and terminating above in a long thick spike of yellow flowers.

It grows naturally in England, &c. by way-sides, and other uncultivated sterile places; but retained in gardens for variety, and as a medicinal plant.

6. VERBASCUM *Thapsoides*. (*Biennial*.)

(Thapsoides)—*or Branching Great Mullein.*] Stem tall, branching; oblong decurrent leaves; and the branches terminated by long spikes of flowers.

7. VERBASCUM *sinuatum*. (*Biennial*.)

Sinuated Mullein.] Hath a biennial root; oblong, sinuated, pinnated leaves; an upright, firm stem, four or five feet high, having the primary or first branches opposite, and garnished with oblong, amplexicaule, naked leaves; and clusters of yellow flowers along the sides of the branches. Grows naturally in France and Italy.

8. VERBASCUM *phlomoides*. (*Biennial*.)

Phlomoide Mullein, with a large Yellow Flower.] Hath a biennial root; oval leaves, woolly on both sides; an upright, purplish stalk, four or five feet high, garnished with small, oval, hoary leaves, the lower ones having foot-stalks; and the stalks terminating in thick spikes of large, yellow flowers. Grows naturally in Italy.

9. VERBASCUM *Lychnitis*. (*Biennial*.)

(Lychnitis)—*or Hoary white Mullein.*] Hath a biennial root; large, oblong, wedge-shaped, woolly leaves; an upright stalk, three or four feet high, garnished with white leaves, and small white flowers in spikes at the joints and ends of the stalk and branches. Grows in England, &c. in sandy, chalky situations.

Variety.] With yellow flowers.

10. VERBASCUM *Blattaria*. (*Annual*.)

Amplexicaule-leaved Moth Mullein.] Hath an annual root; upright stalk four or five feet high; oblong, smooth, sinuated, amplexicaulous leaves; and yellow flowers singly along the sides of the stalk and branches. Grows naturally in England, &c.

Variety.] With white flowers.

All these ten species of the *Verbascum* are of the herbaceous tribe; the first four are perennials

ennials with durable roots, the next four biennials, and the last of all is an annual; most of which rise with erect tall stalks in the spring, attaining to full height, and flower in June and July: all the flowers are monopetalous and five-parted: and produced in spikes and other modes of flowering, as in their respective descriptions; are mostly of an odoriferous nature, and are succeeded, in most of the sorts, by ripe seeds in August or September.

They are all very hardy plants, that will prosper in any common soil and exposure in the common borders, &c. of a garden.

Considered as garden plants, they merit admittance, to diversify the large borders and other similar compartments of the pleasure-ground; particularly the larger sorts, which though not so ornamental as some, yet by their different foliage, luxuriant stems, and different colours and modes of flowering, they will effect a conspicuous variety.

Method of Propagation.

They are propagated by seed and off-sets of the roots.

By Seed.—Sow it either early in autumn or spring, in a bed or border of light earth, and raked in: and when the plants are come up three inches high, plant them out either in the borders to remain, or in nursery-lines till autumn, then transplanted finally; though the annual sort should be planted out early in summer to remain, or sown at once in patches where the plants are intended to stand.

By Off-sets.—All the perennial sorts furnish off-sets from the sides of the roots, which may be detached in autumn, or early in the spring, and planted either where they are to remain to flower, or in nursery-rows till autumn, then removed to the borders, &c.

VERBENA. Vervain.

A genus consisting principally of herbaceous perennials, eligible as garden plants; furnishing hardy kinds for the pleasure-ground, and tender exotics for the green-house and stove-collections; rising with upright stalks, two or three to five or six feet high; roundish-oblong, hastated, spear and heart-oblong leaves, and mostly terminal spikes of monopetalous tubular flowers, having angular, tubulous, quinque-dent permanent calyxes; a cylindric funnel-shaped, curved corolla; two stamina, or some species, four; a four-cornered germen; single style; succeeded by naked seeds lodged in the calyx.

Class and order, *Diandria Monogynia*.

The principal species are,

1. **VERBENA officinalis.**—Official, or Common Vervain.

2. **VERBENA hastata.**—Hastate-spear-leaved Vervain.

3. **VERBENA bonariensis.**
[*Tall Bonarian Vervain.*] Upright stems, four to five or six feet high; spear-shaped amplexicaule leaves; and clustered spikes of blue flowers, with sometimes four stamina.

4. **VERBENA indica.**
[*Indian Smooth-stalked Vervain of Ceylon.*] Upright smooth stalks; lance-ovate leaves; oblique dentated and long naked spikes; with flowers having two stamina.

5. **VERBENA Jamaicensis.**
[*Jamaica Hairy-stalked Vervain.*] Stalks hairy; leaves spatulate-ovate, sawed; and longest naked spikes of flowers, with two stamina.

6. **VERBENA mexicana.**
[*Mexican Loose-spiked Vervain.*] Stalks four-angled; hearted-oblong leaves; and loose spikes of roundish, twin-growing hispid flowers, with two stamina; the calyx of the fruit reflexed.

Of the above six species of Verbena, the first two sorts are hardy perennials for the borders of the pleasure-ground; and the officinal sort also as a valuable medicinal plant; both of which are propagated by off-sets and seed; the other four species are tender exotic perennials for the green-house and stove; of which the third and fourth are commonly retained as green-house plants of the ornamental flowering kind, producing their flowers in autumn; sometimes succeeded by ripe seed, by which they may be raised in the spring, assisted by a hot-bed; also by dividing the roots, and by cuttings of the young stalks: and the fifth and sixth sorts, less generally known, are assembled in some stove collection for variety; in which they are propagated by off-sets, slips, cuttings, and seeds.

VERBESINA, Indian Hemp Agrimony.

Comprehends for the stove some herbaceous, and ligneous, ornamental flowering exotics, rising with upright stalks, two or three to five or six feet high, garnished with ovate, and lanceolate leaves, and compound, orange-coloured and yellow flowers at the axillas and termination of the stalks; having a concave general calyx, composed of a double series of leaves, including many funnel-shaped, hermaphrodite florets in the disk; having each five stamina, and flat female florets compose the radius; and in all the florets a germen and style, succeeded by angular seeds.

Class and order, *Syngenesia Polygamia Superflua*.

The principal species are,

1. *VERBESINA alata*.

Winged-stalked Orange-coloured Verbesina of Curassao.] Leaves obtuse-ovate, waved, decurrent, and placed alternate; and many orange-coloured flowers.

2. *VERBESINA fruticosa*.

Shrubby American Verbesina.] Shrubby stalk and branches; and oval, serrated leaves, furnished with foot-stalks.

3. *VERBESINA chinensis*.

China Verbesina.] Leaves spear-shaped-ovate, serrated, and alternate; and having footstalks.

These plants being exotics, principally from hot countries, require the protection of our stoves, or very warm green-house, but chiefly the former department, especially the first sort, which is the most noted as a very ornamental flowering plant, producing many orange-coloured flowers, from July till the end of autumn; and which, and the other two, are propagated, by seeds, in a hot-bed, in the spring, and by slips, off-sets, &c. continuing them always in pots of light good earth, and retained as above.

VERONICA.

Speedwell.

This genus consists of many herbaceous perennials, &c. and one shrubby: some of them retained in gardens for variety; rising, some with trailing, and others with erect stalks, from five or six inches, to so many feet high, adorned mostly with smallish, oval, oblong, and spear-shaped leaves, and of other different forms in the several species; and monopetalous, wheel-shaped, four-parted flowers, in spikes and bunches, at the sides and ends of the branches.

Class and order, *Diandria Monogynia*.

Characters.] **CALYX** is divided into four spear-shaped segments, and permanent. **COROLLA** is monopetalous, wheel-shaped, and divided above into four oval segments. **STAMINA**, two rising filaments, with oblong antheræ. **PISTILLUM**, a compressed germen, slender declining style, and simple stigma. **PERICARPIUM**, a heart-shaped, compressed, quadrivalve, bilocular capsule, having many roundish seeds.

There are upwards of thirty species of *Veronica*, mostly herbaceous perennials and annuals; a few of the former are the most remarkable, some as medical plants, and for variety; others as showery ornamental plants to decorate the compartments of the pleasure-ground, and are mostly all of the fibrous-rooted tribe; some natives of England, and some are exotics from different distant parts

of Europe and America; and are all of hardy growth.

1. *VERONICA officinalis*.

Common Officinal Speedwell.] Grows with low procumbent stalks, rooting at the joints; oval, serrated leaves, placed opposite; and the stalks terminated by spikes of small blue flowers.

It is a native of woods, commons, and sterile pastures in England, &c. and is a valuable medicinal plant.

2. *VERONICA serpyllifolia*.

Mother-of-Thyme-leaved Speedwell, or Paul's Betony.] Hath trailing stalks, branching and rooting at the joints; small, oval, smooth, crenated leaves; and white flowers in racemous spikes terminating the branches.

It inhabits moist meadows in England, &c. and is sometimes used in medicine.

3. *VERONICA hybrida*.

Hybridan Speedwell, or Welsh Veronica.] Rises with an erect, branchy stalk, eight or ten inches high; oblong, obtuse, serrated, rough leaves, placed opposite; and the stalks and branches terminated by long spikes of blue flowers. Grows on the mountains in Wales, &c.

4. *VERONICA siberica*.

Siberian Septifolious Veronica.] Rises with upright, firm, hairy stems, four or five feet high; broad, oval, spear-shaped leaves, by sevens, surrounding the stalk in a verticillus; and the stalks terminated at top by long spikes of blue flowers.

5. *VERONICA virginica*.

Virginian Quaternate-leaved Veronica.] Rises with upright stalks, four or five feet high, garnished with spear-shaped, quaternate, and quinate leaves; and terminated by long spikes of white flowers.

Variety.] Ruddy, or blush-flowered.

6. *VERONICA austriaca*.

Austrian Blue Veronica.] Rises with upright, branchy stalks, three feet high; linear-spear-shaped leaves, cut pinnately; and spikes of blue flowers at the sides of the stalk and branches.

7. *VERONICA maritima*.

Maritime or Sea Veronica.] Rises with erect stalks two feet high; spear-shaped, unequally serrated, ternate leaves; and the stalks terminated by spikes of bright-blue flowers. Grows near the sea in several parts of Europe.

Varieties.] White-flowered—Flesh coloured flowered.

8. *VERONICA incana*.

Hoary Tartarian Speedwell.] Rises with an erect, hoary stalk, a foot high; oblong, crenated,

nated, hoary, opposite leaves; and the stalks terminating in erect spikes of blue flowers.

9. *VERONICA Teucrium*.

Germander Speedwell.] Rises with erect stalks, three or four feet high; oval, obtuse, indented, rough leaves; and long spikes of blue flowers at the sides of the branches. Is a native of Germany.

10. *VERONICA longifolia*.

Long-leaved Veronica.] Grows two feet high, with spear-shaped, acute, serrated, shining-green leaves, placed opposite; and the stalks terminated by long spikes of blue flowers. Grows naturally in Italy.

11. *VERONICA decussata*.

Cross-leaved shrubby Veronica from Falkland Islands.] Rises with a shrubby stem and branches, of bushy growth, several feet high; with branches numerous, round, smooth, garnished with small, oblong-oval, pointed, opposite leaves; and towards the top of the branches, clusters of funnel-shaped, white, very fragrant flowers.

All these plants of the first ten species, are hardy herbaceous perennials, with fibrous roots of long duration, sending up new stalks annually; arriving to full growth in May, June, and July, when they flower abundantly in spikes and clusters as in their descriptions; each spike and cluster composed of many separate flowers, all monopetalous, wheel-shaped, and divided into four parts, and succeeded by ripe seed in August and September.

They are all hardy enough to grow any where in a garden; but are generally the most prosperous in somewhat shady moist situations.

Their merit for garden culture is principally for variety and ornament to the common borders, &c. as flowery plants; and being arranged in concert with other hardy perennials, they will effect an agreeable diversity in the summer time, when in flower.

Many of these plants are kept in the public nurseries for sale, and may be transplanted in autumn or spring in the gardens, where they will flower annually, and increase considerably by the roots.

They are propagated by parting the roots, and by seed.

By parting the Roots.—This may be effected either in autumn or spring, by taking up the plant and dividing the roots into separate slips, not too small; and planted either where they are to remain, or in nursery-beds for a year, or till wanted.

By seed.—Sow it in autumn or in spring in any bed or border, and raked in; and when the plants are come up and a little advanced

in growth, plant them out either to remain or in the nursery.

The eleventh species is of large shrubby growth, and is easily propagated by cuttings and layers of the young branches.

VERTICILLUS, a Whorl.

A mode of flowering, in which the flowers are placed in whorls or rings round the joints of the stalk as in balm, sage, hyssop, &c.

The Verticillus is also applicable to leaves when placed three or more together in a ray round the stem or branches; likewise branches when they are produced in a radius or ring round the stem, in a circular manner.

VIBURNUM.

Wayfaring Tree, Guelder Rose, Laurustinus, &c.

This genus comprises a fine collection of elegant deciduous and evergreen flowering shrubs, great ornaments to the shrubbery and other hardy plantations, rising with upright branchy stems, some fifteen or twenty feet high, others not half so much; adorned with heart-shaped, roundish, lobated, and oval leaves in the different species; and numerous small, bell-shaped, five-parted flowers in large cymose-umbellate clusters at the termination of the branches, appearing very ornamental.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX is small, five-parted, and permanent. COROLLA is small, monopetalous, bell-shaped, and divided into five obtuse reflexed segments. STAMINA, five awl-shaped filaments, with roundish antheræ. PISTILLUM, a roundish germen under the corolla, no style, but a turbinated gland instead of it, and three stigmas. PERICARPIMUM, a roundish unilocular berry, with one roundish hard seed.

To this genus is added the *Opulus* or *Guelder-Rose*, and the *Tinus* or *Lamus Tinus*; consisting in the whole of nine or ten species, all of the hardy tree and shrub kind, seven or eight of which being of the deciduous kind, and one is an evergreen.

Deciduous Kinds.

Under this head is comprised the common *Viburnum*, *Opulus* or *Marsh Elder*, and *Guelder-Rose*, and five or six other species, all of the deciduous kind, or such as shed their leaves in winter; some are of English growth, others from America, and garnished mostly with large, heart-shaped, round, and lobated leaves, and numerous small white flowers, collected in cymose umbels at the ends of the branches, as in their description.

1. *VIBURNUM Lantana*.

Common Viburnum, Wayfaring, or Plant-Meally

Meally Tree.] Rises with a woody stem, branching twenty feet high, having very pliant shoots covered with a lightish-brown bark; large heart-shaped, veined, serrated leaves, white and hoary underneath; and the branches terminated by umbels of white flowers, succeeded by bunches of red berries. Grows naturally in England in hedges, by road-sides, &c.

Varieties.] Striped-leaved—Oval-leaved.

2. *VIBURNUM Opulus.*

Opulus Marsh Elder, or Guelder Rose.] Consisting of the two following varieties, one with flat-flowers, the other globular, viz.

Flat umbelled Guelder Rose, or Common Marsh Elder.] Grows eighteen or twenty feet high, branching opposite, of an irregular growth, and covered with a whitish bark; large lobated or three-lobed leaves on glandulose foot stalks, and large flat umbels of white flowers at the ends of the branches, succeeded by red berries. Grows naturally in England in marshy places.

Globular-umbelled Guelder Rose, or Rose Marsh Elder.] Grows fifteen or eighteen feet high, branching like the other, garnished with large lobated or three-lobed leaves, on glandular foot-stalks; and large globular umbels of white flowers at the ends of the branches, in great abundance.

Varieties.] Double-flowered—variegated-leaved.

This tree when in bloom exhibits a singularly fine appearance; the flowers, though small, are collected numerously into large globular white umbels round like a ball; hence it is sometimes called Snowball-tree.

3. *VIBURNUM prunifolium.*

Plum-leaved American Viburnum.] Grows ten or twelve feet high, covered with brown and reddish bark; roundish, crenated, serrated, smooth leaves; and the branches terminated by umbels of white flowers, succeeded by dark red berries, rarely ripening in England.

4. *VIBURNUM acerifolium.*

Maple-leaved Virginian Viburnum.] Grows eight or ten feet high; lobated leaves cut into three principal lobes, growing on smooth foot-stalks; and white flowers in umbels along the sides of the branches, rarely succeeded by berries in England.

5. *VIBURNUM dentatum.*

Dentated Virginia Viburnum.] Grows eight or ten feet high, having a smooth light bark; oval, dentated-serrated, plicated leaves; and large round bunches of white flowers at the ends of the branches, rarely succeeded by berries in England.

6. *VIBURNUM nudum.*

Naked-umbelled, or Laurustinus-leaved American Viburnum.] Grows ten or twelve feet high, very branchy on every side to the bottom, covered with a reddish or purple bark; large oval-spear-shaped, wholly entire leaves, of a shining-green colour; and the branches terminated by umbels of white flowers, resembling those of the common *Laurustinus*, not succeeded by berries in England.

Varieties.] Deciduous-leaved—Evergreen-leaved.

7. *VIBURNUM Cassinoides.*

Baylard Cassine, or Cassioberry Bush.] Grows eight or ten feet high, branching numerously, assuming a bushy growth; small oval-oblong, crenated, smooth leaves placed opposite; foot-stalks, keeled, glandless, and small umbels of white flowers at the sides of the branches; is a native of Virginia and Carolina.

8. *VIBURNUM Lentago.*

Marginal foot-stalked Canada Viburnum.] Grows a large, branchy, tree-like shrub, with ovate, sharp-pointed, serrated, thick, smooth leaves, on long marginated foot-stalks.

All these deciduous *Viburnums* come out into leaf in April and May, and commonly flower in June and July, the flowers small, but collected numerously into cymose umbels; are very conspicuous, succeeded by large bunches of red berries in autumn; though seldom any but those of the *Lantana* and *Opulus* attain perfection in England.

Evergreen Kinds.

Under this head is comprised only one species (*Common Laurustinus*), a well-known old inhabitant of our gardens, furnishing several beautiful varieties, valuable both as fine, hardy evergreens and elegant flowering shrubs, remarkable for exhibiting their flowers in winter and early in spring, in defiance of the severest cold.

9. *VIBURNUM Tinus.*

Common Laurustinus, or Evergreen Viburnum.] Grows eight or ten feet high, or more, branching numerously from the bottom upward, assuming a close bushy growth; very closely garnished with oval, wholly entire leaves of a strong green colour, placed in pairs opposite, with the ramifications, hairy-glandulous underneath; and whitish and red flowers, collected numerously in large umbellate clusters all over the plant, at the sides and ends of the branches, in autumn, winter and spring, until March or April, exhibiting a most beautiful appearance.

Varieties.] Narrow leaved—Broad-leaved—Shining-leaved—Hairy-leaved—White striped-leaved—Yellow striped-leaved; all of which

which are of bushy, shrubby growth, closely garnished with leaves all the year, and produce a great profusion of umbellate flowers in winter and spring, as before mentioned.

All these different species of *Viburnum*, both deciduous and ever-green kinds, being of the tree and shrub kind, are woody and durable in root, stem, and branches; the first eight sorts are deciduous, and the ninth is an ever-green, and are all of hardy temperature, to grow freely in the open ground all the year, in shrubberies and other hardy plantations; though the *Viburnum Cassinoides* is rather somewhat tender in winter, whilst young, but may be gradually hardened to bear all weathers like the other sorts, especially if planted in a sheltered situation: but as it is sometimes liable to suffer in very severe winters, it is also advisable to keep some in pots to move under shelter occasionally in rigorous weather; however, all the other sorts, both deciduous and evergreen kinds, will succeed any where at all seasons without trouble.

With respect to their uses for garden culture, they all demand attention as furniture to diversify the shrubbery, and also other ornamental plantations of the tree and shrub kind; all of which may be procured at the public nurseries, at a moderate price, and may be transplanted almost in any open weather from October till March.

In their arrangement in the shrubbery, the deciduous sorts should be disposed principally with others of that tribe, and the *Laurustinus* may be planted both in the evergreen clumps, &c. and some distributed towards the fronts of the deciduous compartments, will exhibit a lively variety in winter and spring; and any of the principal ornamental-flowering sorts may be planted singly in any conspicuous borders, especially the globular Guelder Rose, and the *Laurustinus*; or some also in pots: generally permitting the whole, both the deciduous and evergreens, to assume nearly their own natural growth, except just retrenching occasional lower stragglers from the stem, and pruning long, irregular, rambling shoots of the head.

But the *Laurustinus* are also often employed to plant against unsightly walls, or other disagreeable fences in fore-courts, and other compartments near the main dwelling, &c. to hide their deformity from sight, by their perpetual verdure, and where they will also flower profusely, and have a very ornamental effect.

Sometimes also the *Laurustinus* is planted as detached objects in borders and capacious spaces of grass-ground, and there sometimes

trained to a single stem, a foot or two high, and encouraged to branch out into a close bushy round head; in which it has a pretty effect, both as an evergreen and flowering shrub; and as such is also very proper to plant in pots, to place occasionally to adorn any particular compartment.

Method of Propagation.

Many of the sorts may be propagated by seeds; all of them by layers, and many of them also by cuttings, likewise some by suckers.

By Seeds.—Most of the deciduous kinds may be raised abundantly from seeds in the open ground; some of them producing plenty of berries in England, others not; and those of most of the sorts may be had of the seedsmen; all of which may be sown in autumn or spring, in beds of common earth, and covered an inch deep; they will come up, some the first year, others not till the second; and when the plants are a year or two old, plant them out in nursery rows to remain till they acquire a proper size, of two or three to four or five feet, for the shrubbery, &c.

Or seed of the *Laurustinus* may be sown in pots in the spring, and plunged in a hot-bed, to forward their germination more effectually.

By Layers.—All the sorts, both deciduous and evergreen kinds, grow freely by layers, which is the most expeditious mode of propagating them, and may be effected in autumn, winter, or spring, though the sooner the better; chusing for this purpose the young lower branches, lay them and peg them down in the earth in the common way; they will all readily emit roots in spring and summer, fit for transplanting next autumn.

By Cuttings.—Most of the deciduous kinds, particularly, grow tolerably well by cuttings; though all the sorts, both deciduous and evergreen kinds, may be tried by this method; it is soon done, and autumn is the proper season; chusing cuttings of the robust young shoots, cut into moderate lengths, and plant them in any moist border in rows; many of them will root and shoot at top next summer, and form tolerable little plants the same year.

By Suckers.—Some sorts afford suckers from the roots, particularly the Guelder Rose, and sometimes the *Laurustinus*; which may be taken up in autumn or spring, with roots, and planted in the nursery, to obtain a proper growth for their respective purposes.

VICIA.

Vetch, or Tare, including also the Faba, or Bean.

They are hardy herbaceous annuals and perennials, principally for economical purposes,

poses, as the common Vetch for fodder to cattle, and the seeds for poultry, &c. and the Bean, both as a fine summer esculent for the table, to eat when green and young, and when dry to feed horses and hogs, &c. though some sorts, also both of the Vetch and Bean kinds, are proper to diversify the compartments of the pleasure-ground; all of which are of the fibrous-rooted tribe, and mostly rise with annual stalks, some long and trailing, as in most of the Vetch kinds; others erect, as in all the Bean tribe; garnished mostly with pinnated leaves of several pair of lobes, and papilionaceous flowers along the sides of the branches.

Class and order, *Diadelphia Decandria*.

Characters.] CALYX is monophyllous, tubulous, and five-parted at top. COROLLA is papilionaceous, with an oval, broad vexillum, reflexed on the sides, two almost heart-shaped wings, and short keel, with an oblong, two-parted claw or tail. STAMINA, ten diadelphous filaments, having roundish; four-furrowed, erect antheræ. PISTILLUM, a long, narrow, compressed germen, filiform style, and obtuse stigma, bearded underneath. PERICARPIUM, a long, leathery, bivalvular pod of one cell, containing several roundish and compressed seeds.

There are about eighteen species of *Vicia*, mostly of the Vetch Tribe, and only one species of the Bean, which comprehends many varieties.

Vetch Kinds.

There are many species of the Vetch, though only a few of them have merit for general culture; some to cultivate in the fields to cut green for fodder, and to stand to ripen seed, (Tares) to feed pigeons and other poultry, hogs, &c. and some to cultivate in gardens for variety; consisting of annuals, biennials, and perennials, mostly with long, somewhat trailing, or climbing stalks, and some erect; all garnished with pinnated leaves of many pair of small lobes, terminated mostly by cirrhi or tendrils for climbing; and flowers generally from the sides of the branches, either singly or by twos, or many together on each peduncle, in spikes, &c. succeeded by oblong pods filled with small roundish seeds.

The most remarkable species for use or variety are,

1. *Vicia sativa*. (*Annual*.)

Common cultivated Vetch or Tare.] Rises with weak, angular, streaked, declinating stalks two or three feet long, garnished with pinnated leaves of seven or eight pair of oblong blunt lobes, and spotted stipula; and purple flowers generally two together, succeeded by erect pods in pairs, containing a few round seeds.

Varieties.] Common purple-flowered as above—White-flowered—Early summer Vetch—Black-seeded—White-seeded, &c.

This species is the sort of Vetch or Tare that is commonly cultivated in fields, to cut green for summer fodder, which is excellent feed for horses, &c. and some also to stand to bring forth seeds for the uses before hinted.

2. *Vicia narbonensis*. (*Annual*.)

Narbonne Vetch or Tare.] Long climbing cirrhus stalks; pinnated leaves of about six ovalish folioles; denticulated stipulæ; dark-purple flowers, and erect sessile seed-pods by threes.

3. *Vicia biennis*. (*Biennial*.)

Biennial multiflorous Siberian Vetch.] Grows five or six feet long, having large pinnated leaves of ten or twelve or more spear-shaped, smooth lobes on furrowed foot-stalks, and each peduncle having many light-blue flowers, arising at the sides of the branches, succeeded by short compressed pods.

4. *Vicia sylvatica*. (*Perennial*.)

Wood multiflorous Vetch.] Rises with cirrhus, climbing stalks, five or six feet long; pinnated leaves of seven or eight pair of oval lobes, and denticulated stipulæ, and each peduncle supporting many pale-blue flowers; grows wild in England, &c. in woods and among bushes and hedges.

5. *Vicia Cracca*.

Imbricated or Tufted Vetch.] Rises with climbing stalks five or six feet long; pinnated leaves of ten pair of spear-shaped, hairy lobes, and entire stipulæ; and peduncles supporting each many blue imbricated flowers. Is a native of England and most parts of Europe.

6. *Vicia cassubica*.

Cassubian Ligneous Vetch.] Hath trailing stalks two or three feet long, becoming somewhat ligneous; pinnated leaves of eight or ten pair of oval, acute, lobes, and entire stipulæ; and each peduncle having about six pale-blue flowers. Is a native of Germany.

The above six species are the most noted sorts of the Vetch or Tare kind, some of which being in great estimation for field culture, to produce green fodder as before noticed; but the first sort, in particular, having the most succulent stalks, are in most esteem for general culture, being generally cut whilst the stalks are green and tender, till they come into flower in June and July.

They are also sometimes introduced into gardens, as climbers, for variety, especially to diversify wood-walks, thickets, &c. to climb upon the shrubs and bushes; sowing the seed in the places where the plants are designed to remain, and they will readily come up and flower

flower ornamentally in summer. See their *Propagation* below.

As all the sorts rise with long weak stalks, somewhat resembling the pea tribe, they either trail on the ground or climb upon any adjacent support, or upon one another, by means of their cirrhi or clasps, at the termination of the leaves; and by which they mount upon bushes or hedges, &c. several feet high, shooting up into stalk in spring, and flower in June or July; all producing papilionaceous or butterfly-shaped flowers, some but two on each peduncle, and some many as before observed, succeeded by longish pods of the leguminous kind, containing round seeds, ripening in autumn.

Method of Propagation, &c.

All the sorts are easily propagated by seeds, sown principally where the plants are to remain in autumn or spring, both for field culture and in gardens.

For Field Culture.—They are sown both in autumn or spring occasionally: when intended to raise a crop to cut for early fodder, they are often sown in autumn, about August or early in September, in order that they may come up soon after the same year, and afford an early cutting next summer; though they may also be sown in spring both for fodder and to stand to produce seed or Tares; remarking, however, the summer Vetch in particular, being somewhat tender, should never be sown till the spring; observing in sowing the different sorts, that the common allowance of seed is generally about two bushels to an acre, which may either be sown broadcast and ploughed or harrowed in, or in drills, two or three feet asunder, and earthed over an inch or two deep: that by sowing them in drills, the ground can be readily hoed between by horse or hand hoeing, to kill weeds, and land up the plants, as practised for peas.

For Garden Culture.—When intended to cultivate any of these plants in gardens for variety, sow the seeds in autumn or spring, some in any large open flower borders, and some in the borders of shrubberies, wood-walks, wildernesses, thickets, &c. in the places where they are to remain, in patches near the shrubs and bushes to climb thereon, or in open spaces to climb upon sticks.

Faba or Bean Kinds.

To this genus *Vicia*, is added the article *Faba* or Bean, formerly considered as a distinct genus; but its general characters proving the same as the Vetch, the botanists have ranged it as a species of that family, by the name of *Vicia Faba*; consisting of but one species only, which, however, comprises numerous vari-

eties, and is supposed the Common Field or Horse Bean is the original sort, and parent of all the other varieties commonly called Garden Beans.

7. *VICIA Faba. (Annual).*

(Faba) or cultivated Garden Bean.] Hath fibrous roots; upright, thick, succulent, firm stems, rising from one or two to four feet high or more, garnished with large winged succulent leaves of two or three pair of large lobes, without cirrhi or clasps; and numerous papilionaceous, white, and black-spotted flowers all along the sides of the stalk, succeeded by long, compressed pods, containing the Beans.

It is a hardy herbaceous annual, and said to be originally a native of Ægypt; but all the varieties have been long inhabitants of our gardens, and grow freely any where in the open ground.

Varieties.] There are numerous sorts of Beans, all varieties of the same species (*Vicia Faba*) for their general growth and structure, foliage, flowering, fruiting, &c. are exactly the same, and only vary more or less from one another in their size of growth, size of the leaves, pods, and Beans, times of attaining perfection, domestic properties, &c. for all the different varieties are subject to vary exceedingly; and as in the Common Field or Horse Bean, we shall often find some among them that vary considerably from the original, both in substance of stalk and pods; and from these variations, it is supposed, the different varieties of Garden Bean were first obtained, and by degrees improved by culture to their present state of perfection; all of which are also very apt to vary from one to the other, unless some attention is observed in saving the seed Beans from the best plants of the respective varieties; consisting of the following sorts, arranged under three heads, according to their growth and times of attaining perfection, viz. Small early Kinds—Middling Kinds—and Large late Kinds.

Small early Kinds.

Those under this head are of the lowest growth, rising only from about a foot and half to two and a half high, and some that scarcely obtain a foot stature; but all very great bearers with small pods and Beans, and are valued for arriving earlier to perfection than any other sorts; and are therefore proper to plant on warm borders and other similar compartments in autumn and winter for the early crops to gather in the middle or end of May, and in June.

Early Mazagan Bean.] Grows but half a yard or two feet high, with slender stalks fully

loaded from bottom to top with very small pods, arriving to perfection in May or beginning of June.

This is one of the smallest and earliest of the tribe of Garden Beans.

Early Portugal or Lisbon Bean.] Grows two feet high or more, with somewhat stronger stalks and larger pods than the Mazagan Bean, arriving to perfection a few days after that sort.

Small Spanish Bean.] Grows stronger than the two former, with somewhat larger pods and Beans, arriving to perfection soon after the Portugal Bean.

Dwarf Fan or Cluster Bean.] Grows low, with several spreading stems from six to ten or twelve inches high, very fully loaded with small pods.

This is chiefly planted for variety or curiosity.

Most of these small Beans, if gathered while young, eat very sweet and palatable; particularly the first three sorts; but if suffered to attain full growth, or become the least black-eyed, they eat dry, coarse, and of a disagreeable relish.

These kinds have merit principally to plant for the earliest crops, and the first two or three sorts are the most eligible for that purpose; but the Mazagan kind is the earliest of all, proper to plant for the first crop, and the Portugal and Small Spanish Bean next; all of which are proper for planting early on warm south borders, or other sheltered sunny exposures, under or near walls, pales, or hedges, or any warm defended quarter, every month from October or November, till January or beginning of February; in order that if the first planting should fall by inclement weather in winter, the others may succeed; and if all the crops should survive the frost, they will succeed one another regularly in bearing; planting them in rows, ranging south and north, or as convenient, two feet and a half asunder, an inch and half deep, and two or three inches apart in each row; likewise may plant one row length-ways close along under a south wall, &c. Or any of those small Beans may be continued planting in succession if required, in the several spring months till May or June, or also in June or July for late crops, in which they will then sometimes succeed preferable to larger kinds.

But as to the Dwarf Bean, it is not proper to be planted for any general crop, only a few for variety; and for which purpose it may be planted either in autumn or winter, or in any of the spring or summer months till June or July, in rows two feet asunder, or in patches about the borders.

Middle-sized later Beans.

These sorts are of stronger and taller growth than those of the former class: they rising in stalks from two feet and half to a yard or more high, producing longish middle-sized pods of different lengths and thickness in the different sorts; being proper to plant for the first main crops, any time from November or December till February or March, to succeed the small early Beans, and will arrive to perfection for the table in June and July.

Long-podded Bean.] Rises with stronger stems, a yard or more high; a remarkable great bearer, producing very long, narrowish pods closely filled with oblong, middle-sized Beans.

Varieties of this are,] Early long-podded Bean—Tall long-podded Bean—Sword, or Turkey long-podded Bean, rising with stronger stalks producing the largest and longest pods, well filled with fine large Beans: most excellent to plant for a main crop.

All these long-podded Beans are remarkable great bearers, very profitable for a family and market, and if gathered for use while they are moderately young, they will eat tolerably sweet and well flavoured.

Broad Spanish Bean.] Grows moderately strong, a yard or more high, producing broadish pods and Beans; is a very good bearer, and the Beans boil tender and well flavoured.

White-blossomed Bean.] Grows two feet and half high, producing entire white flowers, and great abundance of smallish, long, narrow pods, filled with smallish oblong Beans.

This is a good bearer and excellent table Bean, remarkable for boiling green and tender, and is eligible to plant both for a secondary early production, and also similarly for middle and late crops; even to plant so late as June and July for young autumn Beans, in August and September.

Green Nonpareil Bean.] Grows about two feet and half to a yard high; very productive in numerous small longish pods, well filled with small very green Beans, sweet and tender eating while quite young.

The dried seed Beans of this sort are of a pale-green colour, and generally permanent.

Red-blossomed Bean.] Rises with firm stalks two feet and half high, producing entire red blossoms, succeeded by smallish pods and Beans not near so palatable to eat as the white blossom kinds.

Other less material varieties of middle-sized Beans are Mumford Bean—Black-blossomed Bean—Green Venetian Bean.

Remark, that of the above varieties of Bean ranged in this class, the first three sorts, Long Pods,

Pods, Broad Spanish, and the White-blossomed Bean are the best for general culture; though some of all the others may also be planted occasionally for variety and experiment; and the season for planting all the sorts is, that for the first crop may plant in November or December on some broad warm border, or in any of the most sheltered kitchen-garden quarters, in rows, two feet and half or a yard asunder; three inches distance in the row, and two or three inches deep: repeating the planting every month till March in the open quarters or in fields, &c. after that, if a longer succession of those sorts is required, plant some every three weeks in an open exposure, till May or June.

Larger late Kinds, commonly called Broad Beans.

These are the strongest growers of all the kinds; they rise with thick stems three feet and half high or more, producing large broad pods with Beans proportionably large; and are superior to all the others to plant for the general crops, to succeed the long pods, and others of that class; being proper to plant principally in the spring, or at least not earlier than December or January, for the first crop; and for the general crops, should be planted every month or three weeks, from January or February, until May; and they will arrive to perfection in July or August, and are all most excellent family beans, and always the most saleable in markets.

Sandwich Bean.—Grows three feet and a half high or more, producing large, broad pods, and oblong broadish Beans; and bears abundantly.

Toker Bean.—Grows strong, three feet and a half high, or more, producing long broadish pods, and large oblongish Beans, and the plants bear very plentifully.

Windsor Bean.—Rises with very large, strong stems, three or four feet high, bearing very large, broad pods, having very large, roundish broad Beans, the largest of all the Bean tribe, and the most excellent for eating.

Of this class of large Beans, the Sandwich and Toker kinds being generally more plentiful bearers, and of somewhat less succulent growth than the Windsor, are rather hardier to resist the frost, and may be planted earlier, that is before Christmas, for the first crop; and any time after, till April or May, if required; but the Windsor may also be planted a small or moderate crop in December, in open mild weather, and a dry soil; the same in January, in a larger supply; and a first full crop in February: and thence may plant freely in full supplies, of these or any of the other larger sort,

every three or four weeks, till the end of April, for the main crops; or may continue planting them till the end of May, to continue the succession of these kinds for the table as long in the season as possible.

All of which large kinds of Beans should be planted in open exposures in gardens and fields; the first plantings before or soon after Christmas may be in the most sheltered, dry situation; after that the succession crops may be planted in any open exposure in gardens and fields; generally planting them by dibble in rows, a yard asunder, or three feet and a half for the large Windsor Beans, four or five inches asunder in each row, and three inches deep.

General Observations.

All the varieties of Bean in the above three classes, are hardy, herbaceous annuals, that will grow in any common soil of a garden, and in the open fields; are all raised annually from seed, planted at several different times, from October till May, in order to obtain a succession of young green Beans for the table three or four months in summer; for by planting early and late kinds every month, from October or November until March; and every three weeks or fortnight, from March till May, June, or July, a constant succession of young Beans is obtained from the latter end of May, or beginning or middle of June, until September, or beginning of October; though as to the general planting season, that after having planted a few of each sort before Christmas, to come in early, the main crops are planted in January, February, March, and April; and the general season of Beans in full perfection of bearing and goodness, is June, July, and August.

As therefore the utility of Garden-Beans, both for private use, and supply of the markets, is very considerable for about three months in summer, a principal share of kitchen-garden ground and field-land should be allotted annually for the culture of the several different crops, succeeding one another in bearing in regular succession from May or June till August or September, as before observed.

They will all grow freely in any common fertile soil, in a garden or field, but should be allowed always an open, free situation, not much overspread with trees, &c. which would draw them up weak and tall, without yielding any considerable produce; generally allowing the warmest dry situations for the early crops before Christmas; but the succeeding ones may after that time be planted in any open exposure, as before observed; and for the late plantings,

plantings in May and June, &c. should generally chuse the moistest strong land.

As to the general method of planting and culture: all the sorts must be planted in rows, the distance before mentioned, according to the size of the Beans, planted either by dibble, or laid in drills; or for early planting in dry ground, may first draw shallow drills, then plant the beans in a row along the bottom; allowing from two to four or five inches distance in the row, according to the size or growth of the different varieties, and from one and a half to three inches deep in the small and large Beans; and when the plants are come up about three inches high, land or earth them up on each side of the row with a drawing hoe, keeping them clear from weeds by occasional hoeing in dry weather: and after having advanced nearly to full growth and in bloom, it is proper to top the plants in general, which throws all the nourishment to the embryo pods, and greatly promotes their setting, and forwards their growth; and in the latter crops prevents their being so much annoyed with the small black fly.

VINCA.

Perwinca, or Periwinkle.

This genus is composed of shrubby evergreen trailers and upright growers, for the shrubbery and stove collections, having all durable stems, and branches adorned with oval, oblong, and spear-shaped, ever-green leaves; and monopetalous, salver-shaped, five-parted flowers, at the axillas of the stalk and branches.

Class and order, *Pentandria Monogynia*.

Characters.] CALYX is divided into five parts, and permanent. COROLLA is monopetalous, and hypocratisform, or salver-shaped, tubular below with a horizontal, broad-spreading brim, cut into five obtuse segments. STAMINA, five short inflexed filaments, having obtuse, erect, membranaceous antheræ. PISTILLUM, two roundish germens, terminating in one cylindric style, larger than the stamina, having two stigmas, one orbicular, and the other headed and concave. PERICARPIUM, two long, cylindric, erect follicles, of one longitudinal valve, containing many oblong, cylindric seeds.

There are four species of *Vinca*, three of them common to the English gardens, two of which are hardy, trailing, and declinated plants for the shrubbery; the other is an upright, tender shrub for the stove collection; and are all of the ever green tribe.

Hardy Kinds.

These have slender stalks, some that trail and extend along the ground, branching nu-

merously, and cover the surface; others grow more erect, with declinated branches: and consist of two species, both evergreens, and natives of England, &c. growing wild, under bushes, hedges, and in woods; but are introduced into most of our eminent shrubberies, to plant as trailers in particular departments, between shrubs, to overspread the ground, and occasionally to mount erect, upon support, and form a bushy growth.

1. VINCA minor.

Minor or smaller Procumbent Periwinkle.]

Hath slender, ligneous, trailing green stalks, branching and running considerably along the ground, emitting roots at the joints; garnished with oval-spear-shaped, thick, smooth, shining-green leaves, in pairs opposite; and flowers growing singly on proper peduncles, at the sides of the branches, of different colours in the varieties.

Varieties are,] Common green Periwinkle with blue flowers—With white flowers—Double blue flowers—Double white flowers—Double purple flowers—Yellow-striped-leaved, with flowers of all the above colours—White striped-leaved, with flowers of different colours.

2. VINCA major.

Greater Upright Periwinkle.] Rises with shrubby, somewhat erect, green stalks, a foot or two high, with the tops inclining to the ground; larger, oval, shining-green leaves, in pairs opposite; and large blue flowers singly on foot-stalks at the axillas of the branches.

Variety.] With white flowers.

Both the species are perennial in root, stem, and branches, with leaves in perpetual verdure, and begin flowering in the spring, about March and April; the flowers moderately large, each being of one salver-shaped petal, spreading at the brim, and cut into five parts; generally continue flowering in succession several months, and even sometimes in winter, in mild seasons, especially the *Vinca major*.

As both the species and their respective varieties are very hardy plants, that prosper under trees and bushes, even in close thickets, &c. and spread and cover the ground, they are proper to plant towards the fronts or verges of shrubbery clumps, wildernesses, and thickets, between the trees and shrubs, next the walks, and on the sides of shady banks, &c. disposed, some to over-run the surface between the shrubs, in particular places contiguous to shady walks, &c. others in patches, to run and entangle with one another in tufts; and some planted entirely detached, particularly the *Vinca major*; and supported with stakes, and trained with an erect stem a little height, and

and encouraged to branch out above into a bushy head; in all of which modes of distributing them in the several plantations, they will encrease fast in growth, and effect a very pretty variety at all seasons of the year.

They are all expeditiously propagated by layers, cuttings, and suckers.

By Layers.—Their trailing branches being layed in the ground any how, at almost any season, they will most readily take root; and those of the *Vinca minor* particularly multiply exceedingly without care; for the trailing stalks root in the ground at every joint as they extend along, furnishing numbers of good-rooted plants in one summer, fit to plant off in autumn.

By Cuttings.—All the sorts will also readily grow by cuttings of the stalks and branches, planted in autumn or spring, in a shady border, and they will be well rooted by the following autumn.

By Suckers.—They naturally send up suckers from the root in summer, which may be taken up with roots any time in open weather, from autumn till spring, and planted where they are to remain.

Tender Stove Kind.

Consists of one shrubby species, a native of Madagascar, and is retained here in stoves, as an elegant evergreen, and beautiful flowering shrub.

3. *VINCA rosea.*

Rose Periwinkle of Madagascar.] Rises with an upright, shrubby, smooth, branching stem a yard or more high; having a brownish bark; oblong-oval, smooth, firm leaves, placed opposite; and large beautiful, rose-like, crimson, and pale-red flowers, singly and in pairs at the sides of the branches, being large, spreading above, and divided into five segments; appearing very ornamentally from spring till winter, succeeded by ripe seeds in the autumn.

Variety.] Rose Periwinkle with white flowers, having purple eyes.

This elegant little shrub being an inhabitant of the hot parts of Africa, in this country must always be kept in pots, in order to be retained in the stove; in which it will flower annually in great abundance, managing it as directed for other shrubby exotics of the stove. See STOVE PLANTS.

It is propagated by seed and cuttings, assisted by a hot-bed.

By Seed.—Sow it in the spring in a pot of light rich earth, half an inch deep, and plunge the pot in a hot-bed or in the bark-bed in the stove; and when the plants are come up about two or three inches high, prick them separately in small pots and plunged again in a hot-bed,

&c. giving occasional shade from the sun, and proper waterings; and as they advance in growth shift them into larger pots and keep them always in the stove.

By Cuttings.—In spring or summer take off some cuttings of the young shoots, plant them in pots; and plunge them in any hot-bed or in the bark-bed, and they will root the same year fit to pot off separately, and managed as directed for the seedling plants.

VIOLA.

Violet.

There are many species of Violets, mostly very low, herbaceous, fibrous-rooted perennials and annuals, some considered as flowery plants to adorn the fronts of borders, others for variety and medical purposes, rising with clusters of leaves and shoots but a few inches high, and low stalks the same height, crowned with small, irregular, pentapetalous flowers.

Class and order, *Syngenesia Monogamia.*

Characters.] CALYX is pentaphyllous, with the leaves oval-oblong, sharp at top and obtuse at the base; differently arranged in the different species, and persistent. COROLLA is irregularly formed of five unequal petals, the upper one is broadest, obtuse, and emarginated, having a corniculated or horned nectarium at the base; the two side-petals equal, obtuse, and opposite, and the lower ones larger and reflexed upward. STAMINA, five small filaments, two of them placed at the upper petal, entering the nectarium by their annexed appendages; and obtuse antheræ that generally coalesce or connect. PISTILLUM, a roundish germen, slender style, and oblique stigma. PERICARPIUM, an oval, trigonous, obtuse, trivalvous capsule of one cell, containing many oval seeds.

There are more than forty species of Violets, mostly very low, herbaceous plants; many of them natives of England, and other different parts of Europe, and of America; and but only a few of them have merit as garden plants for ornament or variety, consisting of some perennials and an annual; comprehending the Common Violet, &c. Heart's Ease or Pansies.

Perennial Kinds.

Consist of the common odoriferous Violet and varieties, and several others of less note; all hardy perennials of humble growth.

I. *VIOLA odorata.*

Odorous, or Common Sweet-scented March Violet.] Hath a fibrous perennial root, sending up a cluster of heart-shaped leaves and small, creeping, rooting shoots; and amongst them rise slender naked peduncles, three or four inches high, crowned with the flowers of different

different colours in the varieties, appearing in March.

Varieties are,] Common blue-flowered—Pale-purple-flowered—White-flowered—Double blue-flowered—Double white-flowered.

The flowers of all the varieties impart a fine sweet odour, and are used in medicine; though the single flowered kinds are the most odoriferous; but the double flowered varieties are largest and the most conspicuous to sight.

It grows naturally in woods, and under hedges, &c. in England and most parts of Europe, but has been a long resident of gardens, as a flowery plant, and for its flowers to use in medicine.

2. *VIOLA hirta.*

Hairy-leaved Inodorous Violet.] Hath a fibrous, perennial root, crowned with heart-shaped, hairy, hispid leaves; and amongst them slender peduncles, a few inches high, terminated by large blue flowers, like the common sort, but without odour; grows wild in woods and hedges in England, &c.

3. *VIOLA palmata.*

Palmated Virginia Violet.] Hath a perennial root, crowned with five-lobed, palmated, or hand-shaped, indented leaves, and low peduncles, supporting white flowers in May or June.

4. *VIOLA montana.*

Mountain upright Austrian Violet.] Hath a perennial root; erect stalks a foot high; heart-shaped, oblong leaves; and purple flowers at the axillas of the branches, in April and May.

5. *VIOLA calcarata.*

Calcarated, or Spur-flowered Yellow Alpine Violet.] Hath a perennial root, sending up very short stalks, four or five inches high, garnished with oblong-oval leaves, and slender peduncles, supporting yellow flowers, streaked with purple; having long spur or awl-shaped nectariums, longer than the petals; flowering most part of summer.

Varieties.] Common yellow purple-streaked-flowered—Plain yellow-flowered—Purple-flowered.

6. *VIOLA mirabilis.*

Marvellous-flowered German Violet.] Rises with short three-sided stalks; reniform-heart-shaped leaves; and the cauline flowers without petals.

7. *VIOLA biflora.*

Two-flowered Alpine Violet.] Kidney-shaped serrated leaves; and the stalks having two flowers.

8. *VIOLA pedata.*

Foot-shaped leaved Virginia Violet.] With-

out stalk; foot-shaped leaves cut into seven parts.

9. *VIOLA uniflora.*

One-flowered Siberian Violet.] Stalks having one flower; and heart-shaped, dentated leaves.

10. *VIOLA ceniffa.*

Ceniffian large blue Violet.] Slender suffruticose creeping stalks; oval, smooth entire leaves; and peduncles having large blue flowers.

11. *VIOLA canadensis.*

Canada American Violet.] Erect low stalks; and heart-shaped, pointed leaves.

Of the above eleven species of perennial Violets, the first sort (*Viola odorata*), is the most remarkable, being highly esteemed for its sweet-scented flowers; and is proper to plant on the verge of shrubberies, wood-walks, and in tufts or patches; and as to the other species, the first four of which are the most noted, and although their flowers are without scent, they, if arranged in concert with the varieties of the common sort, will effect an agreeable diversity. Any of the other species are also eligible to introduce for the same occasion.

Though, when the common Violet is intended to be cultivated for its flowers to gather, it may be planted in beds or borders alone; in rows, a foot asunder, and they will soon increase into large bunches.

They all flower in great abundance every year in their respective seasons; the flowers are small, irregular, and consist each of five unequal petals, continuing in succession three or four weeks, and are succeeded by ripe seeds in summer and autumn.

The propagation of all the sorts is by parting the roots, and sometimes by seed.

By parting the Roots.—They all multiply by the roots; and the common Violet and the other creeping kinds propagate also abundantly by their repent shoots rooting in the earth; they may be parted or slipped in spring, summer, or autumn, as soon as they have done flowering; when in moist weather, or early in spring, each plant may be slipped, or divided into several slips, not too small, and planted either at once to remain, or the weakest may be planted in nursery-beds, to have a summer's growth; and in either method each slip will soon increase into a large tuft, and flower abundantly next year.

By Seed.—Sow it either soon after it is ripe, or early in the spring, in a bed or border of light earth, and raked in; and when the plants are come up an inch or two high in summer, prick them out in a shady border, to grow

grow till October, and then planted out finally to remain.

Annual-biennial Kind; also Perennial occasionally.

One species only come under this head; a well-known, little, tufty, very flowery plant, commonly called Heart's Ease, or Pansy; and is generally considered as an annual, because, being raised from seed in spring, it flowers the same year, and sometimes decays in winter following, but not generally; and more commonly proves of a biennial or perennial nature, remaining in stalk and leaf all the year, in favourable seasons.

12. *VIOLA tricolor.*

Three-coloured Violet, commonly called Heart's Ease, or Pansy.] Hath a fibrous root, sending up slender, triquetrous, or four-square stalks, branching diffusely, from six to ten or twelve inches high, assuming a bushy, tufted growth, garnished with small, oblong-oval, cut leaves; and at the axillas of the branches numerous variegated, tri-coloured flowers, yellow, purple, and white, appearing in constant succession all summer and autumn; grows naturally in cultivated places in the north of England, &c.

Varieties.] Low growing, with small flowers—Larger upright, with large flowers—Large Dutch, with largest flowers—Variegated, yellow, purple and white-flowered—Yellow-flowered, with purple spots—Purple, with yellow or white spots—White, with yellow and purple spots—Entire yellow—Deep and pale yellow—Purple-flowered—Scentless flowered—Sweet-scented flowered.

All the varieties flower very profusely, and some variegated many different ways in the same plant; and the most prevailing colours are yellow, purple, blue, and white; some of which being of a fine velvety hue, particularly the purple, varying in different flowers, and all of which are succeeded by abundance of seed, which soon scatters itself in the adjacent ground, and from which numbers of plants naturally rise, without care of culture.

This elegant little plant merits culture in every garden, for the beauty and great variety of its tricoloured flowers; and it will succeed any where in the open borders, or other compartments, disposed in patches towards the front; either by sowing the seed at once to remain, or by putting in young plants previously raised in a seed-bed, or also by off-sets and slips: they will begin flowering early in summer, and will continue shooting and flowering in succession till winter,

and even during part of that season, in mild weather.

It is easily propagated in all the different varieties, abundantly by seed; also by off-sets, slips, and cuttings of old plants when increased into bunches.

The seed may be sown either at once, where they are to remain, or for transplantation; and when once a few plants are raised, and have flowered and ripened seeds, they will naturally sow themselves, and produce a constant supply of plants.

However, the season for sowing them is in autumn and spring; the autumn sowings come up the same year, stand the winter, and flower early in the spring following; and the spring-sown plants succeed them in flowering, and continue till winter. Sow them either in patches about the borders, half an inch deep, to remain, or in a bed or border, broadcast, and raked in; and when the plants are advanced two or three inches high, prick them out, to remain to flower, one or two plants in each patch, which will soon increase into a large tuft.

By Off-sets, Slips, &c.—Plants of any particular varieties, grown into large bunches, being generally furnished with many bottom off-sets, they may be slipped or divided with full roots, either in autumn, August, or September, or in the spring months, and planted either in the borders to remain, the larger full-rooted slips, or the smaller ones in beds, to grow stronger, then finally transplanted; or in spring or summer, slips or cuttings of the shoots planted in a shady border, watered at planting, repeating it moderately afterwards, in dry weather, they will strike root, and form proper plants; so that by these methods any particular variety may be readily increased, and the plants thereby continued permanent in their respective kinds in a perennial growth.

VISCUM, Mistletoe.

This genus furnishes but one species, an under-shrub evergreen of a singular nature, being of the parasitic tribe, not growing in the earth, but upon other plants, generally on the branches of soft-wood trees, commonly suspended from the under side of said branches, with its root upward and the head hanging down, in a forking-branchy, bushy growth; garnished with narrow spear-shaped stiff leaves, and small calycinal, apetalous yellow flowers, succeeded by white glutinous berries, ripe in winter.

Class and order, *Diœcia Tetrandria.*

Characters.] Male and female flowers on separate plants. CALYX of the male flower

is composed of four oval equal leaves. **COROLLA**, none. **STAMINA**, filaments none, but four oblong pointed antheræ, each growing to a foliole of the calyx. The female flowers consist of a calyx, composed of four small leaves, which are oval sessile, deciduous, and sitting on the germen; corolla, none. **PISTILLUM**, an oblong, three-cornered germen, situated under the receptacles, with no style, having only an obtuse stigma. **PERICARPium**, a round smooth berry with one cell, containing a single obcordated, obtuse, carnosé, and compressed seed.

We know but of one species,

Viscum album.

[*White-berried, or Common Mistletoe.*] Hath woody branches of a yellowish colour, usually growing in pairs, in a sort of a forked manner, dividing from near the base of the main stem, and annually subdividing in a dichotomous form; at the joints of the divisions grow the leaves, spear-shaped, obtuse, of a thick consistence and yellowish-green, continuing all the winter; and the flowers, produced in short spikes from the wings of the branches, are small, and of a yellowish colour, succeeded by large white viscous transparent berries, which are ripe in the winter.

This very remarkable plant is an inhabitant of our woods and orchards, growing upon the branches of ash, hazel, maple, crab, and apple trees, &c. as it will not grow by any means in the natural earth, like other plants; being produced from seed accidentally disseminated by birds, such as the Mistletoe-thrush, &c. feeding on the viscous berries, which casually adhering to their beaks, are thereby carried to the adjacent trees, and lodged on the branches; or probably sometimes by voiding the berries thereon, are washed by the rains to the under side, where, being affixed by their soft glutinous pulp, the seeds contained therein germinate and plant their radical fibres in the bark, running between that and the wood, and thence shoot out into a short robust stem and round bushy head, in a pendulous growth.

Thus, whoever may incline to raise this singular plant, may propagate it in his plantations, garden or orchard, &c. by procuring some of the fully-ripened berries in winter, and stick or rub them on some smooth part of the under side of the branches of any soft-wooded standard trees, as ash, hazel, apple, crab, &c. as before intimated, their glutinous matter will affix them close, where they will grow in the manner above related; though for the greater chance of success, may previously cut the outer bark a little in that part,

and also rub some berries on several different trees and branches, as they do not always effectually succeed.

It is probable the failure of success, sometimes happening, in endeavouring to propagate this plant by art, is owing to the nature of the berries, for being of the diœcious class, male and female flowers on separate plants, the berries gathered from female plants, not situated near a male, when in bloom, may be deprived of the *farina fecundans*, necessary to impregnate and fertilise the berries, which proving thereby abortive, will not grow; therefore it would be more effectual if they could be obtained with certainty from some female plants which grow near those of the other sex.

This plant is said to be possessed of peculiarly excellent medical virtues; and is used successfully in nervous affections.

VITEX. *Agnus Castus*, or Chaste Tree.

Of this genus there is one hardy species cultivated in our ornamental gardens; and two tender kinds for the green-house, all of shrubby growth, garnished with digitated, trifoliate, and quinquelobate leaves, and ringent ornamental flowers growing in spikes and clusters.

Class and order, *Didynamia Angiospermia.*

[*Characters.*] **CALYX**, a short cylindrical monophyllous perianthium, indented in five parts. **COROLLA**, a ringent petal, with a slender cylindric tube; the limb is bilabiated, both lips are divided into three segments, the middle one being broadest. **STAMINA**, four capillary filaments; two of which are longer than the others, having versatile antheræ. **PISTILLUM**, a roundish germen, a slender style, and two awl-shaped stigmas. **PERICARPium**, a globular berry of four cells, each containing a single oval seed.

This tree was much celebrated among the ancients, on a supposition that the influence of it was conducive to chastity (whence the name); but the moderns know of no such peculiar virtue as has formerly been ascribed to it.

The species are,

Hardy Kinds.

1: **VITEX**, *Agnus Castus*.

(*Agnus Castus*)—or *Chaste Tree*.] Hath pliable branches, whose joints are long, rising to the height of about five or six feet; they are of a brownish-grey colour, and are garnished with digitated leaves, composed of several folioles, which are narrow and of a dark green colour, and ending in obtuse points; the flowers are produced at the ends of the branches in whorled spikes, which are pretty long, and

and of a bluish-purple colour; they appear in autumn, but are not succeeded by seeds in this country.

Varieties.] Narrow-leaved, having the folioles long and narrow—Broad-leaved, having broader and shorter folioles—Blue-flowered—White-flowered.

These are desirable deciduous shrubs for ornamental shrubbery compartments; will succeed in any common soil and situation; and may be planted in the usual seasons of autumn and spring.

They are easily propagated either by layers or cuttings any time in the autumn, or winter; will take root the following summer, and may then be taken up in autumn or the spring and transplanted.

Green House Kinds.

2. *VITEX trifoliata.*

Trifoliate Indian Chaste Tree.] Rises with a shrubby stem and branches six or seven feet high; leaves composed mostly of three oval entire lobes, sometimes five; and dichotomous panicles of white flowers.

3. *VITEX Negundo.*

Chinese Quinquifoliate Chaste Tree.] Rises with a shrubby stem and branches six or eight feet high; leaves composed of five spear-shaped sawed folioles; and clustered panicles of blue flowers.

Both these tender species require protection of a green-house in winter; therefore must be planted in pots of light mellow earth, and stationed with the green-house exotics, in which they will effect a conspicuous variety, and produce flowers in summer; and are propagated by layers in the spring; also by cuttings in pots plunged in a hot-bed, or covered close with a hand-glass, which will promote their rooting in a short time, for transplanting into separate pots in autumn following.

VITIS, Vine.

A genus of well known deciduous climbers, of which there are several species, one of which is universally noted and esteemed as a fruit-tree, for its many fine varieties of that most excellent fruit the grape; the other kinds are more noticed for singularity and variety, than the fruit they produce; some hardy for the full ground, others for the hot-house; all of the woody climbing kind; with long flexuose stems, branches, and shoots, rising by support to a considerable height and extent; producing many long trailing climbing, jointed shoots annually, advancing many feet in length in one summer; garnished at each joint with large, mostly simple, lobated leaves, singly, cut into three or five lobes, attended by climb-

ing tendrils; and clusters of small greenish flowers, arising on the same year's shoots; succeeded by large bunches or clusters of berryed fruit; ripening, in the first species, and varieties, with a most rich and delicious flavour in July or August, September and October.

Class and order, *Pentandria Monogynia.*

Characters.] CALYX, a very small perianthium, indented in five parts. COROLLA, five small petals, which are deciduous. STAMINA, five subulate, erect, patent falling filaments, with simple antheræ. PISTILLUM, an oval germen without a style, crowned with a blunt capitated stigma. PERICARPIUM, a large roundish berry of one cell, containing five hard roundish seeds, narrowed at the base.

Species.

1. *VITIS Vinifera.*

Common Vine or Grape Vine.] This hath lobate, sinuated, naked leaves, with herbaceous flowers, growing in a racemus which becomes a bunch of red, white, black, and other coloured berries, in the many different varieties,

Varieties of this species are,

(1.) *July Grape*, this hath a berry, small round, and black, slightly growing on the bunches, esteemed principally for its earliness, though rarely ripening in July, but soon in August.

(2.) *Black Sweet-water*, hath roundish berries, growing compactly together in small bunches; they ripen in August: the flavour being rich, and skin thin, invites the birds, flies, &c. to prey on them, which (in time) should be guarded against.

(3.) *White Sweet-water*, this is an exceeding fine flavoured grape when perfectly grown, but the berries being liable to outgrow each other, makes the whole bunch incomplete; this ripens about the end of August.

(4.) *Muscadine*, this is one of the finest white grapes which ripen against common walls in this climate; the bunches are large, the berries are round, and of a very rich flavour; this will ripen in September.

(5.) *Black Cluster Grape*, hath hoary leaves; the bunches are short and very compact; the berries are small, and ripen the end of September.

(6.) *Royal White Muscadine Grape*, larger full bunches, of fine large, round, white berries; ripening in great perfection against a south wall in September.

(7.) *White Cluster Grape*, short close bunches; ripe in September.

(8.) *Black Frontiniae*, hath shortish bunches, the berries of which grow pretty close to-

gether; when ripe, are round and of a deep black colour, covered with a mealy bloom; the flavour of this grape is very rich, of a muscat taste, and in very hot summers will ripen on a south wall naturally in October.

(9.) *Red or grizzly Frontinac*, hath middling-sized bunches; the berries are round, of a red colour, and striped; this grape, when thoroughly ripe, is of a most rich and excellent flavour: it rarely ripens well in this climate without the assistance of heat.

(10.) *White Frontinac*, this is a high flavoured grape, and hath a peculiar rich juice when perfectly ripe; the bunches are large, and the berries, which are round, are very closely joined to each other, whereby they are apt to rot each other before they are ripe, which in some measure is owing to the thinness of their skins; it is therefore necessary to thin them out when they are about the size of peas, whereby the sun and air will have freer admittance, and those which are left will be larger, more handsome, and higher flavoured; this grape will not succeed without artificial heat.

(11.) *Muscat of Alexandria*, hath long bunches, with oval large berries; there are two sorts, one with white, and the other with red berries; they are a fine grape, but require a hot-house to perfect the fruit.

(12.) *Hamburgh Red and Black*, hath very large bunches; the berries are large and inclining to an oval form; this grape will ripen tolerably out of the stove, if the autumn proves kind, but not before the end of October.

(13.) *Raisin Grape*, hath very large bunches; the berries hang very loosely; they are of an oval form, but will not ripen here without being forced by artificial heat.

(14.) *Aleppo, or Syrian Grape*, the bunches of this grape are the largest yet known, some weighing at least a dozen pounds; the berries are large and white, growing loosely; they are of a good flavour, and their skins being tough can be kept a considerable time after they are ripe; this kind should be constantly kept in the stove.

(15.) *Tokay Grape*, black and white sorts; large and fine bunches and berries: requires protection of glasses, &c. to ripen in perfection.

The above enumerated varieties, which are of the most approved and esteemed sorts, are sufficient to continue against the common walls a succession of ripe fruit, from July or August, till the end of October; or assistance also by forcing, ripe grapes are obtained from May to November, the major part of them being the highest flavoured grapes hitherto known.

To these may be added the following—
Black Burgundy Grape—White Frankendale

Grape—Damascus Grape—Zante Muscat Grape—Rhenish Grape—Provence Grape—St. Peter's Grape, most large bunches and berries; requiring aid of artificial heat.

General Observations.

Vines, although originally natives of distant warm climates, grow freely in this country, in almost any situation and common cultivated soil of our gardens; but it must be observed, they will not produce, or at least ripen their fruit, in any tolerable degree of perfect maturity and good flavour, unless they have the assistance of warm south walls, and their branches regularly trained thereto, in order thereby to obtain all possible benefit of the sun's influence; and even sometimes with that aid, they in unfavourable seasons ripen their fruit in but very indifferent perfection, and not till late in autumn; and some particular large sorts of grapes will not ripen at all in this country, without the protection of glass-houses, aided by artificial heat: however, there are a sufficiency of excellent sorts, which being planted against our common walls, of a south aspect, and well managed, produce fine grapes, when the seasons prove favourably dry and warm; they ripening, in the different sorts, in August, September and October.

All the varieties of the Vine assume the same mode of growth and order of bearing; they in their growth all advance with long slender flexible stems, branches and shoots, sometimes shooting five or six to eight, ten or twelve feet length in one summer; each shoot having many joints, and of a cirrhous-climbing nature, by means of their tendrils or clasps, arising at the joints, which clasping round any adjacent body they encounter, and thereby in some degree elevate and support the shoots in their advancing growth in summer, though not sufficiently in any effectual regular manner; and therefore require a constant regular training, by a general necessary pruning, and nailing every year in summer and winter, and the branches and shoots regularly trained close to the wall: a summer pruning to regulate the shoots of the year, by displacing the improper, and irregular-placed, and superfluous or over-abundant, and to retain and train in all the fruit bearing shoots, and others of proper growth and situation on the Vine, for mother bearers the following year; and a winter-pruning to give a general regulation both among the old branches, and the young wood of last summer, by occasionally pruning out some part of the former, or any unfruitful naked old wood not furnished with young shoots for bearing, as Vines always bear only on the yearling

yearling shoots; and of which in this the winter regulation, pruning out the most irregular and superabundant, and reserving abundance of the strongest and most regular placed in all parts for next summer's bearers, and each shortened less or more as hereafter explained; and then the whole, both old and young branches, to be nailed to the wall in regular order, six or eight to ten or twelve inches asunder, according to situation and strength of the shoots.

As to the order of bearing, and pruning, all the sorts of Vines are exactly similar; always producing the grapes on the young shoots of the same year, arising immediately from the eyes or buds of those produced the year before; seldom immediate bearers from the older wood, but shoots produced therefrom, one year, they in the spring and summer following, when one year old, produce fruitful shoots, yielding fruit the same summer; so that, in Vines, the same individual shoots do not produce immediate fruit from the same eyes the second year, but producing a succession of young shoots one from each eye or bud, and upon these successive shoots, the fruit is produced the same season: and as thus the succession of bearers is invariably continued from year to year, a regular successional supply of the best shoots must be retained every year accordingly; for as Vines always require a regular pruning and training every year in summer and winter, as before intimated, particular attention is requisite in these necessary annual operations to select and reserve a sufficiency of each year's shoots, in all parts of the trees, both for immediate and future bearers, in the order above explained; and at the same time, the useless and superabundant displaced: as likewise, in the winter-pruning particularly, a part of the former bearers and old naked wood must be pruned out to make room for the successional supply of annual young fruit-bearing shoots, advancing regularly from the bottom, one above another upwards to the top or extremity of the Vine every way: all of which retained shoots, in winter pruning, must be shortened or pruned to two, three or four, to five, six or eight joints long, according to their strength, and different situations on the Vine; and then the whole, both young and old wood, to be trained and nailed regularly to the wall, either more or less horizontally or upright, as the allotted space of walling, &c. admits.

The different sorts of Vines are all easily propagated or raised always by layers and cuttings; the laying being performed on the one and two year old shoots and branches,

laid in autumn or spring, five or six inches deep in the earth (see LAYERS), and the tops pruned to two, three, or four joints, they will be well rooted in one summer, to transplant in autumn or spring after, either at once where they are to remain, or some in a nursery for a year or two to grow stronger, then finally transplanted; and cuttings of the young shoots of one year's growth, cut in lengths of two or three joints, planted in the spring, inserted or laid slanting into the ground to the uppermost joint, will emit roots below and shoots above the same year, forming rooted young plants by autumn following; and then the young plants raised by either of these methods will commence bearers in two or three years, especially the layer plants; and also thriving cutting-raised plants will mostly begin bearing the third season.

Vines for final planting against walls, may either be ready-raised young plants of two or three years' growth or more, that have been previously propagated and raised from layers of one or two year's young branches, before intimated, which generally root effectually in one summer for planting off in autumn or spring following; or of plants raised from cuttings of the one year's shoots, which also generally root in one season; and either of which, when of one, two or three years' growth in the nursery, may be transplanted finally, where they are intended, against the proper walls to remain, or may occasionally plant immediate cuttings from the Vine at once in the allotted places, there to strike and always continue, and in which, as they will not have any future removal, to occasion any check in their advancing growth, they will establish their roots firmly, and make very prosperous plants: and thus by the above methods may raise a plantation of Vines, less or more, as may be required; and managed as hereafter advised in their different stages of growth.

But as many persons may be anxious to have their intended walls furnished at once, as it were, with Vines of some advanced growth, to form bearers as soon as possible, ready-raised young plants, of the different varieties, may be obtained at most of the public nurseries of a proper plantable size, of one, two or three years' growth or more, or of eligible advanced growth, for immediate bearing; either in good rooted plants in the full ground, or in pots, which latter being removed in said pots to the places where intended to plant them, may be transplanted from the pots, with the ball of earth about the roots entire, so as to feel but little check by removal; or occasionally the pots with the plants therein

therein placed in the ground, and the pot then carefully cracked or broken not to disturb the ball of earth, and the pieces removed with the same care; and, in either method, filling in the earth closely round the ball.

The season for planting Vines is either in autumn, towards the latter end of October or any time in November, or in the spring, in February, March, or beginning of April.

They may be planted in any light good rich earth of a garden, in common with other wall-trees, in borders under south walls, as aforesaid, or such as incline as much of a southerly aspect as possible.

In planting the Vines in ready raised full rooted plants, if designed for a continued plantation, they may be planted five or six, to eight or ten feet distance; in which, if but low walls, they should be allowed the greater distance; that in default of height, for any considerable upright training, it may admit of arranging the branches more horizontally; but in high walls they can be trained in a more upright direction; or sometimes in wide vacant spaces between wall trees, may plant a Vine in each such space, to be trained upright between the trees; or Vines may be planted against the front or ends of buildings, of a south aspect, open to sun, where having large scope to run or train the branches, they will extend and spread considerably, and produce large quantities of grapes in proportion; and in all of which, those designed to be taken up in the full ground for planting, should be removed with as full roots as possible, and the whole retained, except pruning any casual broken or mangled parts, occasioned in digging them up, or to shorten any very long straggler; and any plants in pots designed for planting, may be planted with the ball of earth about the roots entire, as before suggested; giving the whole, as soon as planted, a moderate watering to settle the earth close about the roots; and then prune the shoots to three, four, or more joints, in length, according to their strength, and nail them to the wall in regular order.

But in planting Vines by unrooted cuttings at once from the trees, in the places where they are always to stand, these, as not having immediate roots, should be planted only a foot asunder, or much closer than the distances above mentioned, for the ready-raised full-rooted plants, that there may be the greater chance, out of the whole, when rooted, and a little advanced in top growth, to make choice of the strongest and most thriving plants for continuance.

As, however, the general methods of rais-

ing the Vines by layers and cuttings, planting and future management, are more fully related below, in their propagation, &c. we refer thereto for further intimations in these particulars.

Vines are also occasionally planted in espaliers, and in vineyard rows, in warm dry sunny situations; in espaliers they may either be planted, a few of the forward ripening sorts, in assemblage with some other choice espalier trees, or arranged separately: they sometimes in fine warm seasons will ripen grapes in tolerable perfection; and in the vineyard order, to produce large quantities of grapes for making wine, &c. they are planted in some dry warm exposure and light dry soil, or on some gently-sloping situation in the full sun, in rows ten feet asunder, and a range of stakes placed to each row on which to train the branches and shoots; and in which order of planting and training, they, when favourable forward springs, warm summers, and a warm dry autumn, will sometimes produce plenty of grapes in good maturity.

Of their Propagation and Planting.

The general propagation of grape Vines is either by layers or cuttings, as before observed: the method of increase by layers is practised as follows: in autumn or winter make choice of strong prolific shoots, of one or two years growth, arising from near the ground, and of the kind you would wish to propagate; let these shoots be bent down in the earth six or eight inches deep at the part where the last summer's shoot issued from; this should be pegged down to prevent its being disturbed, and then shortened at the top to two or three eyes; the next autumn following the layers will be sufficiently furnished with roots for transplantation, when they may be cut from the parent plant, and placed where intended to remain: but to insure the layer's success by such removal, the laying is occasionally performed either by bending the layer down into a large pot and earthed up, or trained through the hole at the bottom of the pot or pots, one layer in each; in these they take root, and in the winter, if they are separated from the mother plant, they may be turned out of the pot undisturbed, and planted with the roots entire, where it may be thought proper.

But to increase this plant by cuttings of the one year's shoots taken off any time from the fall of the leaf till spring; in the choice of which those of a strong vigorous growth, with the buds not far distant from each other, should be preferred, observing also to chuse such as have thick, turgid, blunt buds, as these are most prolific, avoiding those which

are not well ripened, or have their buds pointed. In taking off such cuttings, it is proper where conveniently practicable, to cut them an inch or two in the former year's wood, below the place where the last year's shoot is produced from; for at this joint the roots will more readily spring out and form the plant. Shortening the cuttings, in lengths of three, four, or five eyes, according to their distance from each other: observing, the cuttings may be taken from the parent plant any time between November and February, and planted, or may be laid with their lower part in the ground, and covered in hard weather with litter, where they may remain till the spring season of planting arrives, which is March or the beginning of April; they should then be taken up, cleansed and planted where they are intended to remain, and perfect themselves, as they are not to be removed again, whether for walls or vineyard.

The proper situation for Vines is a south aspect, as full to the sun as possible; for in this country they require every beneficial assistance thereof to forward the growth of the fruit and ripen it in some tolerable degree of perfection and flavour; which cannot be effected in any other than a good southerly exposure, against a south wall, or occasionally in the vineyard, of a similar aspect, trained to a treillage, &c. therefore, in our intention to plant Vines, should always allot them some best southerly walls, &c. or such as incline the most fully to that exposure; observing also the same when designed to plant any in the vineyard manner, in the open ground, in detached rows, trained to stakes, &c. for which the south side of some gently rising ground would be eligible.

With respect to soil for the Vines, this should be attended to with some consideration: if the ground is of a wet nature, or a strong stiff clay, it is the most improper for these plants, as the cuttings or layers will grow very luxuriant, but will produce very ill-flavoured grapes, owing to the redundancy of moisture with which the plants are saturated; a rich light soil is therefore to be preferred; for, notwithstanding the notion of many gardeners, in putting a stratum of stones, brick, rubbish, &c. to impoverish the soil, with a view to render the Vines more prolific, or particularly, by having thereby a dry warm bottom, to forward the growth, ripening, and improve the flavour of the grapes, it, although in some degree may have the desired effect, is sometimes apt to stunt the growth of the plants, and cause the fruit to be small and trifling, whereas, if they have a rich dry soil, the shoots

will grow strong, especially where they can have extent to run, and the bunches will be proportionably large and handsome.

The ground being ready for the reception of the Vines, either in ready raised full rooted young plants from a nursery, &c. plant them against the south wall, five or six to eight or ten feet distance: or if cuttings, let them be planted against the wall, at about six inches asunder, and at such a depth as but one eye of the cutting may appear above ground, observing to press the ground tight about them, and if the season proves dry, let them occasionally have a little water.

But to strike cuttings of Vines as expeditiously as possible, well rooted, and in some advanced top growth for final planting against walls, as above, recourse may be had to the assistance of a stove; therefore where there is the convenience of a stove, in February the cuttings may be planted each in a middling pot, and plunged in the bark-bed; here they will quickly take root, and in the course of the summer make a very great progress, so much as to gain a year of those planted in the common ground, observing, as the pots are filled with roots, to shift the plants with balls into others of a size larger, and this should not be omitted when occasionally necessary; the plants thus forwarded should in autumn be inured to the open air, and turned out of the pots with their balls into the places where they are intended to remain.

With respect to the aspect these plants require, let it be always remembered, that all aspects are improper for grape Vines; excepting the south and south-west, as in other situations scarcely any bunches will ripen in this cloudy changeable climate.

General Management after planting.

When the cuttings, &c. begin to shoot, let them be examined, and leave only two of the best shoots of the year, if so many arise, those which appear the strongest should be chosen; about a month after, the shoots will have made some progress, so as to show which is likely to be the strongest; this shoot should be preserved, carefully nailing it against the wall, to prevent its being broke by the wind, observing to rub off the other; in the course of the summer, as the shoot advances, continue to keep it nailed up, and let all lateral shoots be stripped off as they are produced; this, with keeping the ground clear from weeds, and occasionally watering in dry weather, is all that the plants require in their summer's management; and in autumn, when the leaves turn yellow and begin to drop, the shoot which has been reserved should be topped down to two eyes;

and these will produce shoots the succeeding summer.

The spring following, the borders may be enriched and dug up, so as not to disturb the roots of the Vines: in April and May the shoots now produced from the eyes which were left will be of a considerable length, each should be tacked to the wall to prevent their being broke by the winds, rubbing off all lateral shoots as they are produced, and this work should be repeated occasionally, till the shoots have done growing, observing to keep the ground entirely free from weeds during the summer. The November following, the operation of pruning should be performed by shortening the weakest of the shoots to two or three eyes, and letting the strongest be left to four, six or eight eyes, according to its strength; for if the principal shoot is very strong, the greater length should it be cut to, and the more probability there is of its producing fruit the succeeding summer.

The same care will be required the third year, &c. for in April or May, according to the forwardness of the season, the shoots of the Vines will have made some progress, which should be properly attended to; this is by displacing all unnecessary shoots, leaving none but those which have the appearance of producing bunches, or furnishing shoots for the succeeding year; these should be laid close to the wall in a regular manner; for, if neglected, the first violent wind may break them off, and if not, the shoots will soon run into confusion; the omission of this necessary work will also be attended with other bad consequences, for the growth of the bunches will be retarded, and the shoots, intended for the supply of the next year, will be so much shadowed and stopped in their growth as to prevent the wood from obtaining its proper ripeness, so as to be able to furnish good fruitful shoots in future. The same attention should be paid the Vines in the following months, observing to keep them nailed up as they advance, displacing all useless, straggling and lateral shoots. As they are produced in August, the extremities of the fruit-bearing branches may be shortened, as also those which have run out of bounds to a very great length; this stopping the shoots will assist the bunches to swell their berries out, and forward their ripening; and if that or the former month proves very dry and hot, let them be moderately watered: this will keep the Vine in a ductile state, and be a great addition towards increasing the size of the bunches; but when the fruit is full grown, watering should be disused, as it would de-

bate the flavour of the berries. When the grapes are approaching to ripeness, they should be guarded from the ravages of birds, wasps, and other insects: they may be protected from birds, by placing a net over the Vine; but this prevents not the wasps, &c. from preying on the fruit; therefore, to hinder these insects from making their depredations, provide some fine crape, which being cut to a proper size, bags may be made so as to fit the principal bunches: black crape is best, as it is of a colour which absorbs the rays of light, and assists, by its warmth, the ripening of the bunches. But as our climate will not sufficiently ripen the finer sorts of grapes, I shall concisely mention the method of obtaining them in perfection, and for fuller particulars refer to the articles, *FORCING HOUSES*, *STOVES*, &c.

Forcing Grape Vines.

Various buildings have been contrived to effect the ripening of those kind of grapes, which cannot be effected in the open ground, as likewise for the earlier sorts to be fit for the table in May, June, or July. The construction of these kinds of buildings are different, though all answering the same purpose: some are constructed with flues ranging within the wall where the Vines are trained up; but as the Vines would receive more heat at times by being closer to the wall than is proper, a lattice work is generally detached therefrom, to which the branches are trained, and the whole is covered with a range of sloping glass; but the more common method is to train them under the sloping glasses of the pine-apple stove, the Vines are generally planted close on the outside, and trained in through holes contrived for the purpose; in such places there is a certainty of the grapes ripening in perfection, observing occasionally to train fresh shoots from without in autumn or winter, that there may be no want in the choice of wood; their management differs but little from those of the common walls, therefore needs no repetition.

The other species of Vines are those which more excite curiosity than are of real use.

2. *Vitis Labrusca.*

Ivy-leaved American Vine.] Hath a climbing stalk, furnished with large, trilobate, heart-shaped leaves, downy on their underside and indented on their edges; the flowers are produced in bunches, and are succeeded by round rough flavoured black fruit.

3. *Vitis vulpina.*

Fox-scented Virginia Grape.] The leaves are large and smooth on both sides, of a heart-shaped figure with indented edges; the flowers grow

grow in bunches, and are succeeded by black berries of a very disagreeable stinking flavour.

4. *VITIS laciniosa*.

Lacinated, or Cut, Parsley-leaved Canada Vine.] The leaves of this sort are finely divided; the stem is thick, bearing strong shoots; but the fruit is of no account.

5. *VITIS arborea*.

Tree, Pinnated-leaved Carolina Vine.] The stem more erect, but the shoots rather weak; is admired for the beauty of its leaves, which are supradecomposed, of a fine green colour, and composed of a multitude of delicate folioles; the flowers come out in bunches from the wings of the stalks, and are succeeded by berries of the size and form of pepper.

All these species are propagated by cuttings, layers, or suckers.

Tender Kinds for the Hot-house.

6. *VITIS indica*.

Indian Villose-leaved Vine.] Heart-shaped, indented leaves, villous-hairy underneath; and racemous tendrils.

7. *VITIS trifoliata*.

Three-leaved Indian Vine.] Trifoliate leaves, with roundish folioles.

These two Indian Vines are preserved in some curious stove collections for variety; and are propagated by seed, and by layers and cuttings vegetated in a hot-bed, or the bark-bed in the stove; and managed as other woody exotics of that department.

VOLKAMERIA.

Volkameria.

A genus, furnishing, for the stove, two exotic trees from the Indies, of moderate growth, garnished with oblong-oval and oval leaves; and monopetalous, ringent, irregular flowers, succeeded by roundish berries.

Class and order, *Didynamia Angiospermia*.

Characters.] **CALYX**, monophyllous, turbinate, with the border five-parted. **COROLLA**, monopetalous, ringent, with a cylindric tube double the length of the calyx, divided in the border into five sub-equal segments. **STAMINA**, two very long and two shorter filaments, and simple antheræ. **PISTILLUM**, a four-cornered germen, slender style, with a bifid stigma. **PERICARPIMUM**, a roundish four-furrowed, bilocular bacca, with a single nut in each loculus.

The species are,

1. *VOLKAMERIA aculeata*.

Prickly Jamaica Volkameria.] Rises with a woody stem and diffused slender branches, fifteen feet high or more, garnished with oblong-oval-lanceolate shining leaves; spines at the rudiments of the petioles; and umbels of flowers at the sides of the branches.

2. *VOLKAMERIA inermis*.

Unarmed or Smooth Indian Volkameria.] Rises with a shrubby stem, and upright white branches, without spines, several feet high; garnished with oval leaves, in whorls; and flowers on long peduncles, standing erect.

Both these species require the protection of a stove, especially in winter; in which a plant or two of each will form an agreeable variety.

They are propagated by cuttings in May or June, planted in pots plunged in a moderate hot-bed, in which they will soon emit roots below and shoot at top; and should then, when a little advanced in growth, be transplanted into separate pots; and plunged again in a hot-bed or bark-bed to assist their fresh rooting, and forward them in growth before the approach of winter, when they should be placed on the stove; and have the general culture of similar woody plants of the stove collection.

VOLUBILIS caulis.

A twining or winding-climbing stem.

Volubilate stems are such as ascend spirally round the stem or branches of other plants, or round one another, or round stakes, or any thing similar they meet with in the course of their extending growth; exemplified in honey-suckle, hops, runner kidney beans, &c.

These stems in different sorts of plants wind in different directions either to the left, according to the apparent diurnal motion of the sun, as in honeysuckle, hop, and black bryony; or to the right, as in kidney-bean, convolvulus, and Malabar night-shade.

As many of our garden plants, both hardy and tender kinds and woody and herbaceous, are volubilate climbers, some mounting spirally upon support several feet high; they should all be allowed proper support accordingly, of stakes, or poles, &c. proportioned to their extent of growth; and some of the hardy kinds, extensive growers, may be placed to twine round the branches of trees and shrubs, &c.

W.

W A L

W A L

WACKENDORFIA. (*Wackendorfia*.) This genus consists of two African flowery perennials for the green-house, with thick, tuberous, fibrated, red roots, sending up spear-shaped, channeled, plaited leaves, from half a foot to two feet long, by two or three inches broad, and amidst them, upright flower-stems, three or four feet high in the first sort; the other about a foot, producing hexapetalous triandrous flowers, terminating the top in a thyrses and panicles; having spathaceous, bivalve calyxes, a corolla of six oblong petals, three standing erect, and three spreading; with three spreading stamina; a roundish triangular germen, and declining style; succeeded by an oval-triangular, trilocular capsule, with three seeds.

Class and order, *Triandria Monogynia*.

The species are,

1. *WACKENDORFIA thyrsiflora*.

Thyrses-flowering Wackendorfia.] Large, long, spear-shaped leaves, five-nerved and channelled: and tall single stems, terminated by a thyrses spike of yellow flowers.

2. *WACKENDORFIA paniculata*.

Panicle-flowering Wackendorfia.] Shorter sword-spear-shaped trinervous leaves, and short dividing flower stalks, producing panicle-spikes of purple flowers.

3. *WACKENDORFIA umbellata*.

Umbel-flowering Wackendorfia.] Flowers produced in umbels; the umbels two-parted.

These are desirable ornamental flowering plants, very deserving of admittance in the green-house collection: they being tender, require protection in winter; keep them in pots of light, sandy, loamy mould, and give them the common culture of other herbaceous exotics of similar temperature; they will shoot up flower-stalks annually in the spring, and flower very agreeably in July and August, and are propagated by off-sets, root-suckers, and by seed.

WALKS.

Garden Walks may be considered as both of the useful and ornamental kind; in all gardens Walks are necessary and useful, both for communication with the different districts and compartments, and for dividing the ground into proper divisions in any particular order

required, as well as for occasional pleasurable walking for health and recreation; and ornamental Walks in a pleasure ground, generally more spacious than the common necessary Walks of a kitchen garden, are requisite in conformity with the other decorative compartments of that district, both to form variety in the composition of the general plan, and for communication with, and the pleasure of walking through, the various departments to enjoy the prospect of the beauty of their different or varied arrangements, and the diversified growths of their respective plants, trees, shrubs, flowers, and fruits, &c.

Of the generally necessary useful Walks, may be considered all those of the kitchen-garden, requisite both for dividing the ground into regular quarters, borders, &c. and for communication to the different parts of the ground, and from one part to another, as occasion may require; and in which a Walk should generally be continued all round the garden next to the boundary wall, hedge, or other fence, having a wide border ranging immediately close along under the said boundary fence; and the Walk extended close parallel to the border, four or five to eight or ten feet wide according to the general ground; and if this is considerable, one or more cross Walks of similar dimensions will be necessary; or sometimes where a kitchen-garden and pleasure-ground are connected, or both in one, as it were, the principal Walks should be more capacious than in a common kitchen garden, having a handsome border on each side; and sometimes, if this general garden is of some considerable width, a middle Walk is occasionally adopted, extending right through the middle of the ground, bounded on each side also with a spacious border; and which different borders may be allotted both for some small esculent plants, and a variety of flowers, occasionally, as may be thought necessary, in consideration of economy and ornament.

The general Walks of a kitchen garden should commonly be gravel, especially the most common walks in which much occasional wheel-barrow work may be required in the business of bringing in dung, earth, or other requisites, and wheeling out rubbish of the

the garden, &c. on which occasions grass Walks would not be eligible, as they would be much cut and defaced; and liable to be wet, swampy, and very damp in winter, though sometimes grass walks are adopted in some particular parts of a pleasure-kitchen-garden by way of variety, and for occasional soft walking in summer; but gravel, where conveniently attainable, is greatly preferable for the general walks; or sometimes for common Walks in a kitchen-garden, &c. in default of gravel, dry road soil is substituted; that is, the scrapings of gravelly turnpike roads, shovelled up in wet weather, and lying till dry, will make firm dry walks at all seasons.

In a general pleasure-ground the different Walks may be considered principally both as ornamental in appearance, and requisite in diversifying the general plan, as well as necessary for occasional pleasure walking, and for communication with and to the different districts; and should generally, in the principal conspicuous divisions, be more spacious and elegant than the general Walk of a common kitchen-garden, just above considered; may be ten to fifteen feet wide, or more; or grand walks extending immediately parallel to or from the habitation, are sometimes twenty or thirty feet wide: and which general Walks in this garden should be principally of the best gravel for dry and firm walking at all seasons; or in some particular districts may have a spacious grass Walk for occasional summer walking, or some arranged between elegant shrubberies, rows of trees, or in open groves, for shady walking in the above season; also, sometimes sand Walks in shady plantations.

Respecting the mode of arrangement and disposition of Walks in the pleasure-ground, they may be various according to fancy, or conformably to the general plan; either arranged in a varied serpentine way, in gentle windings, as the most characteristic agreeable to modern designs, or extended in straight lines, either in general or in particular districts, correspondent to the general plan of the garden: but in principal gardens, a natural imitation in varied gentle serpentine turns is more generally adopted as the most agreeably pleasing and entertaining; though in limited situations or small gardens, as there may not be proper scope for any particular variation, common straight Walks continued round and across the garden may sometimes be the most conveniently eligible, or occasionally varied from straight to serpentine, to effect the greater variety.

Generally in every pleasure-ground a spa-

cious gravel Walk should range close parallel to the main dwelling, and thence extended in a proper width and direction into the interior of the garden and plantation; or, according to some designs, a grand Walk, gravel or grass, is extended from the above parallel Walk, right forward in front of the principal habitation, either in a straight line, or easy winding direction; bounded on each side either with a border and adjoining lawn, or more agreeably with an elegant shrubbery, or spacious borders of flowers and curious shrubs: in other plans is led off to the right and left round the outward boundary of a noble lawn, in front of a spacious bank or border of flowers, or shrubbery plantation, either generally in a moderate serpentine order, or straight as the general plan of the ground may admit; or also conducted toward, and into some side or boundary shrubbery, for shady, sheltered and private walking; and carried on gently winding in an easy natural manner, through the extent of the plantation, either in continuation round the general garden, or that of a connected plantation, extending to a park, &c. and with other similar Walks within the limits of the general pleasure-ground, branching off at proper intervals variedly, to other different districts internally; some under the shade of groves, thickets, or shrubberies; others in more open and airy compartments, between spacious grass divisions and detached shrubbery clumps, gently winding in a varied direction, so as to enjoy the pleasure of agreeable prospects in the different arrangements of shrubberies, groves, flower-borders, grass-lawns, water, &c. and in the various growths of the different sorts of trees, shrubs and flowers in their several allotted compartments; and thus the Walks of a general pleasure-ground may be led in various arrangements and dispositions, according to the extent and order of the general plan, either conformably to the more modern natural imitation, or in the ancient style in straight lines.

The general gravel Walks in a pleasure-ground should be formed of the best sort of the middling-sized gravel, not too fine nor roughly large, and such as will bind well, and remain firm and dry in all weathers and seasons of the year; and of the best colour, according to what different places afford, which in some places is high coloured, in abounding with a natural mixture of yellowish, reddish or brownish-yellow, light sandy loam, which not only heightens the colour of the Walks, but proves of a binding nature, fixing the pebbles of the gravel firmly and even, for easy

and agreeable walking; in other places the gravel is sometimes destitute of any binding material, consisting wholly of loose pebbles which never bind firmly in the Walk, but remain scatteringly loose on the surface, uneasy to walk upon; and which kind of gravel should generally be blended with some sort of binding sand, or a portion of light dry sandy loam, where attainable, so as, when formed into a Walk, to render it more fixedly binding, with a firm even surface.

Preparatory to the formation of gravel Walks, the earth of the allotted spaces should be excavated six or eight inches depth or more, to admit of a proportionable depth of gravel; and previous to laying the gravel, the boundary edge of the Walk should be formed regular, either where bound with an adjoining grass lawn, plats, or other grass compartments, by cutting the edges thereof even accordingly; or some occasionally planted with edgings of box or thrift, or sometimes with narrow verges of grass, as may be convenient or thought eligible in different situations, conformable to the plan of the garden; the gravel should then be laid; or, where convenient, may previously lay some rough dry rubble in the bottom two or three inches thick, which will keep the Walk drier above, laying the gravel upon this the proper thickness, with the surface gradually rounding, treading it down evenly, rake it smooth, and give a good rolling across and long ways, with a heavy iron or stone roller. See GRAVEL WALKS.

Where grass Walks are intended, they should generally be of some tolerably spacious width, not in narrow trifling slips, but at least ten or twelve feet wide, or double that, or more, in large pleasure-grounds: and as to their proper situation this may be varied, either sometimes near the habitation, or some more internally distant; accommodating it to their general purposes, as being principally for summer walking in dry weather; and occasionally also for ornament; and may either be arranged, some in straight lines, or others moderately serpentine on the sides, or the whole gently winding, and generally bounded either with noble broad borders of flowers, or with a handsome sloping shrubbery, or some extended between rows of ornamental trees, either distinct or in groves, &c. and in their formation they may either be laid with grass turf (see TURF), especially in Walks of moderate extent, or where too considerably extensive for turving, the sward may be formed by sowing grass seed in spring, summer, or autumn, which will quickly come up, and soon

form a close green sward; observing, previous to either method, the ground should be properly prepared, by necessary levelling, treading and raking, &c. forming the surface firm and even; then either lay turf, beating it well down to form a close smooth surface, or sow grass seed of a proper clean sort, sowing it considerably thick and regularly in every part; then rake it evenly into the ground, and afterwards, when the surface is quite dry, roll it regularly with a moderate roller, to smooth the surface and close the earth more effectually over the seed. See GRASS.

Sand Walks are sometimes introduced in pleasure-grounds, in particular districts, and occasionally under shady plantations, and for wood Walks, &c. in thickets, and as in which situation, either sand or gravel Walks are apt to be over-run with moss, the sand Walks can be more easily and expeditiously scuffle-hoed over than gravel, to destroy the moss, and then raked clean and even; or sometimes where sand Walks are over-run with a short, green, carpet moss, they are permitted to remain in that state, both to effect a more rural variety, and for soft walking to the feet under shade, in the heat of summer; observing, however, where sand Walks are intended, should procure sand of a dry, solid, binding nature, not a loose quick sand, which would never bind firm for solid walking; and in forming the Walks, observe nearly the same method as for those of gravel.

With respect to the general management of Walks—

Those of gravel should be kept always neatly clean by occasional weeding and sweeping; and frequent rolling with an iron or stone roller, once or twice a week in summer, or sometimes oftener when the surface appears loose and disorderly, occasioned either in very dry weather, or after much rain, when should generally give a good rolling to settle all inequalities, and render the surface smooth and firm; giving also occasional rolling in dry open weather in winter and spring: and when the surface is become foul, or mossy, or full of small weeds, the gravel should be turned in the spring in March or April, by digging up the Walk a small depth, turning the surface clean down, and the fresh bottom gravel to the top, treading, raking, and rolling it directly, and will then have a fresh clean surface for the spring and summer. See GRAVEL WALKS.

And grass Walks should have the sward always kept close and even by frequent mowing, sweeping and rolling in spring and summer,

mer, from March or April until October or November; and in winter occasional poling and rolling are necessary in dry open weather; poling with a long pliant pole to scatter the worm-cast earth, and then rolled with a wooden or other roller to clean up the scattered earth by adhering thereto, thereby both cleans the surface, and settles the sward close, firm, and smooth. See GRASS.

WALLS.

Garden Walls.

Walls in gardens are of great utility, especially in some particular districts, such principally as that of the kitchen-garden, or where the kitchen and pleasure-ground are all within the same general boundary, and in other districts occasionally; serving both as an outward fence against the invasion and depredations of interlopers, and as a defence or shelter against cold cutting blasts, and tempestuous winds; and of great importance for the advantage of having Wall-fruit-trees trained thereto, whereby to obtain the production of their respective fruits in the most early and improved state of maturity in the fullest degree of perfection.

But, for Wall-trees, garden Walls are of particular utility, especially as many of our tenderer sorts of fruit-trees, without having the aid of being trained to warm Walls, would not produce fruit in mature ripeness in this country; such particularly as peaches, nectarines, apricots, vines, figs, &c. all which generally require a situation against the best southerly Walls, &c. and to which have their branches trained close in a regular expansion, in order to receive the full advantage of the warm shelter thereof, from cutting cold in the spring when in early blossom, and the young fruit setting, as well as to enjoy the essentially necessary benefit of the full sun in spring, summer, and autumn, to forward and improve the growth of the said fruit, in the different sorts, in the most effectual manner and requisite degree of perfection, as to attain perfect maturity of ripeness in the proper season, and with their peculiar richness of flavour.

Likewise it may be observed, that, by the aid of Walls, many or all of our common hardy fruit-trees, although they bear fruit abundantly in good maturity upon common detached standards, are productive of their respective fruits, both earlier and in some superior degree of perfection in size, beauty, and goodness of flavour; and where any principal sorts are trained against south, or south-west, and east Walls, the fruit ripens in the most early maturity, and generally, both in the early and later kinds, acquire a still more

improved state of full perfection and good flavour, some for immediate eating, others for keeping a shorter or longer time; as in the principal varieties of cherries, choicer sorts of plums, and the capital varieties of the finest eating pears, both summer, autumn, and winter kinds; as likewise some estimable sorts of the best eating summer and autumn apples, &c. and in all of which sorts of hardier fruit-trees, some being planted against full south Walls, produce the earliest and best flavoured fruit, and others planted on Walls of west and easterly aspects, and on north Walls, are productive of fruit in successional and late maturity.

So that garden Walls, besides their utility as boundary fences, are of particular advantage in affording the opportunity of planting and training Wall-trees of the choicest varieties of the respective species, for obtaining the fruit in superior perfection; and for the further advantage thereof, sometimes in places where there is eligible scope of ground on the outside of the boundary Walls, to admit of having an outward slip of ground, fifteen to twenty or thirty feet width or more, inclosed with an outer paling fence, or an hedge and ditch, both sides of the Walls are furnished with Wall-trees; likewise in gardens of some considerable extent, internal cross-Walls are also sometimes erected principally for Wall-trees, whereby to have a larger collection of the best varieties of the different sorts planted on both sides of the said Walls; as in the several different sorts usually trained in Wall-trees, they may be suited to different aspects in the tenderer and common hardy kinds, by planting some on south Walls, others on west and east aspects, and some on north Walls; however, observing generally, that either in single boundary Walls, which are considerably the most general, or in such as, by means of an outside inclosed slip, admit of planting on both sides, or also in cross Walls, should allot those of south aspects for the choicest sorts of fruit, both of tenderer and hardy kinds, such as peaches, nectarines, apricots, vines, figs, of the former; and of the latter, some best cherries, plums and pears; and others of all the sorts may be planted on west and east aspects; and some sorts, of the latter, also on north Walls, especially some summer pears to ripen later in succession, likewise plums and morello cherries, for the same occasions. See WALL-TREES.

Respecting the proper sorts of garden Walls, they may either be brick, as the most desirable for Wall-trees, or of stone, according as these materials can be the most conveniently obtained in different places; or in de-

default of brick or stone Walls both as fences and for Wall-trees, close strongpaling of wood, six to seven or eight feet high, may be substituted; but where Wall-trees are a principal object, brick Walls are much preferable to those of stone, especially as the mortar-joints of the brick-work, being at small and equal regular distances, affords the greater advantage, in training the branches of the trees more effectually in proper regularity, by means of having the continued opportunity of nailing into the said joints at any distances or lengths, as may be necessary, or also occasionally into the bricks, where not of the very hard-burned kinds; especially by having proper Wall-nails, short and robust, which will generally admit of driving into most sorts of common bricks; and which advantages are not so attainable in stone Walls, in which the joints are not generally either so frequent or so regularly distant to admit of nailing the branches with equal regularity, as above; however, as in many places stone Walls may be more conveniently attainable than brick, in regard to the acquirement of the material stone for their erection, and in which case where designed to have Wall-trees, it would be advisable to have the Walls faced with moderate sized stones, as regular in form, and equal as possible, for the greater opportunity of the mortar-joints occurring at small distances, to admit of nailing the branches in regular order.

In regard to dimensions in height, &c. for garden Walls, they should not be less than eight or ten feet high, both as a general outward fence, and for the advantage of having Wall-trees, and for which latter occasion, any intended internal cross Walls should be nearly the same height, or not less than eight feet; and in general about fourteen inches, or a brick and half thick in brick-work; though sometimes brick Walls of lower dimensions are only nine inches or one brick length thick, above ground, but in exposed situations should not be less than a brick and half, otherwise would be liable to be overturned by impetuous winds; and stone Walls should generally be thicker than those of brick, as they have not the advantage of the general regular tie or bond, as in brick-work Walls.

Or, as before intimated, where there are any good close-boarded palings, they may also be eligibly used, against which to plant and train Wall-trees; being of proper height, six or eight feet, and the pales or boarding closely joined, and with an even surface, to admit of training the branches close and regular; and on which may occasionally have any sorts of

Wall-trees, and the fruit will ripen in good perfection, though probably not quite so soon in their respective seasons, as those against brick-Walls, which are generally of a warmer nature, for accelerating and improving the growth of the fruit.

Concerning the position of arrangement of Walls, where Wall-trees are intended,—if the situation is not particularly limited, and there is scope for choice, they should generally, in the principal Walls, range east and west, and the others north and south, or both as nearly in those directions as possible, for the advantage of having the greater benefit of the sun; and in which it would be eligible to have the principal Walls, or such as range east and west, of greater extent than the others, where the situation admits, in order to obtain the advantage of having a more considerable extension of a south aspect, for the trees of the choicer sorts of fruit, and such as will not ripen freely without being trained to Walls of that exposure, consisting of peaches, nectarines, apricots, grapes, and figs, as formerly intimated; and likewise for many varieties of the principal sorts of our hardy fruits, particularly some of the superior varieties of cherries, prime sorts of plums, and fine eating pears; both of the summer and autumn kinds for present eating; and some choicest winter pears, to attain greater perfection in growth and flavour, to gather for keeping till winter, also for some early currants and gooseberries: and the north and south ranging Walls, of east and west aspects, are eligible against which to have trees of many varieties of the above sorts of fruit in a secondary order; some to ripen in succession for autumn supply, and others, as some best sorts of late autumn and good winter pears, to lay up in the fruitery for attaining successional maturity in the winter season, from November and December, till March, April, or May, in different varieties; and the Walls of a north aspect serve for Wall-trees of several sorts of common hardy summer and autumn eating fruit, to ripen in later succession, as cherries, plums, and pears; and for any of the large hard pears that are proper principally for baking and stewing, &c. likewise for late currants, &c. See a list of the different sorts of fruit, times of ripening, and methods of planting and managing the trees as above, in the Wall-tree order, under their respective genera. See also WALL-TREES.

In building garden Walls, those designed for Wall-trees should generally be built quite straight, not in sweeps or curves as sometimes practised, on a supposition of affording greater shelter to some principal sorts of trees planted therein,

therein, but have not the desired effect of the intention, in regard to protecting the blossom and young fruit; for there is generally a particular current of sharp cutting air, circulating in those curvatures or bendings, more hurtful to the early bloom, &c. than occurs on straight Walls; it is therefore always advisable to range the Walls wholly straight or in one continued regular extent, according as the situation may admit, and in which the Wall-trees will generally be the most successful in their production of plentiful crops of fruit.

In some places the surrounding boundary Wall of a garden has been built in a continued circular order, with design that the Wall-trees trained thereto might all equally enjoy the benefit of the sun gradually in its diurnal course; but this kind of Wall often attracting a whirling circumvolution of cold air, not occurring in straight Walls, and which in spring being generally more unpropitious to the early blossom and young fruit of the tenderer kinds, than usually happens to those on common Walls ranging straight east and west, north and south, or nearly in those directions as before observed, and therefore is not commonly adopted.

Sometimes in stone garden Walls for Wall-trees, when the facing of the Walls is very irregular in the stone-work, so as not to admit of nailing the branches of the trees in any tolerable regularity, a light treillis of wood-work is erected close to the Walls, in uprights, and cross horizontal railing, the latter about six inches asunder, on which to arrange and nail the branches in the requisite regular order. See TREILLAGE.

WALL TREES.

Wall-trees, being such fruit-trees as are planted close against walls, and have their branches trained thereto into a fanned regular expansion, three or four to five or six inches asunder, whereby to produce their respective fruits in a superior degree of perfection, are designed both for trees of the more tender kinds, or such as will not ripen their fruits in this country unless they are trained against walls of a southerly aspect, to have every possible beneficial advantage of enjoying the full sun; and likewise for several sorts of the common hardier kinds in the most esteemed principal varieties, &c. thereof, both to obtain their production of fruits in earlier maturity, and in general of an improved growth and goodness of flavour.

On these considerations, a collection of the choicest varieties of the different sorts of fruit trees are trained to walls of different aspects; south walls for the principal sorts of the more

delicate or tenderer fruits, comprising peaches, nectarines, apricots, grapes and figs, to have the benefit of the full sun, as they will not ripen in good perfection without the assistance of having their respective trees trained against warm walls, of the most sunny aspects; and likewise against similar walls to have some best varieties of the principal sorts of the hardier fruit-trees, such as the most esteemed cherries, plums, and pears, both to produce earliest fruits, and in the greatest perfection of full growth and maturity; also some trees of the choicer sorts of summer and autumn apples, to have the fruit of earlier maturity and improved rich flavour for immediate eating; likewise some best red and white currants and gooseberries: and on west and east walls to have trees of most of the above sorts, which will also ripen in good perfection successionally to those on the south walls, especially cherries, plums, and pears, and occasionally some common peaches, nectarines and apricots; but vines and figs most generally on south walls, especially vines, which require all possible benefit of the full sun to ripen the grapes in proper season, and with a rich flavour: the north walls are eligible for any of the common hardier summer and autumn fruits, as cherries, particularly morellos, plums, and pears, for late ripening, to succeed those of the more sunny exposures, and to continue a longer succession of some particular sorts of these kinds, which ripen for immediate eating from the trees: also white and red currants for successional ripening in autumn, from August to September, October, or November.

Thus, the principal utility of Wall-trees is to obtain a collection of the choicest fruits in the fullest perfection, both in early and successional maturity, and are indispensably necessary for all the tenderer fruits before mentioned, and which to be generally trained on walls of the most sunny aspects, to have them ripen in full perfection; and in the common hardier fruits, which also ripen abundantly on standards for the general supply, such as pears, plums, cherries, &c. by having some principal sorts trained in wall-trees, the fruit is obtained earlier and in a superior degree of maturity in its general growth, and generally with some improved flavour, more or less, according to the different aspects of the walls, in having the benefit of the sun in a greater or less degree.

Wall-trees having the advantage of their branches being kept thin in regular order, and trained in a spreading expansion, close to the wall, at regular distances, so as both to have the benefit of the warm shelter of the walls from

from cold when in blossom, and fruiting, and all equally to enjoy the continued benefit of the sun and mild air to forward and improve the growth of the fruit, which is thereby produced earlier, and in some considerable degree of superior perfection than on standards, whose branches being commonly permitted to grow in their natural order, often crowded and very irregular, and being more openly exposed to all weathers, they, although productive of more abundant crops of fruit in common good maturity, in the general hardy sorts as pears, plums, cherries, apples, &c. do not generally produce fruit equal in size, or regularity of full growth, early perfection, and goodness of flavour, as the same sorts produced on Wall-trees: and therefore it is of importance to allot a chosen collection of the finest varieties for training against walls, not only the tender fruits which will not ripen without that assistance, but also the most estimable varieties of all the different hardy kinds, to obtain the fruit in the fullest degree of perfection as above, especially of all the prime eating or dessert table fruits.

The principal species of fruit-trees commonly trained against walls are peaches, nectarines, apricots, vines and figs: all the varieties of each of these sorts, and which most generally is allotted to walls of a south aspect: cherries, plums, and pears, some of the best varieties only, of each of these kinds, both on south walls for earliest production, and on other aspects for successional ripening; also occasionally some best varieties of early and other prime-eating apples, such as Jenneting or June-eating, Margaret apple, golden pip-pin, golden rennet, &c. on south or west walls, and sometimes mulberries on south walls to obtain larger and earlier fruit, ripening with a richer flavour; and generally some best red and white currants, and a few trees of the finest early gooseberries; but more abundantly of the currants, some on south walls, for earliest fruit, and a larger supply on other exposures to ripen fruit in successional order.

Wall-trees may be considered as consisting of two orders; common dwarf wall-trees, and half-standard wall-trees.

The common dwarf Wall-trees are such as are trained with dwarf or short stems, only a few inches high, and branch out near the ground, so as to cover the wall with branches regularly quite from the bottom upwards to the top, arranged horizontally three or four to five or six inches asunder, and are the common Wall-trees for general planting against walls, of all the different sorts usually trained in the Wall-tree order; and for which occasion those commonly raised by grafting and

budding are grafted or budded low in the stock or stem, within four or five inches of the ground, and the first main shoots arising immediately from the inserted graft or bud, are, when a year old, headed or cut down in the spring to four or five eyes, to obtain a production of lateral shoots the same year, from these said remaining lower eyes or buds, near the ground, to give the tree its first proper formation in the head, being trained to the wall in a spreading order to the right and left, at their full length all summer; and in the following spring, in March, are pruned each to six or eight eyes, to gain a further supply of laterals similarly, by which to increase the number of branches near the bottom, trained to the wall horizontally, in a regular expansion, equally on both sides of the tree, which form a proper foundation, as it were, in the advancing head, for furnishing, by degrees, all the other requisite branches, regularly upward to the top of the wall; observing also the same of such trees as are commonly propagated or raised by layers, cuttings, and suckers, as in vines and figs, &c. and afterwards, the whole to be managed as directed for each different sort under its respective genus.

Half-standard Wall-trees are trained with standard stems, three or four to five or six feet high, being grafted or budded at these heights to branch out above accordingly; and are adopted occasionally to plant against high walls, between the common dwarf Wall-trees, in order to have the whole wall, below and above, covered as soon as possible; the common dwarf trees advancing below whilst the half-standards occupy the upper parts, they having their first and second year's shoots from the budding and grafting pruned as intimated above in the formation of the common Wall-trees, to acquire a supply of lateral shoots near the top of the stem, properly situated to train for the first set of branches in the formation of the head; arranging them to the wall, in a spreading order, horizontally, at regular distances; and they will thus furnish others in their turn, and these a further supply similarly, forming by degrees a full head; managing the whole according to the nature of growth and order of bearing of the different sorts, as explained under their respective genera. See also STANDARD TREES and TRAINED TREES.

Young plantable Wall-trees may either be those with one-year-old heads from budding or grafting, &c. planted at once where they are always to stand, and trained as above, by heading the first main-shoots which were produced immediately from the inserted bud or graft the year before, to obtain laterals below; and

and these also pruned in the order above mentioned, thereby to gain a further supply, and afterwards managed as before mentioned; or may be ready-trained young trees of three or four years' growth or more, furnished with spreading heads or branches, having been previously trained in the nursery to walls or other fences, flakes, &c. in a similar manner, two, three, or four years, or more, till advanced to a proper growth for immediate bearing; as is practised in all the public nurseries, for the supply of those who are desirous of having their walls furnished with immediate bearing trees; (see TRAINED TREES) and in which nurseries, are great choice of all the different species and varieties of the fruit-tree kind for walls, both in young trees with one year old, untrained heads, proper for planting finally where they are to remain, and there trained from the beginning in the order required, either as common dwarf Wall-trees, or half-standards, and all of which, with proper management, will arrive to bearing, in from two or three to four or five years, according to the different sorts; and likewise in the same places may be furnished with ready-trained trees, above mentioned, of all the different sorts, arrived to a proper growth for immediate bearing in the ensuing season.

The season for planting Wall-trees is either in autumn, in October, or November, &c. or in spring, February and March, or not later than the beginning of April, but before that time, if possible; as late spring-planting, after the young trees begin to push their shoot-buds, is often attended with ill success, by the trees, either in some, wholly retarded, or others, assuming a stunted unprosperous growth.

With respect to soil for Wall-trees, they will succeed in any good mellow garden earth, not less than one full spade deep; but if two or more, it will be the more advantageous: or where a good moderately light loamy soil occurs, it is superiorly favourable for most sorts of fruit-trees, promotive of a prosperous growth and fine fruit. Or where the soil of the borders under the walls intended for the Wall-trees is very poor or of any bad quality, and requires amendment, if this could be conveniently supplied with fine rich surface loam, and some rotten dung, it would be of beneficial advantage in the prosperity of the trees, and their production of fruit of a superior perfection. See BORDERS, KITCHEN-GARDEN, &c.

And in regard to aspects of the different walls on which to plant the several sorts of trees, always allot south aspects for the

peaches, nectarines, apricots, vines and figs, as before noticed; and some part also of the same exposure for a choicer assortment of the early and other principal cherries, plums, and some finest-eating pears; and on west and east walls are proper for any varieties of all the three last mentioned species, likewise for some of the common peaches, nectarines, and apricots; and on north walls may allot for any of the sorts of cherries, plums, summer and autumn pears, &c. agreeable to foregoing intimations.

It may be proper to observe, that when we speak of Walls in these intimations for planting and training Wall-trees, may also, besides common brick or stone walls, include wood-walls or palings, which being formed of close-joined boarding are also eligible on which to plant any sorts of Wall-trees; though, as not being generally so warm as good brick walls, the fruit probably will not attain maturity so soon in their proper seasons as on brick or stone walls, but otherwise in very good perfection.

In preparing for planting, if a general plantation, have the borders trenched a proper depth, of about two spades, or if only some trees in different parts, may only dig a wide space for each tree for the present; observing to allow proper distances, according to the different sorts; that is, for the peaches, nectarines, apricots, cherries, plums, figs, fifteen to eighteen feet is eligible; pears and apples eighteen or twenty feet, especially those worked on free stocks, or those on dwarf stocks, not less than fifteen to eighteen feet distance; and the same of other trees of similar growth: vines, five to ten or fifteen feet, according as may be intended to train them upright or horizontally, as they admit of both these orders of training; so that, agreeable to these intimations, mark out the distances accordingly.

Then, either previously, or at the time of planting, dig a circular pit for each tree, half a yard to two or three feet wide, proportionally to the expansion of the roots of different trees, and a good spade deep; laying the excavated earth of each hole close by the side, ready to fill in about the roots of the trees at the time of planting.

Having the trees for planting carefully taken up in the nursery, with their full spread of roots as entire as possible, and of which, at the time of planting, cut only any broken, mangled, or bruised parts, or shorten very long stragglers, and any downright tap root; and in the head, if young trees of only a year or two old, with the first main shoots from budding, &c. entire, not having been headed in the

nursery, reserve the said head whole till after they are planted, or not pruned till the spring : and if trained trees of several years' growth, having been headed, and thereby furnished with a spread of branches that have had a regular training in the nursery, two, three, or four years, cut out only any very irregular placed fore-right shoots or any other disorderly growth ineligibly situated for training to the wall, and any casual rank luxuriant of last summer : but continue all the regular-placed side and terminal shoots, wholly entire, at least till after the trees are planted.

Proceeding then in the planting, having digged a proper aperture for each tree, of eligible width and depth, at the requisite distances before mentioned, plant them therein accordingly, placing each tree with the bottom of its stem about three or four inches from the wall, inclining the top-part and head close thereto above ; making the roots spread regularly in the hole, and spade in the earth equally, breaking large lumpy clods, and shaking the tree by the stem gently up and down to make the earth settle in close between all the roots and radical fibres, and thus fill in each hole to the top, being careful that the upper roots are at least three or four inches depth under the surface ; then tread the earth down moderately, both to settle it close about the roots, and to fix the tree with its head inclining to the wall in the proper position.

As soon as planted, if a tolerably dry light soil, a moderate watering to the earth about the roots of the trees would be eligible, thereby to settle it close, and to have it moderately moist, to promote their striking fresh root, especially in early autumn and late spring planting ; and in the latter, if very dry weather prevail, a repetition of moderate watering once a week would be very beneficial.

Thus, the new-planted trees will soon strike root ; those planted early in autumn will often strike the same season, ready to shoot freely in the spring ; and those of the spring planting will quickly take root and soon show signs of renewed growth in their advancing buds.

Then, as to their further management after planting, in regard to pruning and training, observe the following general intimations in their present state, referring to the respective genera for the particulars relative to each sort, both in their young and advanced growth.

First, with respect to the young trees of a year old, having their first head or main shoots from the budding, &c. entire, they should be cut down early in March, to four, five, or six eyes, according to their strength, to procure lower lateral shoots the same year, from the said eyes, as before observed, to form the first

proper set of bottom branches, and then afterwards managed agreeable to former intimations, and as fully explained under their different genera.

And respecting the trained trees, such as previous to planting have been formed by proper training in the nursery, furnished with an expansion of several mother branches, and these furnished with a production of young shoots of the last summer ; they may be pruned and trained in the proper order as soon after planting as may be convenient ; in which prune out any irregular-placed shoots, and such as appear of an unpropitious nature, either rankly luxuriant, or very slender feeble growths, and any watery unripened and thickclubbed shoots ; as also any superfluous or over-abundant that may occur in any particular parts of the tree ; observing at the same time to preserve all the proper grown regular-placed shoots, both laterals and a terminal one or leader to each branch ; and which, in peaches, nectarines, apricots, and vines, should be shortened more or less, as directed for each of these sorts under its proper genus : and in pears, plums, cherries, apples, and figs, &c. the reserved proper shoots should generally be continued entire, as is also directed under their respective genera ; then let the whole, thus regulated in the operation of pruning, be trained to the wall horizontally, and equally to both sides of the tree in a regular expansion, three or four to five or six inches asunder, or more, according to the different sorts ; and thus nailed along straight and close to the wall, in a neat manner.

All Wall-trees in their general growth, from that of one or two years to their utmost advanced state, require an annual regulation of pruning and training ; consisting of a summer and winter dressing, in order both to continue them in proper regularity, and each tree within its limited bounds, and to preserve the whole in a prosperous state of plentiful fruitfulness, a principal article of consideration.

The summer-pruning consists of a general regulation among the young shoots of the year only ; which may be commenced in May or early in June ; first, by displacing the fore-right and other irregular-placed advancing buds or young shoots, not eligibly situated for training to the wall, taking them off quite close ; which, if proceeded in early in summer, whilst the shoots are yet tender and herbaceous, as it were, may be performed with the hand, without the assistance of the pruning-knife, by rubbing or detaching them close off with the thumb and finger ; but when more advanced, of a woody nature, the knife must be used in that operation ; observing also, in this the summer dressing or regulation of the shoots of

of the year, to displace many of the superfluous or such as appear any where too numerous, cutting out some of the worst or most irregular, likewise any rude luxuriant or singularly rank growth, in very thick sappy shoots; being careful, at the same time, to leave an abundant supply of the regular-placed, well-formed shoots in all parts of the trees, both of the laterals, and a terminal to every branch, in order for training close to the Wall during the summer, both to preserve the requisite regularity in the trees, and that, by being thus continued close and regular, to give full admission to the sun and air, &c. for the benefit of the fruit; the whole to remain in this order till winter, to have plenty to choose from in that season in the general pruning, according as they may then be wanted: but at this time, the summer pruning, retain considerably the most abundant in peaches, nectarines, apricots, vines, figs, which all produce their fruit on the young year-old wood, and require a successional supply annually; and retain a more moderate supply of the best-placed in pears, plums, cherries, &c. as these trees continue bearing several years on the same branches, not requiring a general annual succession of young wood, as the above sorts.

And thus proceeding in divesting the trees of the improper and unnecessary shoots, let all the others, now retained, be trained in close and regular to the wall, the whole at their full length during the summer, except where any extend much out of their allotted bounds in a disorderly growth; or in vines particularly, the long advancing fruit-shoots, furnished with grapes, may be shortened in July or August, to give greater nourishment to the growth of the fruit; and observing during the summer's growth of the Wall-trees in general, that, according as the retained shoots extend in length, to train them along close to the Wall in regular order; as also any that start from their places, or project from the Wall, train them in close; both to preserve the regularity of the trees as before observed, and that the fruit may not be too much shaded by projecting growths, but that, by having the whole continued always trained close and regular, it may thereby enjoy the full advantage intended by Wall-trees, of receiving all possible benefit of the sun's influence, warm, free air, rains, dews, &c. to promote that superior growth and degree of mature perfection, both in its early ripening, and improved flavour, peculiar to Wall-tree fruit.

Sometimes, in the summer pruning, either in young trees under training, or in others of advanced growth, in which there are va-

cancies, and supplies of branches wanted; may occasionally, in June, pinch or prune down one or more strong shoots, situated in or near the vacant spaces, shortening them to three or four eyes, to obtain a supply of the like number of lateral shoots therefrom the same season, and thereby furnish the vacancies in some degree the same year accordingly; by which acquisition, a year's advanced growth is gained, on consideration that if the said shoots now advised to be pruned are left unshortened till the following winter or spring pruning, and pruned for the above occasion, they consequently would not produce the laterals before the ensuing summer.

The winter pruning of Wall-trees consists of a general regulation, both in the supply of young shoots reserved and trained in the preceding summer; and in the general older branches occasionally.

This general pruning may be proceeded in any time after the falling of the leaf in October or rather November, till the spring, not later than March; and in which period of time it may be performed on most sorts of wall-trees; or may first proceed in the early part of winter, in November and December, principally in pruning pears, plums, cherries, apples, and vines; and may delay pruning peaches, nectarines and apricots, till more towards the spring, January and February, when their blossom-buds, which arise principally on the young shoots of the last summer, will be more advanced and conspicuous to enable you to make a proper choice of the most fruitful shoots to retain for producing the fruit next summer: and in figs particularly, it is advisable to defer pruning them wholly till the spring, on account of their succulent shoots being more liable many of them to be killed by frost in rigorous winters, than those of other wall-trees, and by leaving them unpruned till spring, there will be the greater chance, out of the whole, of a sufficiency surviving the frost to choose from to retain for next summer's bearers; for these trees always produce their fruit on the year-old shoots only; however any other wall-trees may be winter-pruned any time in the period above-mentioned, from November till spring, but should be wholly finished by the end of March or beginning of April at farthest; or generally in the early blossoming trees, should be completed much sooner, or not later than February or beginning of March, if possible; such as peaches, nectarines and apricots. as the blossom-buds of these trees will then be considerably advanced, and many of them would be unavoidably rubbed off in the pruning and nailing.

Observe generally, in proceeding with the winter pruning, that it is proper to unnaïl all or most of the young shoots trained in last summer, to have the better opportunity both of examining what are proper to retain, and what to cut out, as well as to admit of performing the operation of pruning more accurately; in which, observe, that in all the trees as produce their fruit on the young wood, principally the year-old shoots of the preceding summer, such as peaches, nectarines, apricots, vines, and figs, also morello cherries, a general supply of the said young shoots must now, in the winter-pruning, be retained in all parts of the trees, for training in at three, four or five inches distance or more, according to the different sorts, as successional bearers, to produce fruit the ensuing summer, choosing the most regular-placed, of the best moderately strong growth, and that appear of the most fruitful nature; and of which to retain both sufficiently of the laterals situated on the sides of the mother branches, and a terminal or leading shoot to each branch, either placed naturally at the termination thereof, or occasionally some part of the branches, where advanced long and naked above, pruned down to some eligible shoot for a leader; cutting out all the superfluous or overabundant, irregular and improper shoots, quite close, not leaving any stumps, but cut close to the old wood: pruning away also, in these trees, part of the former year's bearers, and occasionally any casual naked old branches, to make room for training the eligible succession of the above mentioned young bearers; observing in the general pruning, that in occasionally shortening any too long advanced naked parts, either of the former years' bearers or older branches, furnished with eligible young shoots, should generally prune down to some proper young shoot, situate on the said branches, so as each branch may still have a terminal one for its leader: likewise observing, in proceeding in this pruning, that in peaches, apricots, and nectarines, most of the retained shoots should be shortened about one third of their length, or a little more or less, according to their strength, and as the blossom-buds thereon are situated higher or lower: and in vines, prune the shoots to three or four to five or six joints, according to their strength and situation on the vine; but in figs and cherries, none of the shoots must be shortened, all retained at their full length; as these trees bear their fruit mostly on the upper part of their respective shoots; and generally observing, in pruning the peaches, nectarines, and apricots, that as these trees are often furnished with some small short natural

spurs, situated on the two or three years, wood, of an inch or two in length, generally having each several good blossom-buds, they should be preserved, as these also produce very good fruit.

Then as soon as one tree is thus winter-pruned, let the whole be regularly trained to the wall, both young and old branches, extended horizontally, and nailed along straight and close to the wall at regular distances; the peaches, nectarines, apricots, and morello cherries, three, four, or five inches asunder, figs about six inches, and vines six or eight inches distance. See the different sorts under their respective genera, *Amygdalus*, *Prunus*, *Ficus*, and *Vitis*.

And in winter-pruning pears, plums, cherries, and apples, in wall-trees; observe that as all these sorts, when advanced to a bearing state, continue fruitful on the same branches many years, generally on small spurs, thick short natural shoots, one or two inches long, arising from the sides and ends of the general branches, of two, three, four or five, to many years' growth; and which branches must be retained accordingly as long as they continue of a good fruitful state: and accordingly as any, in their advanced old growth, casually decline bearing, a succession of young wood must be trained in, ready to supply their place.

So that having in the preceding summer trained in a portion of the best well-placed shoots, ready to choose from where any are now wanted in the winter pruning, either to supply vacancies in young trees under training, or occasionally in deficient parts of old trees; and of which shoots selecting what may be necessary for the above occasions, in proper parts of the tree where wanted, either to supply a present vacancy, or to train up between particular branches, where any appear on the decline or defective in bearing, and retain them accordingly; also a leader young shoot to each branch in all parts of the tree, where room, to extend them, cutting out all others, not wanted for these occasions, close to the mother branches; or any old branch extending beyond the limited bounds, prune it down to some convenient lateral branch, or young shoot, as they may occur properly situated; also where any old branch or other discovers a declined unfruitful state, cut it out, especially where young wood, either in previous training, or neighbouring fruitful branches, are properly situated to bring in to supply its place; observing also, in these trees, that all the shoots and branches are to be continued always entire, not however shortened except on some particular occasion either of defect in growth,

growth, or of too considerable extension out of their proper limits; but otherwise all retained at their full length; as they mostly produce their fruit-spurs both along the sides, and at their extreme parts, that if generally shortened, it would both demolish the said extreme fruitful parts, and force out strong lateral, useless shoots below instead of fruit-buds, and thereby greatly diminish their production of fruit: therefore observe the above precaution in the general course of pruning these sorts of wall-trees; retain the branches generally at their full length, and carefully preserve all the proper fruit-spurs, and they will bear abundantly. See each sort under its proper genus.

According as each tree is thus winter-pruned, let all the branches, &c. be regularly trained and nailed in straight and close to the wall horizontally, four to five or six inches distance, according to the different sorts, the cherries and plums three or four inches asunder, the pears and apples five or six inches distance.

For nailing wall-trees, should be furnished with the proper sorts of nails, which are obtained at all the ironmongers' shops by the name of garden wall-nails, having those for brick-walls that are of the short robust kind, as will occasionally drive into a brick, or hold fast in the mortar of the joints; but some stone walls will require nails of a longer size; and for nailing to paling or board walls, the nails may be narrower and more pointed than those for brick-wall nailing.

Likewise have proper supplies of woollen cloth shreds, either listing of broad cloth, as the most eligible, both in strength, and convenient for cutting into proper breadths and lengths, or, in default of this, any cuttings of cloth will suffice; observing generally in cutting the shreds for the nailing, neither to cut them too wide nor uncommonly long, half an inch to an inch at most wide, by two or three inches long, for the general common shoots and smaller branches; but for the larger, must be longer an inch or two in proportion; likewise generally cut them somewhat regular in width, and with the ends even; not leave them with long, dangling, pointed ends, which have a slovenly appearance when on the trees.

And in the work of nailing the trees, arranging the branches horizontally, extend them always parallelly and as straight as possible, close to the wall, by means of the shreds and nails; generally placing the shreds round the shoots, &c. in the spaces between the eyes, not too near together, or than what is necessary to fix the shoots or branches straight in the pro-

per position, and commonly with both ends of the shreds even; and thus nail them to the wall; in which observe not to girt the shreds too tight, but moderately close, about each branch and shoot, and not to drive the nails farther into the wall than just to take sufficient hold; for when driven too far they are apt to loosen the mortar, &c. in brick or stone walls, especially when occasionally un-nailing preparatory to the winter pruning.

And generally observe, in unnailing wall-trees, as is generally necessary in the Winter-pruning, more or less, especially in most of the young shoots trained in the preceding summer, and often in many of the older branches, it is proper, previous to drawing the nails, to give each a gentle stroke of the nailing-hammer to loosen it in its place, by which it will more readily draw clean out without tearing the mortar of the joints of the wall.

WALTHERIA. *Waltheria*.

The plants are woody exotics, from the warm parts of America and India, and retained here in stoves for variety; rising with woody stems, from two or three to four or five feet high, adorned with oval and spear-shaped leaves, and bunches of pentapetalous flowers.

Class and order, *Monadelphia Pentandria*.

Characters.] CALYX is monophyllous, cyathiform or cup-shaped, five-parted, and permanent. COROLLA, five heart-shaped spreading petals. STAMINA, five short monadelphous filaments, having distinct antheræ. PISTILLUM, an oval germen, slender style, and pencilled stigma. PERICARPIUM, an oboval, bivalved, unilocular capsule, and one obtuse seed.

The species are,

1. WALTHERIA *americana*.

American Waltheria.] Rises with a ligneous soft stalk, branching sparingly two or three feet high; large, oval, plicated, sawed, indented leaves; and from the upper parts of the branches, round heads or bunches of yellow flowers, on proper peduncles.

2. WALTHERIA *indica*.

Indian Waltheria.] Rises with a woody stem, dividing and branching eight or ten feet high; having soft, woolly branches; large, oval, serrated, plicated leaves; and smallish yellow flowers, in round bunches, sitting close, without peduncles or foot stalks.

3. WALTHERIA *angustifolia*.

Narrow-leaved American Waltheria.] Rises with ligneous stalks, dividing and branching six or seven feet high; spear-shaped sawed leaves; and round bunches of yellow flowers, on proper peduncles.

They

They all flower in summer, continuing in succession several months; succeeded by ripe seeds in autumn.

All the three sorts are somewhat shrubby; durable in stem and branches, at least for several years; though, as they are generally raised from seed, they arrive to perfection in two years, so as to flower and produce seeds; and sometimes continue several years, and flower annually in summer.

As they are tender exotics from hot countries, they must always be kept in a stove here.

They are propagated by seed, sown in a hot-bed; and when the plants are fit to remove, plant them separately in pots, and plunge them in the bark-bed; and managed as other woody plants of the stove collection.

WATER.

Water, where attainable to introduce in garden designs in smaller or larger expanse, is an important object, and may be considered both useful and ornamental in general gardening: it being of great utility in every garden district, in the article of Watering numerous sorts of young plants and trees, seed-beds, &c. occasionally, especially in the drought of spring and summer, both to such as grow in the full ground, and in pots in the open air, and to those in green-houses, stoves, hot-beds, &c. many of which could not exist without occasional Watering; and in ornamental designs, a body of Water properly disposed in eligible situations in pleasure grounds, parks, &c. either formed into regular compartments, circular, oval, or in oblong canals, &c. or varied in a somewhat natural expanse in curves and bendings, has a beautiful effect, especially as it may be agreeably accommodated to almost every situation and exposure; and delightful, where it is conspicuous at some small distance within view of the habitation, lawns, and other principal districts, being bounded with open expanded spaces of grass, and its banks diversified with some detached clumps of plantation.

But one great article to be considered is the attainment of proper supplies of Water to supply the intended design, either by springs in or near the place, or by currents or streams passing through, or nearly adjacent, to admit of being conducted to the proper situation in the garden, &c. which will afford a superior advantage in executing any particular design the most effectually; or conducted from some neighbouring river, brook, or lake, &c. by means of pipes or small cuts, or by collected Waters issuing from higher grounds, conducted by proper channels to the allotted places, in which any space or compartment of water is intended,

useful or ornamental: all of which requisite accommodations should be considered, how far attainable, previous to the formation of any design of this kind.

It is likewise to be considered, the means by which to retain the water sufficiently, after being acquired in the allotted place as above; which, if a loose earthy, sandy, or gravelly bottom, it will soon sink away, especially in dry weather, unless there is a constant current or flow of water running in, either by springs, or some running stream; but when of a naturally strong clayey bottom of proper thickness both at sides and below, it may probably retain the water in some tolerable degree: as however this kind of bottom is rarely equally effectual in all parts of it; and therefore generally in this case, and that of the natural bottom being of any loose soil above intimated, the whole, after being excavated to the proper depth, must be well secured by addition of a thick coat of strong clay laid at bottom and sides; and well rammed, as hereafter directed, also under the article BASONS, &c.

For useful occasions in the article of watering the various plants of gardens, reservoirs of Water, where easily attainable by either of the means before intimated, should not be omitted, in a smaller or larger scale, especially in principal gardens of any considerable extent; proportioned in some moderate dimensions according to the supply of Water that can be acquired; but where intended principally as a useful reservoir for watering the garden, may be of much more moderate dimensions than when designed also for ornament; and may be formed either in a circular manner, or an oblong canal, pond, or cut, &c. generally adopted in some lower part, or where the furnishing supply of Water can be most conveniently procured; or however some reservoirs of Water may be introduced in a general garden, both to serve for the above occasion of Watering, and for ornament: in which they may be of more capacious dimensions, and decoratively formed.

But Water is most essentially useful in every principal kitchen garden, pleasure ground, and nursery, for occasional Watering in dry weather in spring and summer; and also in winter in green-houses and stoves, &c. but more considerably in numerous articles in the open ground, both of seed-beds, and the various young plants therein raised: and to numerous sorts of young plants, cuttings, slips, off-sets, &c. newly pricked out or transplanted, both at the time of first planting, and afterwards occasionally, when dry hot weather prevails; as also in many sorts of new planted young

trees

trees and shrubs in spring and early autumn planting; and to all plants in pots, both hardy sorts and others in the open air in dry hot weather, in spring and summer; and to all the tender kinds in pots, of the green-house and stove; and all plants in hot-beds under glasses, &c. as before observed; and for all of which occasions, if the Water is contained in any kind of reservoir formed as above mentioned, it is not only more convenient for immediate use, but is considerably more salutary for the growth of all vegetables than raw sharp Water drawn for use immediately out of wells.

Or as in many places there are natural ponds, canals, or other reservoirs of Water close in the neighbourhood of gardens, commodiously situated for obtaining sufficient plenty for watering, the trouble and expense of making basons, canals, or other reservoirs, principally for that purpose, may be saved, except in particular occasions in extensive kitchen grounds, &c. where the articles for watering are considerable, and disposed in many different distant compartments: and for which, Water-cuts, canals, basons, or small ponds, would be essentially convenient in proper situations where a sufficiency of Water could be obtained by the means before mentioned, to keep them properly furnished.

Ornamental compartments of Water in pleasure-grounds are very desirable objects, as a great addition to the beauty, variety, and embellishment of these districts, when properly disposed, and contrasted with some nearly adjoining, detached clumps of plantation, and bounded with a proper expanse of grass ground, spreading from the verge considerably outwards, and the extent of Water proportioned in some degree to designs of large composition, or adapted to smaller, or according to the situation of the place, and the supply of Water that can be commodiously obtained by the means before suggested, sufficient to continue the allotted space always equally full to the requisite height and extent.

With regard to the proper situation in a pleasure-ground, park, &c. in which to have any intended piece of Water, this consequently must either be in some lower part, less or more, or where the most eligibly convenient for the attainment of a sufficiency of Water at all times to supply the extent of space allotted for the intended purpose, and for the advantage of having it more conspicuous to sight at some moderate distance; generally in some principal part disposed in a conspicuous point of view, at some convenient distance from the main habitation, as also to show agreea-

bly from the principal lawns and Walks extending immediately from or contiguous to the said mansion; and with occasional interval views from other principal parts of the pleasure-ground, especially where the surface of Water is of some considerable dimensions; but where unavoidably small, that is the less material in extensive grounds, as it would not make any conspicuous appearance at a distance.

However, in general designs, where any spaces of Water, on a larger or smaller scale, are intended, they should always be disposed as conspicuously as convenient, in some principal division; either sometimes at or near the termination of a spacious open lawn, or occasionally in some other similar open space; and sometimes disposed more or less internally in some central or other grand opening; in all of which a noble expanse of Water would have a fine effect; and where the attainment of Water for that occasion is abundant, and the situation not too much limited, it might be extended in a diversified order in some natural imitation, which, in large designs particularly, should generally be adopted in preference to a perfectly formal regularity: but in smaller gardens, the regular form may be more conformably admissible, either circular in the manner of a bason, or oblong in the order of a canal, &c. or even in these forms the stiff regularity may be broken, by varied curves in the margin.

Respecting, however, the general form and extent for any intended design in ornamental compartments of Water, they, in regard to form, may either be of a regular figure, as circular, oval, oblong, &c. or in a varied natural imitation, in different moderate curves and bendings; and in dimensions may either be considerably extensive, or of middling or small extent, conformably to the general plan of the garden, &c. and different situations of the ground: for as no particular dimensions can be assigned, this must depend on circumstances, both in regard to the nature of the situation, and extent of the proposed space, eligible for that purpose, and according to the supply of Water attainable therein for the desired occasion, or as may be thought expedient, either consistent with convenience, or the eligibility, more or less, of the particular parts of the pleasure-ground, park, or the most desirably situated for adopting the design with the greatest successful effect; as sometimes, in extensive designs, an ornamental piece of Water forms an expanse of one or two to several acres extent; and in others of more contracted or small plans, is sometimes

not

not half an acre, and in some not half that space; and in all of which larger or smaller designs, the form may be varied more or less accordingly; such as when intended to have any compartment of Water formed in some imitation of a natural order, the figure may be varied either in the roundish spreading, or oblong manner in gentle bendings, swells and curves, of different forms and dimensions; or in some situations may be formed in imitation of a natural river, or lake, &c. in easy varied windings: and the extreme terminations of which by a peculiar sweep round projecting swells of ground, furnished with clumps of plantation, may seem to proceed in continuation in another direction: or in gardens where a natural stream can be introduced, it will afford great opportunity in forming any particular or different designs in Water, sometimes in the form of a gently winding rivulet, or more copious river, or in some particular situations, spread out in a wide expanse of surface.

Cascades or Water-falls are also occasionally introduced in extensive grounds where there is the advantage of a rivulet, by which a cascade may be formed either in one larger fall, or in two or three smaller in succession, having large rough stones placed below to break the Water, and increase the sound of the torrent in its fall and passage over them, in some degree similar to that peculiar to natural cascades.

Fountains, spouting Water from some image, are sometimes introduced in the centre of small or moderate basins, or other reservoirs of Water in gardens, where a supplying head of Water is conveniently situated sufficiently high to raise and throw the Water from the jet or spout in a continued full stream to some considerable height, which falling in the basin or reservoir, keeps the Water thereof in motion, prevents stagnation, and is thereby rendered more beneficially wholesome for keeping and breeding fish of the gold and silver kind, &c. and the spouting and fall of the Water conveys a refreshing idea in the heat of summer.

In the formation of the ground designed for compartments of Water, the earth must be excavated as much as necessary to a proper depth, gradually sloping from the verge to the middle, two or three to four or five feet deep, not more; but as sometimes in low situations, the eligible place is naturally hollowed in some degree more or less, as not to require a general excavation, or only in particular parts, and some general regulations to the whole, which in extensive designs, would be a con-

siderable advantage; observing, however, in general, if the sides and bottom are of a sandy, gravelly, or stony nature, or abound in any loose soil, and that there is not a constant supplying stream, it must be well secured with the application of a thick coat of wrought clay to retain the Water; or even if the general natural bottom is clayey, it is seldom wholly effectual in every part to hold Water sufficiently well at all seasons, without the above advantage of a constant supplying stream; and therefore in these deficiencies the addition of a proper stratum of clay is commonly necessary, except as above said, in such places where there is a copious natural flow of Water, in which probably no claying will be required; which will be a particular advantage in large designs.

However, where claying is necessary, generally observe, in the preparatory excavation, to allow for a proper depth and width of the additional coat of clay twelve or fifteen inches thick, and of several inches of gravel over this, to preserve the clay from being wasted by the motion of the Water, and to keep the Water always clear, which otherwise would be muddy from the nature of the clay; and observing, previous to the claying, generally to ram any loose or uneven parts in the bottom or sides of the cavity, making the whole firm, even, and smooth; then applying the clay, begin first in the middle space, proceeding gradually outward, being careful that no stones, sticks, or other matter, get mixed therewith to occasion fissures or chasms for the Water to escape; laying it evenly, a small thickness at a time, and spread it regularly, treading it with men's naked feet; and if dry weather cast water on it occasionally, ramming it well from time to time with wooden rammers; applying more clay by degrees, in the same manner, to the proper thickness as above, giving attention that every part is well kneaded and rammed, not to leave the smallest vacancy; for the Water is apt to escape at the least cranny, and would occasion great trouble afterwards to find out the defective place; and thus continue the claying regularly each way from bottom to the top of the circumference, smoothing the surface evenly; and if dry weather cover it, as you proceed, either with mats or straw litter, or with the necessary stratum of pebbly gravel, three to four or five inches thick, to preserve the clay from cracking, by the sun, air, and wind; and when the whole is thus finished, let in the Water as soon as possible.

Then proceed to regulate and level the top superficies of the circumference or verge, and the

the immediately adjoining ground, forming it evenly from the Water edge in a gradual regular expansion to some tolerable extent outward, without forming any stiff slope immediately close to the Water, distinct from the surrounding superficies; but if any is thought necessary, whereby to admit of a more conspicuous view of the Water at a distance, generally form it in one continued gradual slope from the margin evenly outward, correspondent with the general surrounding surface of the adjacent ground; and then either lay the ground with grass turf, especially along the margin, continued as far down as the Water will apparently stand in general; and the other part may either be also turfed, or if of very considerable extent, in which a sufficiency of turf may not be easily attainable, may be sown with grass seed, or according as either shall seem the most convenient: or, in some designs, may have some width of grass next the Water, and then a space of gravel, either as a regular walk, or extended of any eligible width as may be thought expedient.

In preparing for the formation of a body of Water, in situations where the place intended is in any parts deficient, or too low in the boundary, either at the ends or sides, being lower than the general surface, or than the requisite height intended the Water shall stand, this must be strongly banked up accordingly to the required height, very substantially in thickness, especially where it happens to form a head at one end of a canal, &c. and have the whole faced inwardly with a strong body of clay.

WINTERA.

Winter's Bark, or Bastard Cinnamon.

For the stove, one species; a curious aromatic tree from South America, very branchy all round the stem; garnished with oblong, light-green leaves; and pentapetalous dodecandrous flowers in terminal umbels.

Class and order, *Dodecandria Monogynia*.

Characters.] CALYX is bell-shaped, trilobed, with the lobes roundish and concave. COROLLA, five oblong, sessile petals, longer than the calyx; and a conical, pitcher-shaped nectarium. STAMINA, no filaments; but twelve or sixteen linear, distant antheræ, affixed to the outside of the nectarium. PISTILLUM, an oval germen, cylindric style, with three obtuse stigmas. PERICARPIUM, a roundish, trilocular berry, with two heart-shaped seeds.

There is but one species, which is wholly a fine aromatic.

WINTERA *Canella*.

American Wintera.] Rises with a thick woody stem, branching on every side, almost the whole length, growing near twenty feet high; having a lightish-coloured aromatic bark; oblong, obtuse, light-green leaves; and red flowers, in umbellate clusters, at the ends of the branches, succeeded by roundish berries.

This tree, being a native of the hot parts of America, must always be kept in a stove in this country, and in which it merits observation as a curious aromatic tree, to increase the variety of the exotics in that department; and should be planted in pots of light, mellow, loamy earth, and treated as other woody plants of the stove collection.

X.

X E R

X E R

XERANTHEMUM. Eternal flower.

This genus furnishes herbaceous, curious flowering annuals for the pleasure-ground, and shrubby kinds for the green-house, growing two or three to four or five feet high; garnished with spear-shaped and linear leaves in the different species; and compound flowers at the sides and ends of the branches, com-

posed of many dry rigid florets, collected into one general scaly cup; and being of a dry chaffy nature, are remarkable for retaining their colours and beauty many months after being gathered.

Class and order, *Syngenesia Polygamia Superflua*.

Characters.] CALYX, a compound flower, having

having the general calyx composed of many long spear-shaped scales. COROLLA, composed of many hermaphrodite florets in the disk, each consisting of one funnel-shaped petal, five-parted at top; and tubular female florets in the radius, more slightly cut at the brim. STAMINA, five very short filaments, and long cylindric antheræ. PISTILLUM, a short germen; filiform style, having a bifid stigma in the hermaphrodites, and in the females two reflexed stigmas. PERICARPIMUM, none; each floret succeeded by an oblong, coronated seed, placed on a chaffy receptacle.

The plants of this genus derive the name Eternal Flower from the great durability of the flowers, which being gathered when fully blown, will retain their beauty many months.

There are many species, but the most remarkable of which are the following eight sorts, consisting of one hardy annual, and seven tender shrubby kinds.

Hardy annual kind.

Comprising the common Eternal Flower furnished with several varieties; all hardy herbaceous, ornamental-flowering annuals.

1. XERANTHEMUM *annuum*.

Annual Xeranthemum, or Common Eternal Flower.] Rises with an herbaceous, angular, downy, branching stalk, two or three feet high; spear-shaped, spreading, hoary, close-sitting leaves; and all the stalks and branches terminated by large flowers singly, of different colours in the varieties, appearing in July, August, and September, and are very ornamental, succeeded by ripe seeds in autumn.

Varieties are,] Large White-flowered—Purple-flowered—Double White-flowered—Double Purple-flowered—Double Violet-coloured.

The flowers of all these varieties are of the compound kind; consisting of many small florets in one common calyx, together forming one large flower, which in all the sorts is very ornamental, and in high estimation for the singularity of their durable beauty, even after being gathered; for if gathered when fully blown in dry weather, with part of the stalk to each, and hung up to dry in a shady place, they will retain their respective colours in full beauty all winter; and by placing the stalks in glasses or pots, not with water, but sand to make them stick fast, and placed in any apartment of a house, they will appear very ornamental.

They are all easily propagated by seeds sown in the full ground, in autumn or spring, or in both seasons; as the autumn-raised plants will flower earlier and strongest, and the spring plants will succeed them, and thereby

continue the succession of flowers proportionably longer.

Sow them for transplantation in any bed or border of good light earth, either on the surface and raked in, or in drills half an inch deep, and five or six inches asunder; and when the plants are come up two or three inches high, thin out a quantity of the strongest, and prick them either in beds in rows a foot asunder finally to remain, or in patches about the different borders to flower in assemblage with other hardy annuals; giving water as soon as planted, and repeated occasionally in dry weather till they have taken good root, and they will require no farther care except keeping them clean from weeds.

Or the seeds may be sown in patches in the different borders, in the places where you intend the plants shall flower.

Shrubby Green-house kinds.

These are tender exotics from Africa, trailing and upright shrubby plants, of three or four feet growth, closely garnished with small spear-shaped, linear and oval, hoary and silvery leaves; and large compound radiated silvery and yellow flowers, of long continuance in beauty, even after being gathered.

2. XERANTHEMUM *retortum*.

Reflexed-leaved Eternal Flower.] Under-shrubby, trailing stalks, garnished with recurved, reflexed, hoary-silvery leaves; and at the axillas of the branches, flowers with white rays and yellow disks.

3. XERANTHEMUM *speciosissimum*.

Most-specious Golden Eternal Flower.] Rises with an upright shrubby stem, branching three or four feet high; garnished with spear-shaped, trinervous, sessile leaves; and, at the termination of the branches, large bright, golden-yellow flowers.

4. XERANTHEMUM *sesamoides*.

Sesamum-like Silvery Eternal Flower.] Upright shrubby stem and slender hoary branches, three or four feet high; small, linear, adpressed leaves, laid close to the branches, and the branches terminated by large, silvery-flowers.

5. XERANTHEMUM *vestitum*.

Vestite, Leafy-flowered Xeranthemum.] Upright shrubby stem, branching three or four feet high; linear-spear-shaped, mucronated leaves; and terminal, leafy, white flowers.

6. XERANTHEMUM *fulgidum*.—Fulgid or Shining Eternal-Flower.

7. XERANTHEMUM *proliferum*.

Proliferous Eternal Flower.] Shrubby prolific stalks; granulous-roundish, lightly imbricated leaves, and close-sitting flowers.

8. XERANTHEMUM *imbricatum*.

Imbricated

Imbricated Eternal Flower.] Shrubby stalks, oval-awl-shaped, smooth, imbricated leaves.

Of the above green-house kinds of *Xeranthemum*, the first three or four species are the most noted; they are all tender plants, mostly from Africa, near the Cape of Good Hope, requiring protection in this country in winter, from October or November till May or June; therefore must be planted in pots, and have residence among the green-house exotics, where they will form a very agreeable variety at all seasons, and a pleasing singularity in their flowers, which appear conspicuously about July and August, continuing long in beauty; but are not generally succeeded by good ripe seeds in our gardens, for sowing; so that their propagation here is commonly effected by cuttings of the young shoots in summer, planted in pots of light mould, watered and shaded from the sun: or might be forwarded in a hot-bed, or covered close with a hand-glass, to expedite their emission of roots, and shooting in a moderate top growth the same season; and in autumn may be transplanted singly in pots, and afterwards managed as other green-house plants of the shrubby kind.

XYLOPHYLLA, Love Flower.

Comprehends two or three tender exotics for the stove, from the hot parts of America and the West-Indies: distinguish some with four-angled branches, others round; garnished with linear and spear-shaped leaves, and apetalous flowers.

Class and order, *Pentandria Trigynia*.

Characters.] CALYX, a six-parted coloured cup. COROLLA no petals; but nectariums

composed of six glandules affixed to the germen. STAMINA, five short filaments and single antheræ. PISTILLUM, a roundish germen, three short styles, crowned with lacerated stigmas. PERICARPIUM, a roundish trilobular capsule; seeds double.

The species are,

1. XYLOPHYLLA longifolia.

Long-leaved Love Flower.] Rises with four-angled branches, garnished with long linear leaves.

2. XYLOPHYLLA latifolia.

Broad-leaved Love Flower.] Rises with round branches, and broad spear-shaped leaves.

3. XYLOPHYLLA falcata.

Falcated Love Flower.] Rises with a woody stem and branches, garnished with linear-spear-shaped shining leaves placed irregularly; and at the upper part of the branches, flowers produced upon the edges of the leaves, very closely placed.

These three exotics, natives originally of hot countries, are introduced in our stove collections for variety and curiosity; in which they must always reside in winter, but may be placed, in their pots, in the full air in the middle summer months, in a sheltered situation, and removed to the stove in September.

They are propagated by seeds in pots placed in a hot-bed, and when the plants are come up two or three inches in growth, prick them in separate pots, and plunge them in the bark-bed: and afterwards managed as other stove plants of a similar nature.

Likewise some of them by off-sets, slips and cuttings, assisted also by a hot-bed.

Y.

Y U C

Y U C

YUCCA.

Adam's Needle.

This genus consists of shrubby succulent evergreens of America, both hardy and tender kinds, to diversify the pleasure-ground and green-house collection, rising with upright, thick, woody stems several feet high, adorned at top with clusters of very long, aloe-like,

stiff leaves, ending in long sharp spines; and at top, from among the leaves, long spikes of bell-shaped, six-parted, liliaceous flowers.

Class and order, *Hexandria Monogynia*.

Characters.] CALYX, none. COROLLA is monopetalous, bell-shaped, and divided into six large oval segments. STAMINA, six very short reflexed filaments, having small antheræ.

7 S 2

PISTIL-

PISTILLUM, an oval three-cornered germen longer than the stamina; no style, but an obtuse three-furrowed stigma. **PERICARPIUM**, an oblong, triangular, trid, trivalved capsule of three cells, containing many seeds lying over one another in a double series.

There are four species of *Yucca*, all of which are of singular growth; they rising with erect stems from two or three to six or eight feet high, terminated by a large tuft of very long leaves, resembling those of the aloe, but much narrower; have all durable stems and evergreen leaves; are natives of different parts of America, and two of them are moderately hardy to grow here in the full ground; and the other two, being more tender, require shelter of a green-house in winter.

Hardier kinds.

1. *YUCCA Gloriosa.*

Common Adam's Needle.] Rises with an erect, ligneous, thick stem, two or three feet high, having very long, narrow, stiff, entire leaves, ending in a long, sharp, black spine, garnishing the stem almost to the bottom, and in a large tuft at top; and from the centre of the top leaves rises a long branching peduncle, sustaining a panicle of bell-shaped white and purple flowers.

2. *YUCCA filamentosa.*

Filamentous, or Thready Virginia Yucca.] Rises with an upright, thick, ligneous stem two or three feet high, adorned at top with a tuft of very long spear-shaped, stiff, blunt-pointed, sawed, filamentose leaves, emitting long threads from the sides, hanging downward; and from the top of the stem amidst the leaves an erect peduncle or flower-stalk, several feet high, garnished with many large, white and purple striped leaves.

Both these species flower in August and September, and make an ornamental appearance, but are not succeeded by seeds in England.

They are natives of North America, the former that of Canada, and the latter of Virginia, and are both tolerably hardy; so as after having a little occasional shelter whilst young, for two or three winters, they may be turned out into the open ground in a sheltered situation in the shrubbery; though it is also proper to keep some always in pots, and treated as green-house plants, as a reserve in case those in the open ground should be cut off in very severe winters.

Tender Kinds for the Green-house.

3. *YUCCA aloifolia.*

Aloe-leaved Yucca.] Rises with an erect,

thick, fleshy stem, eight or ten feet high, crowned with a large tuft of long, narrow, stiff, crenated, aloe-like leaves ending in sharp spines; and from the centre of the crown of leaves comes out the flower-stalk, branching pyramidally two or three feet high, having all the branches terminating in a spike of flowers, purple without and white within, appearing in August and September.

4. *YUCCA Draconis.*

Dragon Tree-leaved Yucca.] Rises with an upright, thick, brown stem, three feet high, crowned with long, narrow, serrated leaves ending in spines and nodding downward; and in the centre of the leaves, arises the flower-stalk very branchy, with all the branches terminating in spikes of flesh-coloured flowers in August and September.

All these four species of *Yucca* being of singularly curious growth, they are worthy of culture in every good collection, keeping some of all the sorts in pots, to move to shelter of a green-house in winter; as they will afford a conspicuous and entertaining variety in this collection; and some plants of the two first sorts may also, after attaining a little strength and gradually hardened, be planted out in the full ground in some dry warm situation, sheltered by adjacent shrubs and trees, &c.

As all the sorts are of a succulent nature, they should always be planted in a light dry soil; if somewhat sandy, the better.

The propagation of all the sorts is by off-sets and suckers, from the root and head of the plants; also by seed.

By off-sets, &c.—These may be detached almost any time in spring and summer, and lay them in some dry place for a few days, till the wounded part made by separation from the plant is dried and healed over; then plant them in pots of light sandy compost, and place them in a shady situation till they have taken root.

By Seed.—This is obtained from abroad, and should be sown in the spring in pots of light earth, and plunged in a hot-bed, in which the plants will soon come up; and when they are two or three inches high, prick them separately in small pots of light sandy mould, plunging them also in a hot-bed to forward their growth, assisting them with moderate waterings and fresh air daily; and harden them by degrees to the full air in June and July, to remain till October, then removed into the green-house.

Z.

Z A N

ZAMIA. Dwarf Pinnated Palm.

Comprises some low species of the Palm tribe, of the West Indies, some of which are retained in our stove collections for variety, particularly one species, rising in robust stems only two or three feet high; ornamented with frondose pinnated leaves of many pair of oblong folioles; and male and female flowers separate on different plants, produced in a club-shaped spadix protruded from a spatha, each floret of the spadix having three petals, with proper stamina in the males, and germen and style in the females, succeeded by many red berries.

The principal species in our garden is,

1. ZAMIA pumila.

Dwarf Pinnated Palm with sawed Leaves.

Leaves thick, short, rigid, and slightly sawed.

The two following are also retained in some of our stoves.

2. ZAMIA spinosa.—Thorny Dwarf Palm.

3. ZAMIA integrifolia.—Entire-leaved Zamia.

They require a constant residence in the stove, planted in pots of rich light earth, and managed according to the general culture of other similar exotics of that department.

ZANTHOXYLUM. The Tooth-ach Tree.

This genus comprehends two species known in our gardens, one for the shrubbery, the other for the green house; the former of which is the most noted; a hardy exotic, originally from North America; the other from China; both of moderate growth, ten or twelve to fourteen feet high; garnished with large pinnated and trifoliate leaves; and dioecious apetalous flowers, in terminal paniced spikes.

Class and order, *Diœcia Pentandria*.

Characters. Male flower. CALYX, a perianthium deeply cut into five oval coloured parts. COROLLA, none. STAMINA, five awl-shaped erect filaments, with didymous, sulcated, roundish antheræ. Female flower. CALYX, as the male. COROLLA, none. PISTILLUM, a roundish germen, an awl-shaped style, with an obtuse stigma. PERICARPIUM, an oblong capsule, formed of two valves and

one cell, containing a single smooth roundish seed.

The name of Tooth-ach Tree being applied to this plant, arises from the use made of the bark in cleansing the teeth, and preventing that troublesome disorder among the inhabitants of Canada.

The species are,

1. ZANTHOXYLUM Clava Herculis.

Canada Tooth-ach Tree, or Hercules's Club.

It grows to the height of twelve feet, with a rough bark armed with short spines; the leaves are winged, of a dark-green colour, growing irregularly on the branches; each consists of four or five pair of spear-shaped folioles, which are terminated by an odd one; the flowers come out from the end of the branches in loose panicles; they being apetalous have no great appearance, and are succeeded by unilocular capsules, containing the seeds.

Variety. The Ash-leaved Tooth-ach Tree, with oval-oblong folioles, and prickly mid-ribs.

2. ZANTHOXYLUM trifoliatum.

Trifoliate Chinese Tooth-ach Tree. Rises with a woody stem, branching several feet high, garnished with trifoliate leaves, composed of three egg-oval folioles.

Of these two species, the first is the most noted and generally known in our garden plantations; the second is sometimes retained as a green-house plant, but will also succeed in the open ground in a warm situation: and both the sorts are very eligible to arrange in the shrubbery in assemblage with other deciduous kinds to increase the variety; generally allotting them a sheltered situation and dry soil, where they will succeed, and form an agreeable diversity in their pinnated and trifoliate leaves; but it is also proper to keep some of the Chinese sort in pots to move under protection, in winter, of a green-house, or awning, &c.

They are propagated by seeds and layers. Sow the seeds in the spring, either in an east border, or in pots placed in the morning sun all summer, sheltered in a frame in winter; and in spring removed to the full air till October,

ber, giving proper waterings all summer; and towards winter placed again under shelter from frost till March; then the young plants may be potted separately; and thus continued for a year or two, and sheltered in winter, then may be transplanted into the shrubbery.

By layers of the young wood in autumn or spring, they may also be propagated.

Likewise by cuttings in spring or summer, assisted by a hot-bed in which they will strike, then should be inured to the full air; and they will form young plants for transplanting in autumn or spring following.

ZEA (*Mays*), Indian corn, or Turkey wheat.

Consists of a tall-growing, herbaceous, hardy annual to cultivate for variety in the borders and other compartments of the pleasure-ground, &c. ornamented with long pendulous leaves, and monœcious husky flowers in long spikes, at the sides and upper part of the stalks; succeeded in the female flowers by many large, roundish seeds, closely placed round an oblong receptacle, which are the corn, the eatable part; though not used in this country for that occasion.

Class and order, *Monœcia Triandria*.

Characters.] Male and female flowers separate on the same plant; loosely disposed **CALYX**, a bivalve, two-flowered husk. **COROLLA**, two oblong valves, the outward one obtuse and bellied, and the interior bidentate at top, and are inclosed in the calyx, with a very short, diphyllous nectarium. **STAMINA**, three capillary filaments in the males, with bifid prismatic antheræ, opening at top; the female flowers are closely collected in a spike below the males on the same plant; the calyx a single-flowered husk, with two valves; with a corolla, a glumose husk, and four membranous unequal valves. **PISTILLUM**, a very small germen, slender pendulous style, and simple stigma. **PERICARPIUM**, none; many compressed, roundish seeds, immersed in an oblong, thick five-angled receptacle, forming together a long, thick, close head of corn.

The species is,

ZEA Mays.

Mays, or Indian Corn.] Rise with a large, strong, herbaceous stem, ten or twelve feet high, garnished with long, broad, pendulous leaves; male flowers, at the upper part of the stalks in spikes eight or ten inches long; and females arising at the axillas of the leaves below the males, in long, close, thick spikes, covered with thin leaves; and succeeded by the numerous seeds placed round the long receptacle in a compact order.

Variety.] Yellowish-white seeds—Deep yellow seeds—Purple-blue seeds.

This plant is very much cultivated in America and south of Europe for the seeds or corn, which being ground to meal, serve as food for the poorer inhabitants.

But in this country the plant is raised principally for curiosity and variety of its singularly tall growth, superior to most of our herbaceous plants; and in favourable seasons will produce ripe seeds in autumn.

It is raised from seed in the spring, March or April, either in a dry warm situation, where the plants are intended to remain: sowing them in patches, two or three seeds or more in each place, about an inch and half deep; but when the plants are up, leave generally but one of the strongest; or to have the plants as forward as possible to produce ripe seed-spikes more effectually, some may be sown in a hot-bed in March or beginning of April, and when the plants are three or four inches high, may be forwarded by pricking upon another hot-bed, either under a deep frame or an awning of hoop arches to cover with mats occasionally; allowing them plenty of free air; and in May, they may be transplanted, with balls of earth about their roots, into the full ground in borders, or shrubbery clumps, &c. in a warm sunny situation, and watered; and that if the summer proves warm and dry, they will produce perfect heads, and the seeds will ripen.

As the plants run up fast in tall stalks, it may be proper to support each with a tall neat stake, especially where exposed to the wind.

ZINNIA.

A genus of annual plants, cultivated for ornamenting the pleasure and flower gardens, growing with erect stalks, garnished with oblong leaves, and producing radiated flowers.

Class and order, *Syngenesia Polygamia Superflua*.

Characters.] **CALYX**, the general cup is oval, cylindric, and imbricated, with many blunt, upright, persistent scales. **COROLLA**, compound and radiated, consisting of hermaphrodite florets, placed in the disk, and female ones, which are ligulated, and form the rays. **STAMINA**, of the hermaphrodites, are five short filaments, with cylindric tubulose antheræ. **PISTILLUM**, an oblong aristated germen, with a slender semibifid style, and two erect obtuse stigmas; in the female flowers the germen is oblong and triquetrous, with a capillary style, and two recurved stigmas. **PERICARPIUM**, the calyx containing oblong solitary seeds crowned with down, and placed on a paleaceous receptacle.

Of

Of this genus there are two species.

1. *ZINNIA pauciflora*.

Few-flowered Yellow Zinnia.] The root of this plant is fibrous, from which arises the stalk to about three feet high; it is woody below, and branches upwards, which are placed opposite; these are furnished with oblong leaves of a pleasing green colour; the flowers terminate the ends of the branches on long foot-stalks; they are of a yellow colour, which decays before the seeds are ripe.

2. *ZINNIA multiflora*.

Many-flowered Red Zinnia.] This plant is also annual; the stalk rises erect with upright branches; these are channeled and hairy; the leaves are oval, lanceolate, and placed opposite; the flowers come out at the extreme part of the branches; the florets of the disk are yellow, and those which form the rays are of a dusky red; these continue till the seed is ripe, which is in autumn.

These plants being annual are propagated from the seeds, which should be sown on a slight hot-bed; in March, and afterwards, when the plants arising are a few inches high, they should be pricked out on another bed previously prepared to receive them; here they may remain till the advance of summer, when they may be taken up and transplanted in the borders of the pleasure or flower garden, where they will blow and complete their seeds for the next year.

ZYGOPHYLLUM.

Bean Caper.

It furnishes herbaceous and woody succulent exotics of Asia and Africa, cultivated here for variety in the pleasure ground and green-house collections: rising with erect stalks three or four feet high, adorned with oval, oblong, and spear-shaped, fleshy, succulent leaves, and pentapetalous flowers along the sides of the branches.

Class and order, *Decandria Monogynia*.

Characters.] **CALYX**, five oval, obtuse, concave, erect leaves. **COROLLA**, five obtuse petals emarginated at top, and a ten-leaved closed nectarium, which includes the germen. **STAMINA**, ten awl-shaped filaments, and oblong incumbent antheræ. **PISTILLUM**, an oblong germen, awl-shaped style, crowned by a simple stigma. **PERICARPium**, an oval, pentagonous, quinquevalvulous capsule of five cells, having many roundish seeds.

There are several species; one is herbaceous and moderately hardy, with perennial roots and herbaceous annual stalks; the others are of a woody durable growth, and tender, requiring shelter of the green-house in the win-

ter. The principal sorts in the English gardens are the following.

1. *ZYGOPHYLLUM Fabago*.

(Fabago)—or Common Bean Caper.] Hath a thick, fleshy, deeply striking, perennial root; upright, round, smooth, jointed, herbaceous, green stalks, three or four feet high; garnished with oval, smooth, fleshy, bluish-green leaves, two or three together on each petiole; and reddish flowers, by two or three together at the axillas of the stalks, appearing in July, succeeded by long capsules, containing the seed, ripening in autumn.

It is durable in root; but the stalks, being herbaceous, perish every autumn; is tolerably hardy, only requiring a little shelter in winter when young, afterwards may be planted in the full ground in the borders, in any dry light soil, there finally to remain; where they will abide many years by the root, and send up stalks, and flower abundantly, and ripen seeds.

As it is of a succulent nature, it should have a dry rubbishy soil.

It is propagated by seeds sown in the spring; some in a hot-bed to bring them forward, and some on a warm border; and when the plants are come up about two inches high, plant some out in small pots separately, and plunged into a hot-bed to facilitate their rooting, and forward their growth; but harden them by degrees to the full air; others may be planted in a warm border to take their chance; allowing those in the pots shelter of a garden-frame in frosty weather, and in spring some of them may be turned out into the full ground where they are to remain.

Tender Green-house Kinds.

These are mostly of a shrubby nature, durable in root, stem, and branches, garnished with succulent leaves.

2. *ZYGOPHYLLUM sessilifolium*.

Sessile-leaved African Bean Caper.] Rises with an upright woody stem, branching numerous and irregularly, three or four feet high; oval-spear-shaped, thick, smooth, succulent sessile leaves, surrounding the branches by fours; and yellow flowers on long slender footstalks at the sides of the branches, in succession great part of summer.

Varieties.] Yellow-flowered—Sulphur-coloured flowers—White-flowered—Copper-coloured, having mostly a reddish or brown spot near the base of each petal.

3. *ZYGOPHYLLUM Morgsana*.

Purshian-leaved Ethiopian Bean Caper.] Rises with a shrubby stem, dividing and branching irregularly, three or four feet high; oval, thick, obtuse, succulent leaves, surrounding

ing the branches by fours; and sulphur-coloured flowers on long foot-stalks from the sides of the branches, appearing most part of summer.

Variety.] Flame-yellow-flowered.

4. *ZYGOPHYLLUM spinosum.*

Thorny Bean-Caper.] Under-shrubby stalks; close-sitting leaves with linear acute folioles.

5. *ZYGOPHYLLUM album.*

White Egyptian Bean Caper.] With leaves foot-stalked, and clubbed fleshy lobes.

These tender species of *Zygophyllum* being natives of the warm parts of Africa, they require shelter of a green-house in this country in winter, planting them in pots of light sandy earth, as being succulent, and manage them as other plants of similar quality. See GREEN HOUSE PLANTS.

They are propagated easily by cuttings and by seed.

By Cuttings.—These may be planted, any time in the spring or summer; if in spring

about March or April, plant them in pots; and if plunged in a hot-bed, and occasionally watered, they will quickly emit roots, and shoot at top; and if in the summer months, plant them in a shady place, or in pots placed in the shade, giving frequent waterings, they will also take good root; and in either method pot them off separately towards autumn, in order to be moved into the green-house or glass case, in October.

By Seed.—The plants sometimes produce seeds in this country, or are procured from abroad by the seedsmen; sow them in spring in pots of light earth, and plunge them in a hot-bed, where they will soon come up; and when a little advanced in growth, prick them in separate small pots, watered and plunged again in the hot-bed till well rooted, then hardened gradually to the full air in June and July, to remain till October, then placed in the green-house, &c.

Ferraria	<i>Ferraria.</i>	Hesperis	{ Rocket, Dame's Violet, &c.
Ferula	Fennel Giant.	Hibiscus	{ Syrian Mallow, or Al- thæa Frutex, &c.
Ficus	Fig Tree.	Hieracium	Hawk-weed.
Filices	Ferns.	Hippophæ	Sea Buckthorn.
Fothergilla	<i>Fothergilla.</i>	Humulus	Hop.
Fragaria	Strawberry.	Hura	Sand-box Tree.
Fraxinus	Ash Tree.	Hyacinthus	Hyacinth.
Fritillaria	{ Fritillary, including Crown Imperial, and Persian Lily.	Hydrangea	<i>Hydrangea.</i>
Fuchsia	<i>Fuchsia.</i>	Hydrastis	Yellow Root.
Fumaria	Fumatory.	Hymenæa	Locust Tree, &c.
G.		Hypericum	St. John's-wort.
Galanthus	Snow-drop.	Hyssopus	Hyssop.
Garcinia	<i>Garcinia</i> or Mangostan.	I.	
Gardenia	Cape Jasmine.	Jacquinia	<i>Jacquinia.</i>
Genista	Jointed Dwarf Broom.	Jasminum	Jasmine Tree.
Gentiana	Gentian and Gentianella.	Jatropha	Cassava or Cassada.
Geranium	{ <i>Geranium</i> or Crane's Bill, see also <i>Erodium</i> and <i>Pelargonium.</i>	Iberis	Candy Tuft.
Geum	Avens or Herb Bennet.	Ilex	{ Holly or Holly Tree, &c.
Gladiolus	Gladiole or Sword Lily.	Impatiens	{ Touch-me-not, and Bal- samine or Balsam.
Gleditsia	Three-thorned Acacia.	Indigofera	Indigo.
Globularia	Globular Blue Daisy.	Ipomœa	{ Quamoclit or Scarlet Convolvulus.
Gloriosa	Superb Lily.	Iris	{ <i>Iris</i> , Flower-de-Luce, or Flag-flower.
Gloxinia	<i>Gloxinia.</i>	Itea	<i>Itea.</i>
Glycine	{ Knob-rooted Liquorice- vetch, or Carolina Kidney-bean Tree.	Iva	False Jesuit's Bark Tree.
Glycyrrhiza	Liquorice.		Juglans

I N D E X.

<i>Generic Names.</i>	<i>English or common Names.</i>	<i>Generic Names.</i>	<i>English or Common Names.</i>
Juglans	Walnut Tree.	Matricaria	Fever-Few.
Juniperus	{ Juniper-Tree, Cedars, and Savin.	Mauritia	{ Ginkgo, or Maiden- Hair Tree.
Justicia	Malabar Nut.	Medeola	{ Climbing African Aspa- ragus.
Ixia	<i>Ixia.</i>	Medicago	Medick, &c.
Ixora	Indian Wild Jasmine.	Melastoma	American Gooseberry.
K.		Melia	Bead Tree.
Kalmia	<i>Kalmia.</i>	Melianthus	Honey-Flower.
Kæmpferia	Galangale.	Melissa	Balm.
Kiggelaria	<i>Kiggelaria.</i>	Menespermum	Moon-Seed.
L.		Mentha	{ Mint, and Penny-Roy- al.
Lachenalia	<i>Lachenalia.</i>	Mesembryanthemum	{ Fig Marigold, or Fi- coides.
Lactuca	Lettuce.	Mespilus	Medlar, &c.
Lagerstroemia	<i>Lagerstroemia.</i>	Mesua	Indian Rose Chesnut.
Lantana	American Viburnum.	Michella	<i>Michella.</i>
Lathyrus	{ (Chickling Vetch) E- verlasting Pea.	Mimosa	{ <i>Mimosa</i> , or Sensitive Plant, including Aca- cia, &c.
Lavendula	Lavender.	Mimulus	{ Monkey-Flower, or A- merican Fox-Glove.
Lavatera	{ <i>Lavatera</i> , or Cretan and Tree Mallow.	Mirabilis	Marvel of Peru.
Laurus	{ Bay Tree: including Sassafras, and Cinna- mon Tree, &c.	Momordica	Male-Balsam Apple.
Lawsonia	{ <i>Lawsonia</i> or Egyptian Privet.	Monarda	{ Oswego Tea, or Lion's- Tail.
Ledum	{ Marsh Cistus, or Wild Rosemary.	Monsonia	<i>Monsonia.</i>
Lepidium	{ (Dittander,) Garden Cress.	Moræa	<i>Moræa.</i>
Leucojum	Greater Snow Drop.	Morina	<i>Morina.</i>
Ligusticum	Lovage.	Morus	Mulberry Tree.
Ligustrinum	Privet.	Musa	{ Plantain Tree, or Bana- na.
Lilium	Lily.	Musci	{ Mosses, a tribe of im- perfect Plants, of the Class Cryptogamia.
Limodorum	Bastard Hellebore.	Myrica	Candle-Berry Myrtle.
Linum	Lint or Flax.	Myrsine	African Box Tree.
Liquidambar	Sweet Gum Tree.	Myrtus	Myrtle Tree, &c.
Liriodendron	Tulip Tree.	N.	
Lobelia	Cardinal Flower, &c.	Napæa	{ <i>Napæa</i> , or Virginia Mallow.
Lonicera	Honeysuckle.	Narcissus	{ <i>Narcissus</i> , or Daffodil, and Jonquil.
Lopezia	<i>Lopezia.</i>	Nepeta	Nep, or Cat Mint.
Loranthus	<i>Loranthus.</i>	Nerium	Oleander, or Rose Bay.
Lotus	{ Bird's Foot Trefoil, Winged Pea, &c.	Nicotiana	Tobacco Plant.
Lunaria	{ Moon-wort, Satin Flow- er, or Honesty.	Nigella	{ <i>Nigella</i> , Fennel-Flow- er, or Devil-in-a- Bush.
Lupinus	Lupine.	Nolana	<i>Nolana.</i>
Lychnis	{ <i>Lychnis</i> , or Champion, &c.	Nyctanthes	Arabian Jasmine.
Lycium	Box Thorn.	Nymphæa	Water Lily.
Lyfimachia	Loose-strife.	Nyssa	Tupelo Tree.
Lythrum	{ Willow Herb, or Purple Loose-strife.	O.	
M.		Ocymum	Basil or Basilicum.
Magnolia	{ <i>Magnolia</i> , or Laurel- leaved Tulip Tree.	Oenothera	Tree Primrose.
Mahernia	<i>Mahernia.</i>	Olea	Olive Tree.
Malpighia	Barbadoes Cherry.	Oldenlandia	<i>Oldenlandia.</i>
Malva	Mallow.	Ononis	<i>Ononis</i> or Rest Harrow.
Mammea	Mamnee Tree.	Ophioxylon	<i>Ophioxylon.</i>
Mangifera	Mango Tree.	Ophrys	{ Twy-Blade, or Bee Flow- er.
Maranta	Indian Arrow-Root.		
Martynia	<i>Martynia</i>		
Massonia	<i>Massonia</i>		

Orchis

I N D E X.

<i>Generic Names.</i>	<i>English or common Names.</i>	<i>Generic Names.</i>	<i>English or common Names.</i>
Orchis	Orchis, (Fool's-Stones).	Poinciana	Barbadoes Flower Fence.
Origanum	Origany, or Marjoram.	Polemonium	Geek Valerian.
Ornithogalum	Star of Bethlehem.	Polyanthes	Tuberose, or Indian Tuberous Hyacinth.
Orobus	Bitter Vetch.	Polygala	Polygala, or Milk-wort.
Osteospermum	Hard-Seeded Chrysanthemum.	Polygonum	Knot Grass, Persicaria, &c.
Osyris	Poet's Cassia.	Populus	Poplar Tree.
Othonna	African Rag-wort.	Portlandia	Portlandia.
Oxalis	Wood-Sorrel.	Portulaca	Purslane.
P.		Portulacaria	Purslane Tree.
Pæonia	Peony.	Potentilla	Cinquefoil.
Panax	Genseng.	Poterium	Garden Burnet.
Pancratium	Pancratium Lily, or Sea Daffodil.	Prasium	Shrubby Hedge Nettle.
Pandanus	Screw Pine.	Primula	Primrose, including Polyanthus and Auricula.
Papaver	Poppy.	Prinos	Winter Berry.
Parkinsonia	Parkinsonia.	Protea	Silver Tree.
Passerina	Sparrow-wort.	Prunus	Plum Tree, including Cherry, Apricot and Laurel.
Passiflora	Passion-Flower.	Psidium	Guava Tree.
Pastinaca	Parfnepe.	Pforalea	Pforalea.
	African Geranium; comprising all the principal shrubby Geranium kinds, formerly ranged under that genus; and several of the herbaceous tribe. See also <i>Erodium</i> and <i>Geranium</i> .	Ptelea	Shrub Trefoil.
Pelargonium		Pulmonaria	Lung-wort.
Penstemon	Bastard Asarum.	Punica	Pomegranate Tree.
Periploca	Virginian or Virgin-Silk, Climbing Dog's Bane.	Pyrus	Pear Tree: comprising also Apple and Quince.
Petiveria	Guinea Hen Weed.	Q.	
Petrea	Petrea.	Quercus	Oak Tree: including also Cork Tree, &c.
Phaseolus	Kidney Bean.	R.	
Philadelphus	Syringa, or Mock Orange.	Randia	Randia.
Phillyrea	Phillyrea, Mock Privet.	Ranunculus	Ranunculus, Crow Foot, &c.
Phlomis	Phlomis, or Jerusalem Sage.	Raphanus	Radish.
Phlox	Lychnidea, or Bastard Lychnis.	Rauwolfia	Rauwolfia.
Phoenix	Great Palm, or Date Tree.	Reseda	Bastard Rocket: including Mignonette.
Phyllica	Bastard Alaternus.	Rhamnus	Buckthorn, comprehending Alaternus, &c.
Phyllanthus	Sea Side Laurel.	Rheum	Rhubarb.
Phyllis	Bastard Hare's Ear.	Rhexia	American Soap-wort.
Physalis	Alkekengi, or Winter Cherry.	Rhodiola	Rose Root.
Phytolacca	American Nightshade.	Rhododendron	Rhododendron, or Dwarf Rose Bay.
Pinus	Pine Tree, Fir, &c.	Rhus	Sumach: comprising Toxicodendron or Poison Tree, &c.
Piper	Pepper.	Ribes	Currant Tree; also Gooseberry.
Piscidia	Piscidia, or Jamaica Dog-wood Tree.	Ricinus	Palma-Christi.
Pisonia	Fingrigo.	Rivinia	Rivinia.
Pistacia	Pistachia Nut, or Turpentine Tree.	Robinia	False-Acacia.
Pisum	Pea.	Rondeletia	Rondeletia.
Platanus	Plane Tree.	Rosa	Rose, or Rose-Tree; and Sweet Briar.
Plinia	Plinia, or Pedunculated Myrtle.	Rosmarinus	Rosemary.
Plumbago	Lead-wort.	Royenia	African Bladder-Nut.
Plumeria	Red Jasmine.	Rubia	Madder.

Rubus

I N D E X.

<i>Generic Names.</i>	<i>English or common Names.</i>	<i>Generic Names.</i>	<i>English or common Names.</i>
Rubus	{ Bramble; and Raspber- ry, &c.	Sorbus	{ Service Tree; with Mountain Ash.
Rudbeckia	{ Dwarf American Sun- Flower.	Spartium	Broom.
Rumex	Dock, Sorrel, &c.	Spathelia	Spathelia.
Ruscus	Butcher's Broom, &c.	Spermacoce	Button-Weed.
Ruta	Rue.	Spigelia	Worm-Grass.
S.		Spinacia	Spinach
Saccharum	Sugar-Cane.	Spiræa	Spiræa-Frutex, &c.
Salix	{ Sallow, or Willow- Tree.	Spondias	Brasilian Plum, &c.
Salsola	Glass-Wort.	Stapelia	Stapelia.
Salvia	{ Sage; including Clary, &c.	Staphylæa	Bladder-Nut.
Sambucus	Elder-Tree	Statice	Thrift or Sea Pink.
Sanguinaria	Puccoon.	Stewartia	Stewartia
Santolina	Lavender-Cotton.	Strelitzia	Strelitzia.
Sapindus	Soap-berry Tree.	Styrax	{ Storax or Sweet-Gum Tree.
Sarracena	Side-saddle-Flower.	Swietenia	Mahogany Tree.
Satureia	Savory.	Symphytum	Comfrey, or Comphrey.
Satyrion	{ Satyrion, or Lizard- Flower.	Syringa	Lilac.
Saxifraga	Saxifrage.	T.	
Scabiosa	Scabius or Scabious.	Tabernæmontana	Tabernæmontana.
Scandix	{ Shepherd's Needle, Gar- den Chervil.	Tagetes	{ African and French Marigold.
Schinus	Indian Mastic Tree.	Tamarindus	Tamarind Tree.
Schotia	Schotia.	Tamarix	Tamarisk Tree.
Scilla	Squill, or Sea Onion.	Tamus	Black Bryony.
Scorpiurus	{ Caterpillar, or Caterpil- lar-Plant.	Tanacetum	Tansy, &c.
Scorzonera	Scorzonera, Viper's Grass.	Tarchonanthus	{ Shrubby African Flea- Bane.
Scrophularia	Fig-wort.	Taxus	Yew Tree.
Scutellaria	Skull-cap.	Telephium	True Orpine.
Sedum	{ Sedum, or Lesser House- leek, including Stone- crop, &c.	Tetragonia	Tetragonia.
Selago	Selago.	Teucrium	{ Tree Germander; in- cluding Polium, and Marum, &c.
Sempervivum	{ Greater or Common House-leek; Tree Sedum, &c.	Thalictrum	Meadow Rue.
Senecio	Groundsel, &c.	Thea	Tea Tree.
Serratula	Saw-wort.	Theobroma	Chocolate-Nut Tree.
Sida	Indian Mallow.	Thuya	Arbor Vitæ.
Sideritis	Iron-wort.	Thymbra	Mountain Hyssop.
Sideroxylon	Iron-wood.	Thymus	Thyme.
Silene	Viscous Campion. &c.	Tilia	Lime Tree.
Silphium	{ Bastard Chrysanthe- mum.	Tinus	Tree Volkameria.
Sinapis	Mustard.	Toluifera	Balsam of Tolu Tree.
Sisymbrium	Water-cress.	Tournefortia	Tournefortia.
Sisyrinchium	Bermudiana.	Trachelium	Throat-wort.
Sium	{ Water Parsnep; and Skirret.	Tradescantia	Virginia Spider-wort.
Smilax	{ Smilax, or Rough-Bind- weed, &c.	Tragopogon	{ Goat's-Beard; including Salsify, &c.
Smyrniacum	Alexanders.	Trichomanes	Maiden-Hair Fern.
Solanum	{ Nightshade; including Egg-plant, Love-ap- ple and Potatoe, &c.	Trifolium	Trefoil, or Clover.
Solidago	Golden Rod.	Trillium	{ Herb True-Love of Canada.
Sophora	Sophora.	Triopteris	Triopteris.
	8	Triticum	Wheat.
		Triumfetta	Triumfetta.
		Trollius	Globe Ranunculus.
		Tropæolum	{ Indian Cress or Nastur- tium.
		Tulbagia	Tulbagia.
		Tulipa	Tulip.
		Turnera	Turnera.
		Tussilago	Colt's Foot.

INDEX.

<i>Generic Names.</i>	<i>English or common Names.</i>	<i>Generic Names.</i>	<i>English or common Names.</i>
U.		Viscum	Mistletoe.
Ulex	Furz, Gorse, or Whins.	Vitex	Agnus Castus; or Chaste Tree.
Ulmus	Elm Tree.	Vitis	Vine.
Urena	Indian Mallow.	Volkameria	Volkameria.
Urtica	Nettle.	W.	
V.		Wackendorfia	Wackendorfia.
Vaccinium	Whortle-Berry.	Winterana	Winterana, or Winter's Bark.
Valeriana	Valerian.	X.	
Veratrum	White Hellebore.	Xeranthemum	Eternal Flower.
Verbascum	Mullein.	Xylophylla	Love Flower.
Verbena	Vervain.	Y.	
Verbesina	Indian Hemp-Agrimony	Yucca	Adam's Needle.
Veronica	Veronica, or Speedwell.	Z.	
Viburnum	Wayfaring Tree; including the Guelder Rose, and Laurustinus.	Zamia	Dwarf Pennated Palm.
Vicia	Vetch; and Garden Bean.	Zanthoxylum	Tooth-Ach Tree.
Vinca	Periwinkle.	Zea	Mays, or Indian Corn, or Turkey Wheat.
Viola	Violet; including Pansy or Heart's Ease.	Zinnia	Zinnia.
		Zygophyllum	Bean-Caper.

I N D E X

OF THE

ENGLISH AND MOST COMMON NAMES OF THE PLANTS.

Containing the general English Names, and such others, whether English or Latin, as are the most generally known and received, both of the Genera and of all the principal or most remarkable Species, arranged in the first column; and in the second are the names or titles of the Genera to which they respectively belong, and under which they are arranged in the foregoing work, according to the Linnæan System of Botany.

<i>English Names.</i>	<i>Botanic Names.</i>	<i>English Names.</i>	<i>Botanic Names.</i>
A BELE tree - -	<i>Populus.</i>	Amellus of Virgil -	<i>Aster.</i>
Acacia - -	<i>Mimosa.</i>	Amomum Plinii -	<i>Solanum.</i>
Acacia, false - -	<i>Robinia.</i>	Ananas - -	<i>Bromelia.</i>
Acacia, scarlet - -	<i>Robinia.</i>	Ananas, wild - -	<i>Bromelia.</i>
Acacia, three-thorned	<i>Gleditsia.</i>	Andrachne - -	<i>Arbutus.</i>
Acajou - -	<i>Anacardium.</i>	Andromeda - -	<i>Andromeda.</i>
Aconite - -	<i>Aconitum.</i>	Anemone - -	<i>Anemone.</i>
Aconite, winter - -	<i>Helleborus.</i>	Anemone, wood - -	<i>Anemone.</i>
Adam's needle - -	<i>Yucca.</i>	Angelica - -	<i>Angelica.</i>
Adder's wort - -	<i>Polygonum.</i>	Angelica, berry-bearing	<i>Aralia.</i>
African marigold - -	<i>Tagetes.</i>	Angelica tree - -	<i>Aralia.</i>
Agaric - -	<i>Agaricus.</i>	Anotta - -	<i>Bixa.</i>
Agnus-castus - -	<i>Vitex.</i>	Apple tree - -	<i>Pyrus.</i>
Agrimony - -	<i>Agrimonia.</i>	Apple, custard - -	<i>Annona.</i>
Agrimony, hemp - -	<i>Eupatorium.</i>	Apple, love - -	<i>Solanum.</i>
Agrimony, Indian hemp	<i>Verbena.</i>	Apple, mad - -	<i>Solanum.</i>
Alaternus - -	<i>Rhamnus.</i>	Apple, male balsam -	<i>Momordica.</i>
Alaternus, bastard -	<i>Phytica.</i>	Apple, pine - -	<i>Bromelia.</i>
Alder tree - -	<i>Betula.</i>	Apple, soap - -	<i>Sapindus.</i>
Alder, berry-bearing -	<i>Rhamnus.</i>	Apple, star - -	<i>Chrysophyllum.</i>
Ale-cost, or costmary	<i>Tanacetum.</i>	Apple, sweet - -	<i>Annona.</i>
Alexanders - -	<i>Smyrnum.</i>	Apple, thorn - -	<i>Datura.</i>
Alkekengi - -	<i>Physalis.</i>	Apple, water - -	<i>Annona.</i>
All-spice - -	<i>Myrtus.</i>	Apricot tree - -	<i>Prunus.</i>

Alligator pear - -	<i>Laurus.</i>	Arbutus - -	<i>Arbutus.</i>
Almond tree - -	<i>Amygdalus.</i>	Arbutus, dwarf - -	<i>Arbutus.</i>
Aloe, American - -	<i>Agave.</i>	Arbutus, trailing -	<i>Epigæa.</i>
Aloe, African - -	<i>Aloe.</i>	Arrow-root - -	<i>Maranta.</i>
Althæa frutex - -	<i>Hibiscus.</i>	Arse-smart - -	<i>Polygonum.</i>
Alysson - -	<i>Alyssum.</i>	Artichoke - -	<i>Cynara.</i>
Amaranth - -	<i>Amaranthus.</i>	Artichoke, Jerusalem	<i>Helianthus.</i>
Amaranthus, globe -	<i>Gomphrena.</i>	Arum, African - -	<i>Calla.</i>
Amaranthus, tree - -	<i>Amaranthus.</i>	Asarabacca - -	<i>Asarum.</i>
Amber tree - -	<i>Anthospermum.</i>	Ash-tree - -	<i>Fraxinus.</i>
Amelanchier - -	<i>Mespilus.</i>	Ash, mountain - -	<i>Sorbus.</i>

<i>English Names.</i>	<i>Botanic Names.</i>
Ash, poison	- <i>Rhus.</i>
Asparagus	- <i>Asparagus.</i>
Asparagus, climbing	} <i>Medeola.</i>
African,	
Aspen tree	- <i>Populus.</i>
Asphodel	- <i>Asphodelus.</i>
Asphodel, African	- <i>Anthericum.</i>
Asphodel lily	- <i>Crinum.</i>
Asphodel lily	- <i>Hemerocallis.</i>
Atamasco lily	- <i>Amaryllis.</i>
Avens	- <i>Geum.</i>
Avogato pear	- <i>Laurus.</i>
Auricula	- <i>Primula.</i>
Azarole	- <i>Crataegus.</i>
B.	
Balm	- <i>Melissa.</i>
Balm of Gilead	- <i>Dracocephalum.</i>
Balm, Moldavian	- <i>Dracocephalum.</i>
Balm of Gilead fir	- <i>Pinus.</i>
Balsam or Balsamine	- <i>Impatiens.</i>
Balsam apple, male	- <i>Momordica.</i>
Balsam of Tolu	- <i>Toinifera.</i>
Balsam tree	- <i>Clusia.</i>
Balsam tree	- <i>Pistacia.</i>
Balsam of Gilead tree	- <i>Amyris.</i>
Balsam of Capivi tree	- <i>Copaifera.</i>
Balsam of Mecca tree	- <i>Amyris.</i>
Balsamine, female	- <i>Impatiens.</i>
Bamboo cane	- <i>Arundo.</i>
Banana tree	- <i>Musa.</i>
Bane-berries	- <i>Africa.</i>
Barba Jovis	- <i>Anthyllis.</i>
Bark, true Jesuit's	- <i>Cinchona.</i>
Bark, false Jesuit's	- <i>Iva.</i>
Bark, Winter's	- <i>Wintera.</i>
Barren wort	- <i>Epimedium.</i>
Base trefoil tree	- <i>Cytisus.</i>
Basil	- <i>Ocimum.</i>
Batchelor's button	- <i>Lycnis.</i>
Bay tree	- <i>Laurus.</i>
Bay, loblolly	- <i>Gordonia.</i>
Bay, rose	- <i>Nerium.</i>
Bay, dwarf rose	- <i>Rhododendron.</i>
Bay plum	- <i>Psidium.</i>
Bead tree	- <i>Melia.</i>
Bean, common	- <i>Vicia.</i>
Bean, kidney	- <i>Phaseolus.</i>
Bean tree, kidney	- <i>Glycine.</i>
Bean caper	- <i>Zygophyllum.</i>
Bean trefoil, stinking	- <i>Anagyris.</i>
Bearberries	- <i>Arbutus.</i>
Bearbind	- <i>Convolvulus.</i>
Bear's breech	- <i>Acanthus.</i>
Bear's ear	- <i>Primula.</i>
Bear's ear, fanicle	- <i>Cortusa.</i>
Bear's foot	- <i>Helieborus.</i>
Beard, old-man's	- <i>Clematis.</i>
Beard, Jupiter's	- <i>Anthyllis.</i>
Bee flower	- <i>Ophrys.</i>
Bee larkspur	- <i>Delphinium.</i>
Beech tree	- <i>Fagus.</i>
Beet	- <i>Beta.</i>

<i>English Names.</i>	<i>Botanic Names.</i>
Bell flower	- <i>Campanula.</i>
Bell flower, Canary	- <i>Canarina.</i>
Bell flower, steeple	- <i>Campanula.</i>
Bells, Canterbury	- <i>Campanula.</i>
Bells, hair	- <i>Hyacinthus.</i>
Bell-pepper	- <i>Capicum.</i>
Belladonna lily	- <i>Amaryllis.</i>
Belvedere	- <i>Chenopodium.</i>
Benjamin tree	- <i>Laurus.</i>
Bennet, herb	- <i>Geum.</i>
Berberry	- <i>Beiberis.</i>
Bermudiana	- <i>Sisyrinchium.</i>
Betony	- <i>Betonica.</i>
Betony, Paul's	- <i>Veronica.</i>
Bilberry	- <i>Vaccinium.</i>
Bind-weed	- <i>Convolvulus.</i>
Bind-weed, rough	- <i>Smilax.</i>
Bind-weed, black	- <i>Tamus.</i>
Birch tree	- <i>Betula.</i>
Bird cherry	- <i>Prunus.</i>
Bird-pepper	- <i>Capicum.</i>
Bird's eye	- <i>Adonis.</i>
Bird's foot, trefoil	- <i>Lotus.</i>
Bird's nest	- <i>Ophrys.</i>
Bird's nest, purple	- <i>Orchis.</i>
Bird's service	- <i>Sorbus.</i>
Birthwort	- <i>Aristolochia.</i>
Bistort	- <i>Polygonum.</i>
Bitter vetch	- <i>Orobis.</i>
Bitter wort	- <i>Gentiana.</i>
Blackberry	- <i>Rubus.</i>
Blackthorn	- <i>Prunus.</i>
Bladder-nut	- <i>Staphylæa.</i>
Bladder-nut, African	- <i>Royena.</i>
Bladder senna	- <i>Colutea.</i>
Bladder senna, jointed	} <i>Coronilla.</i>
podded	
Blea-berry	- <i>Vaccinium.</i>
Blite	- <i>Blitum.</i>
Blood-flower	- <i>Hemantibus.</i>
Blood-wood	- <i>Hæmatoxylum.</i>
Blood-wort	- <i>Rumex.</i>
Bloody-dock	- <i>Rumex.</i>
Blue-bottle	- <i>Centaurea.</i>
Bonduc tree	- <i>Guilandina.</i>
Borecole	- <i>Brassica.</i>
Borage	- <i>Borago.</i>
Bottle-flower	- <i>Centaurea.</i>
Box tree	- <i>Buxus.</i>
Box tree, African	- <i>Myrsine.</i>
Box-thorn	- <i>Lycium.</i>
Box-thorn, Æthiopian	- <i>Celastrus.</i>
Bramble	- <i>Rubus.</i>
Brank	- <i>Polygonum.</i>
Brank ursine	- <i>Acanthus.</i>
Bread-fruit tree	- <i>Artocarpus.</i>
Break-stone	- <i>Saxifraga.</i>
Briar, sweet	- <i>Rosa.</i>
Briar, wild	- <i>Rosa.</i>
Broccoli	- <i>Brassica.</i>
Broom	- <i>Spartium.</i>
Broom, African	- <i>Aspalathus.</i>

Broom,

I N D E X.

<i>English Names.</i>	<i>Botanic Names.</i>
Broom, dyer's	- <i>Genista.</i>
Broom, dwarf	- <i>Genista.</i>
Broom, Spanish	- <i>Spartium.</i>
Broom, butcher's	- <i>Ruscus.</i>
Bryony	- <i>Bryonia.</i>
Bryony, black	- <i>Tamus.</i>
Buckthorn	- <i>Rhamnus.</i>
Buckthorn, sea	- <i>Hippophae.</i>
Buckwheat	- <i>Polygonum.</i>
Bugle	- <i>Ajuga.</i>
Bugloss	- <i>Anchusa.</i>
Bullace tree	- <i>Prunus.</i>
Burnet, garden	- <i>Poterium.</i>
Burning thorny plant	- <i>Euphorbia.</i>
Butcher's broom	- <i>Ruscus.</i>
Butter-burr	- <i>Tussilago.</i>
Button tree	- <i>Cephalanthus.</i>
Button weed	- <i>Spermacoce.</i>
C.

In this Index of the English and other most generally known names of the plants, trees, &c. described in the general process of this work, both of the genera, and the principal or most noted species, with the botanic names of the respective genera; it may be observed, that as many of the genera are not known by any English name, or any other besides that of the botanic, they, together with the other names of the genera only, no species, are wholly arranged in the first Index under their said generical Latin or botanic names, with that of the English, where any occur; and that in regard to the species belonging to the different genera, this Index contains principally the English and most generally received names of all the most remarkable or material plants, &c. thereof; and as most of the genera comprise also several, and some many other less noted species, which could not possibly be all arranged under this head in the Index order, without swelling it considerably beyond the proper necessary limits; the whole belonging to each genus of the eligible garden plants, both of the most noted and other species, are inserted under their said respective genera by their general English and other proper names.

Likewise select lists of the different species belonging to most of the various genera may be seen collectively under several different heads in the body of the work, distributed into tribes, as it were, according to their respective modes or natures of growth, general habit, temperature, particular uses in the different garden districts, and oeconomic qualities, &c. arranging under the following articles—Annual, Biennial, and Perennial Plants, Bulbous, Tuberous, and Fibrous-rooted Plants, &c. Aromatic Plants, Kitchen-garden Plants, Green-house and Stove Plants, Herbaceous Plants, Succulent Plants, Deciduous Trees, Evergreen Trees, Fruit Trees and Forest Trees, and some other similar arrangements occurring in alphabetical order in different parts of the book.

I N D E X

OF THE ESSENTIAL ARTICLES OF GENERAL GARDENING, AND PRINCIPLES OF BOTANY.

IN TWO DIVISIONS.

FIRST DIVISION.

Containing a List of the principal Essentials of General Gardening, comprehended in this Work; comprising the different Garden Districts and Compartments, Plantations, Shrubberies, Green-houses, Hot-houses, Forcing-houses, Hot-walls, Hot-beds and Stoves, with the respective Plants and Trees, &c. separately, of each Department; the principal necessary Garden Materials, different Requisites, proper Earths, Dungs, Manures, and Composts; with the different Methods of Propagation, Planting, Sowing, &c. principal Garden Implements, and general Methods of performing the different Practical Operations, in the various necessary Works in the several Departments; all of which, according as they alphabetically occur in the different Parts of the Book, are fully described and explained.

A.

A LLEYS, forming divisions to beds, borders, and other compartments.
Annual Plants, a numerous tribe, both of flowers and esculent vegetables: arrangement of the different sorts.

Arbours, their uses, and different sorts.

Aromatic Plants, their uses, and different species.

Aquatic Plants and Trees, such as grow near or in water.

Ashes, for manure and other occasions.

Autumn Plants.

Autumn Season.

Avenues of trees, their disposition, and proper trees in their formation.

B.

Bark, or Tan, for bark-beds.

Bark-beds, their different uses and formation.

Bark-pits, in which to make bark-beds.

Baskets, different useful sorts for gardens.

Basons, or Reservoirs of water:

Bafs, for ligaments in tying up plants, &c.

Bafs Mats.—See Mats.

Beds, proper sorts in the different garden departments.

Beds, Hot.—See Hot-beds.

Biennial, or two years' plants.

Blights on trees and plants.

Borders, the different sorts and uses described.

Bosquets of shrubs and flowers, &c.

Bowling-green.

Brooms, proper sorts for gardens.

Budding, for the propagation of trees.—See Inoculation.

Bulbous-rooted flowers, &c.—See *Bulbus*.

C.

Capful, a seed vessel.—See *Capsula*.

Cascades.—See Water.

Caterpillar Insects, on trees and plants.

Clay.—See Earth, Basons, Water, &c.

Climbing Plants, various sorts; both shrubby and herbaceous.—See also *Caulis*, *Cirrhus*, and *Volubilis Caulis*.

Compound Flowers.—See *Compositus Flos*.

Composts of Earths, Dungs, &c. of various compositions, for different occasions.

Cone, a seed-vessel.—See *Conus*, &c.

Creeping Plants.—See *Caulis*, Climbing Plants, and *Hedera*.

Culinary Plants, and Fruit.

Cuttings, to plant for propagation in raising many sorts of trees, shrubs and plants.

D.

Deciduous Trees and Shrubs; their description and different sorts.

Dibble, or Setting-stick, different sorts described.

Digging ground, different methods; as plain digging, trench digging, and digging in ridges.

Drawing;

I N D E X.

Drawing Frame, for annual-flowers, to draw them up tall in stature.
 Drill-sowing, &c.
 Dung for hot-beds.
 Dungs for manure.
 Dwarf fruit-trees, their different orders of training.

E.

Earth, different sorts, proper for gardens, &c.
 Edgings, their utility, different sorts, planting, and culture.
 Edging-Iron.
 Edging-Shears.
 Esculent Plants, such as are eatable.
 Espalier Trees, their general description, utility, and order of training.
 Evergreens, their nature of growth, different sorts, uses, &c.

F.

Flower-garden.—See Pleasure-ground.
 Forcing-frame, for early plants, flowers and fruit.
 ——— by Dung heat.
 ——— by Bark-bed heat.
 ——— by Fire heat.
 ——— Plants and trees for forcing.
 Forcing-house.—See Forcing-frame.
 Forest Trees, their utility and different sorts.
 Fosse, or Haha.
 Frames, Garden Frames, the different sorts described.
 Framing, raising early plants, &c. in hot-beds, under frames.
 Fruit-trees, the different sorts, their different orders of training. See Standard-trees, Dwarf-trees, Trained-trees, Wall-trees, and Espaliers; also, Grafting and Inoculation.
 ——— Their general methods of pruning and training.—See each sort under its respective Genus; also the article Pruning; likewise Wall-trees, Espaliers, Standards, Dwarf-trees, Trained-trees, Orchards, &c.
 ——— Defending the blossom of early blooming Wall-trees.—See Peaches, Nectarines, Apricots, under the articles *Amygdalus* and *Prunus*.

G.

Gardens, referring to the different departments.
 Genus of Plants, comprising one or two to many species.
 Glass-case.
 Glass-lights.—See Lights, and Hand Glasses.
 Grafting, different methods.
 Grass Lawns, Walks, &c.
 Gravel, proper sorts for walks.
 Gravel Walks.
 Green-house, its general description.
 Green-house Plants, the different sorts and general culture.
 Groves of Trees.

H.

Hand Glasses.
 ——— Square-formed.

Hand Glasses, bell-formed.
 Hedges, different sorts, proper trees, consisting of—Deciduous Hedges—Evergreen Hedges.
 Herbs.—See *Herba*.
 Herbaceous Plants.
 Hoes, different sorts, and respective uses.
 Hoeing.
 Horse-dung, for hot-beds, and manure.
 Hot-beds.
 ——— Horse-dung Hot-beds.
 ——— Tanner's-bark Hot-beds.
 Hot-house.—See also Stove.
 Hot-house or Stove plants.—See Stove.
 Hot-walls, for forcing early fruit.

I.

Ice-house.
 Inarching.—See Grafting.
 Inoculation, or Budding, means of propagating numerous sorts of trees.

K.

Kitchen-garden, its general description.
 Kitchen-garden Plants, arrangement of the different sorts.

L.

Labyrinth or Maze.
 Lawns, their proper situations, dimensions and form.
 Laying, the propagation by Layers, in raising many sorts of trees and shrubs, and some kinds of herbaceous plants.
 Light, its beneficial agency in vegetation.
 Lights, Glass-lights of garden frames, &c.
 Lining hot-beds, to renew the heat.
 Loam.—See Earth.
 Luxuriant Plants, Trees, and Flowers, &c.—See *Luxurians*.

M.

Manure, different sorts.
 Marle, for Manure.
 Mats, Bass Mats, for covering and shading plants, seed-beds, &c.
 Medicinal Plants, the different sorts.
 Melonary, general utility, and description.
 Motion of Plants.—See *Motus*.
 Mould or Mold.—See Earth.
 Mowing.—See Grass.
 Mulch, half-rotted strawy dung; useful in protecting the roots of new-planted and tender young trees from frost and drought.

N.

Nursery, its great utility; general description and management.

O.

Off-sets, means of propagating numerous sorts of plants.
 Oiled-paper frames.—See Paper-frames.
 Orchard, of standard fruit-trees, its general utility, description, proper sorts of trees, planting, and culture.

Others,

Offers, proper plants for supplies of twigs, rods, &c.—See also *Salix*.

P.

Paper Frames.

Parasitic Plants, such as grow upon others.

Parterre, a flower compartment, divided into various small partitions of beds, borders, alleys, &c.

Parting-roots, a method of abundant propagation in numerous herbaceous and under-shrubby plants.

Perennial Plants, or plants of many years' duration; consisting of fibrous-rooted, bulbous and tuberous-rooted kinds.

—— Bulbous-rooted. See *Bulbus*.

—— Fibrous-rooted.—See *Radix perennis fibrosa*.

—— Tuberous-rooted.—See *Tuberous-rooted Plants*.

Piping, a method of propagation applicable principally in pinks and carnations.—See *Dianthus*.

Plantations, in groves, clumps, thickets and shrubberies, &c. in different orders; and of forest trees for timber, and coppices of under-wood.

Planting, the various methods explained.

Plashing, or laying hedges.

Pleasure-ground, its general description, proper plantations, shrubberies, and general management.

Pot-herbs, the different sorts; propagation, and general culture.

Pots, the proper sorts and different sizes for various garden plants, and for green-house and stove exotics.

Propagation of trees and plants, by various methods.—See Sowing Seed, Planting Suckers, Cuttings, Slips, Layers, Off-sets, and Pippings; also Parting-roots, Spawn, Grafting, Budding, and Inarching.

Pruning, the general method, in different sorts of fruit-trees, and others.

Q.

Quick-set-hedges.—See *Crataevus*.

Quincunx Planting.

R.

Racer, or Sward-cutter, used in cutting turf.

Rakes, the different sorts for gardens.

Raking ground, in preparation for sowing and planting; also for raking in seeds in broadcast sowing.

Reed Hedges, their use in gardens, and method of formation.

Ridging ground, in digging and trenching.

S.

Sallad-herbs, the different sorts for general and occasional use.—See also Small sallad-herbs.

Sand. See Earth.

Sand Walks.—See Walks.

Seeds of Plants, general description.—See *Semen*.

Sexes of Plants.—See *Sexus*, also *Classis*, and *Genus*.

Shading plants, seed-beds, &c.

Shifting plants in pots, into larger.

Shrubs, their nature of growth described.—See *Frutex*.

Shrubs and Trees, many different sorts.—See Deciduous and Evergreen Trees and Shrubs.

Shrubberies.—See Pleasure-ground and Plantations.

Slips, means of propagation for raising many sorts of plants.

Small-sallad Herbs, the different sorts, and general culture.

Soup-herbs, the general, and principal sorts.

Sowing seeds, the different methods explained.

Spades, different sorts, for general, and particular uses, in spade work.

Spawn, a progeny of the mushroom tribe, and some other plants.

Species of plants, individuals of a genus.

Sprouts, an off-spring from the stems of plants.

Stage for carnations and auriculas.—See *Dianthus* and *Primula*.

Standard Trees, different orders of training.

Stocks, for grafting and budding, describing the different sorts proper for those occasions.

Stools, for the propagation, by layers.

Stove, or hot-house, the different sorts, and general uses.

Stove Plants, the different genera and species, and general management.

—— Plants, trees, and flowers, for forcing in stoves.

Succeſſion-house, and pits, appertaining to the stove.—See Stove.

Succulent Plants, list of the principal sorts.

Suckers, a progeny from the roots of trees and shrubs, &c. for the propagation of many sorts.

Sun, its great beneficial influence in the growth of plants, &c.

T.

Tan, or Tanner's bark, for bark-beds.

Terrace-walks, their description, and uses in pleasure-ground.

Thermometer, for regulating the degree of heat in stoves.

Thicket plantations of trees and shrubs.

Trained trees, for walls and espaliers.

Tree, its difference in growth from a shrub.—See *Arbor* and *Frutex*.

Trees and shrubs, the different hardy sorts.—See Deciduous and Evergreen Trees, Forest and Fruit Trees.

Trellage or Treillis for espalier trees, and other occasions in gardening.

Trenching.—See Digging and Ridging Ground.

Tribes of Plants.—See *Tribus*.

Trowels, for various uses in gardens.

Tuberous-rooted Plants, consisting both of flowers and esculent kinds.

Tubs, for large green-house plants.
Turf, Grass Turf, for laying lawns, walks, plats, and other grass compartments in gardens.
Turning Iron, for cutting turf.
Turning gravel walks.—See Gravel, &c.

U.

Umbelliferous Plants, producing flowers in umbels.—See *Umbella*.

V.

Varieties of the species of plants, flowers, and fruits.—See *Varieties*.

Verticillate Plants, producing flowers in whorls.
—See *Verticillus*.

W.

Walks, their utility, proper sorts, and order of arrangement in the different garden districts.
Walls of gardens, both as fences and for wall trees, proper sorts and disposition.
Wall Trees, their peculiar merit, the different sorts, planting, and general method of training, &c.
Water, its utility in gardens, for use and ornament, proper disposition, and means of acquirement.

SECOND DIVISION

Comprising a general List of the Botanic Terms and Descriptions contained in this Work, as generally used by the Botanists in describing the different Parts of Plants, and the Principles of the Botanic System; comprehending Descriptions of the Root, Stem, Branches, Leaves, Flowers, Fruit, Seed Vessels, Seeds, &c. and of the Classes, Orders, and Characters of the Genera, Species, and Varieties; with the different Modes of Inflorescence, or Manner of Flowering, and the different Sexes of Plants and Flowers, in Male, Female, and Hermaphrodite; all of which under the said different Heads, as below, are fully explained accordingly as they alphabetically occur in the different Parts of the Book: which, in the whole, after properly consulting the Articles, Characters, Classes, Orders, Genera, and Species, will be sufficient to convey the general essential Principles of the System of Botany.

A.

AGGREGATUS Flos, an aggregate flower composed of many small florets.
Amentaceus Flos, many small flowers produced in an amentum.
Amentum, a catkin or slender string of small chaffy flowers.
Androgyna Planta, a plant producing male and female flowers.
Annuae Plantae, annual plants, or but of one year's duration.
Anthera, top of the filament or stamen of flowers, and the male part.
Apetalus Flos, a flower without petals.
Aquaticae Plantae, water plants.
Arbor, a tree, different in growth from a shrub.
Arista, Acreus or beard of grass and corn flowers.
Arma, armature of plants.
Aromaticae Plantae, aromatic or odoriferous plants.
Axilla, armpit of plants.

B.

Bacca, a Berry.
Bacciterae Plantae, berry-bearing plant.
Barba, beard of leaves and flowers.
Barbatus Flos, a bearded flower.
Biennis Planta, a biennial or two years' plant.
Bractea, a floral leaf.
Bulbus, a bulb or bulbous root.
Bulbus Caulinus, a bulb produced on the stem, &c.

C.

Calyx, the flower-cup, different sorts.
Campaniformes Plantae, plants with bell-shaped flowers.
Capitulum, a little head of flowers.
Capsula, capsule or hollow seed-vessel, various sorts.
Catkin, an amentaceous flower.—See *Amentum*.
Caulis, a stalk or stem of a plant or tree, different sorts described.
Caulescens, having a stalk or stem.
Characters, description of the genera of plants.
Cirrhus, a clasper or tendril of cirrhous-climbing plants.
Classis, a class or collection of different kindred genera of plants, and thus similarly the whole vegetable kingdom is divided into twenty-four classes, all arranged by name under this said head *Classis*.
Compositus Flos, compound flower.
Coniferae, cone-bearing trees and plants.
Conus, a cone, a species of seed-vessel.
Corolla, composed of the petals, or flower-leaves.
Corymbus, an order of cluster-flowering.
Cotyledones, side lobes of a seed.
Cruciformis Flos, a cross-shaped flower.
Cyma, a mode of umbel-flowering.

F.

Femineus Flos, a female flower.
Femina Planta, a female plant, bearing female flowers only.

Fibrous

Fibrosa Radix, a fibrous root.—See *Radix Perennis Fibrosa*.

Filamentum, thread like part of the stamina of flowers.

Flos, the flower of plants and trees, consisting of the different parts of the fructification.

Flosculus, a little flower or floret.

Foliola, lesser leaves of a compound leaf.

Folium, a leaf of a plant or tree, consisting of numerous different sorts.

Frut, a shrub: difference from a tree explained.

G.

Genus, a fraternity or assemblage of different species of plants.

Germen, seed-bud, or base of the pistillum, of flowers.

Germinatio, germination or sprouting of seeds.

Gluma, a husk, or the calyx of grasses.

H.

Herba, an herb, a plant not becoming woody.

Herbacea Planta, an herbaceous plant, being of an herb-like nature.

Hermaphroditus Flos, hermaphrodite flower, having both male and female parts.

I.

Inflorescentia, inflorescence, or manner of flowering of all sorts, of plants, &c.

Involucrum, a calyx of umbelliferous-flowering plants.

L.

Labiatus Flos, a lipped flower.

Lactescentes plantæ, lactescent or milky plants.

Legumen, a seed pod of the pea, bean, and other pulse.

Liliaceæ, like a lily, liliaceous plants, producing lily-shaped flowers.

Loculamenta, and *Loculi*, cells or seed departments of a capsule.

Luxurians Flos, a luxuriant flower.—See *Luxuriant Plants*.

M.

Mas Planta, a male plant, producing male flowers only.

Masculus Flos, a male flower.

Monopetalous Flos, a flower of one petal.

Monophyllus, of one leaf.

Motus, motion of plants.

Multicapularis, many-capsuled.

Multifidus Flos, a flower or calyx cut into many parts.

Multiplicatus Flos, a multiplied flower.

Musci, mosses, a tribe of imperfect plants.

N.

Nectarium, a part of the corolla, or sort of appendage to the petals of a flower.

O.

Ordo, an order or first subdivision of a class in the classes of plants.—See also *Classis*.

P.

Panicula, a panicle, or mode of flowering.

Papilionaceus Flos, a butterfly-shaped flower.

Pappus, down of flowers.

Parasitus Planta, a parasitic plant, growing upon other plants or trees.

Pedicellus, a pedicle or little foot-stalk of a flower.

Pedunculus, a peduncle, or main foot-stalk of a flower.

Pendulus Flos, a pendulous or hanging flower.

Perennis Planta, a perennial or many years' plant.—See also *Radix Perennis*.

Perianthium, a flower cup, or most common species of calyx.

Pericarpium, the seed-vessel of plants, different sorts.

Petalum, petal or flower-leaf.

Petiolus, the petiole or foot-stalk of a leaf.

Pistillum, the pistil or style, the female organ in the centre of a flower.

Plenus Flos, a full or double flower.

Pollen, meal, or male prolific powder of the anthera.

Polygamia, many marriages, or intercommunication of different sexes in the flowers of particular plants.

Pomum, apple or fleshy fruit, a species of seed vessel.

R.

Racemus, a raceme or cluster of flowers or berries.

Radiatus Flos, a radiated flower of the compound tribe.

Radius, the ray, radius, or outer spreading circumference of a compound flower, &c.

Radicula, radicle or little root.

Radix, the root of plants and trees, &c. many sorts.

Radix Perennis Fibrosa, perennial fibrous roots, applicable to a numerous tribe of plants.

Ramus, a branch of a tree.—See *Caulis*.

S.

Semen, seed of plants, various sorts.

Sexus, sexes of plants, in producing male, female, and hermaphrodite flowers.

Spadiceus Flos, a flower or aggregate of flowers produced on a spadix.

Spadix, the receptacle of spadiceous or spathaceous flowers produced from a spatha.

Spatha, a sheath or common calyx of spadiceous flowers.

Species, the individuals, or different kindred plants of a genus or family, as arranged under the various genera in the course of this work, their distinctive difference explained.—See *Species* and *Genus*.

Spica, spike of flowers, a mode of flowering.

Spina, a spine or thorn, one of the armature of plants and trees.

Stamina, male organ of flowers, consisting of the filaments or thread like parts in the centre, supporting the antheræ, containing the male powder.

Stellata

I N D E X.

Stellata planta, a starry plant.

Stigma of the flower, summit of the pistillum or female organ.

Stipulæ, small scale-like leaves at the base of the larger.

Strobilus, a seed-vessel of the cone kind.

Stylus, the style in the centre of a flower, placed on the top of the germen, elevating the stigma or female part.

Succulentæ, juicy, or succulent plants.

Suffruticosus, under-shrubby.

T.

Thyrus, thyrse, a mode of cluster-flowering.

Tomentosa Planta, a plant having the leaves tomentose or white-downy.

Tribus, tribes of plants, various.

Truncus, stem or stalk of trees and plants.

Tuberosa Radix, a tuberous-root.

U.

Umbella, an umbel of flowers, a mode of flowering.

Umbelliferous Plants, such as produce flowers in an umbel.

Umbilicatum folium, a navel-shaped leaf, &c.

V.

Valvula, a valve, or opening of a seed-vessel.—
See also *Capsula*.

Varietas, a variety, applicable to plants, seeds, and fruit, off-spring of certain species; and some, very numerous.

Verticillus, a Whorl, a mode of flowering, the flowers growing in whorls.

Volubilis Caulis, a twining or winding-climbing stalk, in many sorts of shrubby and herbaceous plants.

F I N I S.
